The calculation of residue volumes is part of the larger problem of protein density and the most rigorous approach to this is undoubtedly that of Richards[19] who adopted the approach used by Bernal and Finney[20] to describe the structure of liquids, and introduced the use of Voronoi polyhedra to calculate the volumes occupied by protein atoms The volume occupied by a protein atom is found, by first constructing vectors to all neighbouring atoms, second, at a point along each vector related to the van der Waals' radii constructing a perpendicular plane, and third, finding the smallest polyhedron described by these planes (Fig 3) The method and its implementation is fully described in refs 19 and 20 By its application Richards showed the interior of lysozyme and ribonuclease to have a packing density of 0 75, similar to that of small organic crystals

I have calculated the volumes occupied by residues buried in the interior of the calcium binding protein, ribonuclease S, lysozyme, subtilisin, α-chymotrypsin, carboxypeptidase A, papain, thermolysin and lactate dehydrogenase As a working definition, proteins were taken to be buried if less than 5 % of their potential accessible surface was available to solvent contact Atomic volumes were found by using the B version of Richards' computer program[19] and residue volumes found by summing the value calculated for each atom The results are summarised in Table 2 which also lists the volumes which residues occupy in crystals of amino acids

Richards observed that protein interiors are close packed[19] From Table 2 this observation can be extended to state that, in general, the volume occupied by a particular residue in the interior of a protein is constant (the standard deviations are ~6 %), and that it is the same as that occupied by the residue part of the amino acid in its crystal form Thus the "oil drop" model of protein structure with its implication of the micelle-like association of pieces of secondary structure is incorrect, while the description of proteins as "molecular crystals"[21] is accurate The close packing of protein interiors prevents water molecules being trapped in non-polar cavities, maximises the packing energy and implies that the stable association of pieces of protein secondary structure depends on the existence of interfaces that can close pack and are large enough in area to give sufficient hydrophobic energy This can probably be generalised to apply to recognition processes that occur between other kinds of biological molecules

Of the buried residues listed in Table 2 those with non-polar side chains (Val, Ala, Ile, Leu, Gly, Phe and Pro) make up 67 % by number (and 66 % by volume) of the total while those with polar side chains make up 33 % Experimental solution studies indicate that as long as unchanged polar groups retain their

hydrogen bonds their hydrophobicity is similar to that of non-polar groups[8], and, indeed, Lee and Richards found that when ribonuclease S, lysozyme and myoglobin go from an extended conformation to the native structure the reduction that occurs in the accessible surface area of polar and non-polar groups is the same[6] But the necessity for, and geometrical requirements of, hydrogen bond formation by interior polar side chains severely limits the possibilities of formation of close packed molecules by pieces of secondary structure Twenty-six per cent of the serine and threonine residues are buried but only 10% of the asparagines and 6% of the glutamines, both of which have two side chain polar groups that need to form hydrogen bonds (Table 2) The high proportion of non-polar side chains that occur in protein interiors essentially results from the necessity of forming a close packed structure in which nearly all buried polar groups form hydrogen bonds

It follows that structural homology between proteins of different amino acid sequence is essentially a packing phenomenon

Protein folding

The folding problem of a globular protein is how to gain enough energy from hydrophobicity, hydrogen bonds and van der Waal's interactions to overcome the loss of configurational entropy and the steric strain that occurs in the folded state The calculations described here show that the structural solution to at least part of this problem is described by a set of simple expressions, and raise the question are there regularities present in the topology of the folded chain—in the amount of secondary structure and

the manner in which it is assembled—which are responsible for these simple expressions?

Much of this paper arose from discussions with Michael Levitt, Frederic M Richards and Joel Janin and the gifts of computer programs by the first two I thank Professors D C Hodgkin, K Hardman, M G Rossmann and B W Matthews for allowing me to use unpublished atomic coordinates Most of this work was supported by an EMBO fellowship and part by a grant to F M Richards from the National Institutes of Health

Inhibition of release of prostaglandins as an explanation of some of the actions of anti-inflammatory corticosteroids

G. P. Lewis & Priscilla J. Piper

Department of Pharmacology, Royal College of Surgeons of England, Lincoln's Inn Fields, London WC2A 3PN, UK

Corticosteroids as well as non-steroid anti-inflammatory drugs inhibit the prostaglandin-mediated vasodilatation accompanying lipolysis in subcutaneous fat Whereas the non-steroids produce their effect by inhibition of prostaglandin synthesis, however, corticosteroids inhibit their release This mechanism may be the basis of some actions of corticosteroids in inflammation, in the gastric mucosa and in the CNS

A PROSTAGLANDIN (PG), probably E_2 (refs 1 and 2) is a mediator of functional vasodilatation (vasodilatation accompanying activity) in subcutaneous adipose tissue In 1971 it was discovered[3] that non-steroid anti-inflammatory agents such as aspirin and indomethacin prevented PG formation by inhibition of PG synthetase It was subsequently shown that such anti-inflammatory agents inhibit PG formation and functional vasodilatation in subcutaneous fat but do not prevent lipolysis[4] Therefore, it seems likely that these actions are the result of inhibition of PG synthetase activity in adipose tissue We have now shown that functional vasodilatation in fat is inhibited not only by non-steroid anti-inflammatory drugs of the aspirin type,

but by the anti-inflammatory steroids hydrocortisone, betamethasone and prednisolone as well

Inhibition of vasodilatation

The method used was that described earlier[1] in which the venous outflow from the epigastric adipose depot of rabbits was measured directly with a drop counter and fat mobilisation was induced by a close-arterial infusion of adrenocorticotrophic hormone ($ACTH_{1-24}$) This lipolysis was accompanied by PGE_2 formation in the fat tissue and dilatation of the blood vessels giving an increased blood flow

When hydrocortisone (2 nmol min^{-1} to 2 μmol min^{-1}) as hemisuccinate was infused into the fat depot immediately before the infusion of $ACTH_{1-24}$, the vasodilatation was greatly reduced or abolished The blood steroid level during the infusion was about the same as that in a rheumatoid patient on steroid therapy Figure 1 shows the percentage inhibition of the vasodilatation produced after activating the fat tissue with a close-arterial infusion of $ACTH_{1-24}$ (1 μg min^{-1}), brought about by 15 min infusions of various concentrations of hydrocortisone

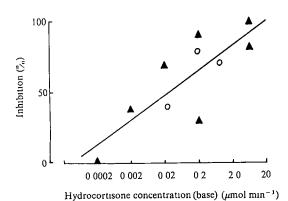
The first interpretation of this finding was that anti-inflammatory steroids as well as aspirin-like drugs inhibit PG synthetase in adipose tissue It has been suggested that PG biosynthesis in


Fig 1 The effect of hydrocortisone (as hemisuccinate) on the vasodilatation in subcutaneous adipose tissue (▲), and on the output of a prostaglandin-like substance into the venous effluent blood (○), during lipolysis brought about by a 5 min close-arterial infusion of $ACTH_{1-24}$ Each point represents the result from one rabbit The inhibition is plotted as a percentage of control and the concentration of hydrocortisone in μmol min⁻¹ is plotted on a log scale The line is the regression line calculated from the points plotting the inhibition of vasodilatation

human skin is inhibited by corticosteroids[5] The same research group[6], however, working with a microsomal fraction from skin, have more recently agreed with other groups who found that anti-inflammatory steroids do not inhibit the PG synthetase activity of homogenates prepared from lungs, spleen or other tissues When we studied prostaglandin formation and leakage from another tissue, the rabbit jejunum, as described earlier[8], our results were in agreement with theirs We found that although indomethacin (30 nmol ml⁻¹) inhibited the leakage of PG from segments of rabbit jejunum suspended in 15 ml Krebs solution at 37 °C, hydrocortisone caused no reduction This finding implied that unlike indomethacin, hydrocortisone did not inhibit PG synthetase

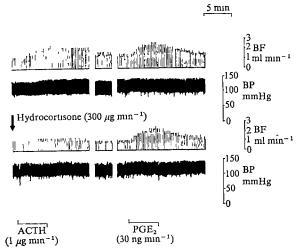
We therefore analysed further the hydrocortisone-induced inhibition of the PG-mediated functional vasodilatation 'n adipose tissue We wanted to determine whether hydrocortisone was inhibiting the vasodilatation by inhibiting lipolysis itself, or by antagonising the action of PG, or by preventing its formation, or by interfering in some way with the release of PG after its formation


Fig 2 Record of venous outflow (BF) upper record, from the right epigastric fat pad and arterial blood pressure (BP) in a 4 5 kg female New Zealand White rabbit Responses to 5 min close-arterial infusions of $ACTH_{1-24}$ (1 μg min⁻¹) and PGE_2 (30 ng min⁻¹) Upper tracings before and lower tracings after close-arterial infusion of hydrocortisone hemisuccinate (300 μg min⁻¹) (equivalent to hydrocortisone 600 nmol min⁻¹) The gaps between each block of tracing is equivalent to 30 min The increased venous outflow following $ACTH_{1-24}$ is almost abolished whereas the response to PGE_2 is unaffected

First, we were able to show that hydrocortisone does not inhibit lipolysis When hydrocortisone (600 nmol min⁻¹) was infused close-arterially to the epigastric fat depot immediately before the lipolytic substance ACTH (1 μg min⁻¹), the free fatty acid content of the epigastric venous blood reached a level of 3–5 meq l⁻¹, that is the same level reached after stimulating with $ACTH_{1-24}$ in the absence of hydrocortisone

Second, the inhibition of vasodilatation was not the result of a direct antagonism of the action of PG by the corticosteroids In three experiments, infusions of hydrocortisone (600 nmol min⁻¹) (the ED_{75} used to inhibit functional vasodilatation) did not inhibit the vasodilatation produced by close-arterial infusions of PGE_2 at 30–100 ng min⁻¹ A typical experiment is illustrated in Fig 2 In a second series of experiments betamethasone (as disodium phosphate) given at a rate of 2–20 nmol min⁻¹ inhibited the vasodilatation accompanying lipolysis more than 90 % whereas the vasodilatation produced by infusions of PGE_2 (30–100 ng min⁻¹) was not reduced at all In some experiments it was even potentiated

Third, using the method of Bowery and Lewis[4] it was possible to show that hydrocortisone did not inhibit the formation of PG in the fat tissue during lipolysis The epigastric fat depots of both sides of the animal were isolated from the skin and abdominal wall and prepared for close-arterial injection of a fat-mobilising agent $ACTH_{1-24}$ (1 μg min⁻¹) was infused close-arterially to the right epigastric fat pad for 5 min, and 15 min after beginning the infusion the fat pad was excised and placed immediately into ice-cold ethanol, chopped finely and homogenised at 0 °C using an Ultra Turrax homogeniser After allowing the rabbit to recover for 1 5 h after the $ACTH_{1-24}$ infusion,

Table 1 Prostaglandin activity in fat pad extracts in equivalents of PGE_2 ng per g tissue formed after activation with $ACTH_{1-24}$

Experiment	$ACTH_{1-24}$ (1 μg min⁻¹)	Hydrocortisone (6 0 μmol min⁻¹) + $ACTH_{1-24}$	Indomethacin (30 nmol min⁻¹) + $ACTH_{1-24}$

2	36 0	47 0	
3	8 0	7 1	
4	47 6		< 0 25

hydrocortisone (600 nmol min⁻¹) was infused close-arterially to the left fat pad for 15 min followed immediately by $ACTH_{1-24}$ (1 μg min⁻¹) for 5 min Again 15 min after the beginning of the infusion of $ACTH_{1-24}$ the fat pad was excised and placed immediately into ice-cold ethanol, chopped and homogenised as before Both fat pads were examined for prostaglandin content by extraction into ice cold ethanol and ethyl acetate at pH 3 The extracts were evaporated to dryness under reduced pressure at a temperature not exceeding 45 °C The residues were taken up in 0 1 ml ethanol and applied to thin-layer chromatographic plates using the A1 solvent system[9] PGE_2 and $PGF_{2\alpha}$ standards were chromatographed simultaneously with the extracts and were made visible by exposure to iodine vapour The silica gel was scraped from the thin-layer plates at 1–2 cm intervals and suspended in 1 ml Krebs solution The PG activity of the supernatant was estimated by bioassay on the isolated rat stomach strip (RSS), rat colon (RC) and chick rectum (CR) All the PG activity from the fat pad extract appeared in fractions corresponding to the PGE_2 standard

The results given in Table 1 show that hydrocortisone does not prevent the formation of PG when the fat tissue is activated The increased PG content of extracts of fat pads which occurs on activation[2] was not inhibited by hydrocortisone On the other hand, as shown in the Table, a similar experiment confirms the earlier observation[4] that indomethacin prevents or reduces the formation of PG

Prostaglandin release

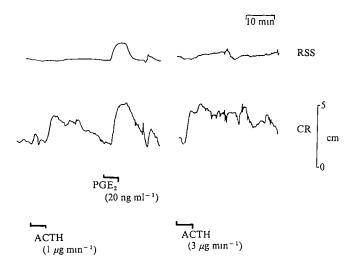
Since the corticosteroids inhibit the vasodilatation but not the formation of PG in the tissue, it seems possible that they prevent the release of PG from the fat cells thereby preventing their


Fig 3 The venous effluent from the epigastric fat pad of an anaesthetised New Zealand White rabbit (female, 4 3 kg) was superfused over two isolated assay tissues, rat stomach strip (RSS) and chick rectum (CR) and returned to the animal by way of a jugular vein When PGE_2(20 ng ml^{-1})was infused into the blood bathing the assay tissues (IBB) both RSS and CR contracted When $ACTH_{1-24}$ (1 and 3 μg min^{-1}) was infused close-arterially to the fat pad for 5 min a substance causing contraction of CR (approximately equivalent to PGE_2 20 ng ml^{-1}) but not RSS was released into the venous blood In other experiments $ACTH_{1-24}$ did not contract the assay tissues when given IBB Vertical scale 5 cm, time 10 min

action on the blood vessels A suggestion that this might be true arises from a study of the release of a PG -like material from the fat pad into the blood during lipolysis The method was to prepare the fat depot as before for recording venous outflow and for making close-arterial infusions In this series of experiments, however, the venous blood from the fat depot was superfused over a series of isolated smooth muscle tissues, RSS, CR and RC[10] before being returned to the animal The tissues were made more specific for PG-like materials by bathing them before superfusion in a solution containing antagonists of histamine, 5-hydroxytryptamine (5-HT), acetylcholine and catecholamines and infusing these inhibitors through the lumen of CR and RC during the experiment[11] Figure 3 illustrates the release into the venous effluent of a substance which contracts the isolated chick rectum which is sensitive to PGs of the 'E' type Like the vasodilatation[4], the output of this material was reproducible when repeated stimulations by ACTH were made at hourly intervals When the venous effluent was tested on the RSS, RC and CR and compared with responses to PGE_2 it was obvious that the substance in the venous blood was not PGE_2, although the substance formed in the fat tissue itself is PGE_2 (ref 2) as recently confirmed[12] using mass spectrometric analysis Although the venous effluent blood consistently contracted CR and to a lesser extent RC, it caused little or no contraction of RSS In addition, when the epigastric venous blood collected during lipolysis was extracted with solvent systems similar to those used for extraction of PGs[13], a little PG-like activity was retained The substance however, was not PGE_2, compared with which it was more active on CR and RC than on RSS Neither $ACTH_{1-24}$ itself nor any substance released during infusion of $ACTH_{1-24}$ altered the responsiveness of the isolated tissues to PG

In further experiments of this type we have found that the output of this material during activation of the adipose tissue is prevented by previous infusion of indomethacin This finding strongly suggests that although the material is not PGE_2, it is a product of the PG synthetase system This effect was observed not only with indomethacin, however, since infusions of hydrocortisone or betamethasone before the $ACTH_{1-24}$-induced activation of the adipose tissue also prevented the output of the PG-like material as illustrated in Fig 4 Figure 1 shows that

when the output is plotted against concentration of hydrocortisone, the points fall along the same curve obtained from a plot of inhibition of vasodilatation

In spite of its resemblances to PGs, the possibility exists that the chick rectum contracting substance is an unrelated new kind of chemical mediator the release of which is inhibited by both steroid and non-steroid anti-inflammatory agents

Active transport inhibition

In summary we have found that like non-steroid anti-inflammatory drugs such as aspirin and indomethacin, anti-inflammatory steroids such as hydrocortisone, betamethasone and prednisolone inhibit the PG-mediated functional vasodilatation in subcutaneous adipose tissue The mechanism of action of the steroids is, however, different Like indomethacin, hydrocortisone inhibits vasodilatation, prevents the output into the blood of a PG-like substance, possibly a metabolite, and does not antagonise the vasodilator action of PG directly But whereas indomethacin inhibits the formation of prostaglandin in the fat tissue itself, hydrocortisone does not, it therefore seems likely that hydrocortisone inhibits the release of prostaglandin Perhaps it does this by preventing the transport of prostaglandin from inside the fat cell to the extracellular space where it would normally act on the blood vessels This is the first indication that formation and release of PGs may be distinguishable since previously the two processes were thought to be equitable[13]

Since the discovery that non-steroid anti-inflammatory drugs produce at least some of their anti-inflammatory effects by inhibition of PG synthetase thereby preventing the formation of PGs, it has been difficult to explain the same kind of anti-inflammatory activities of corticosteroids, since it has been demonstrated by several groups of workers that anti-inflammatory steroids do not inhibit PG synthetase

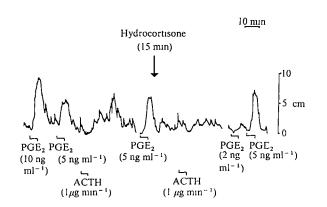
In situations where PG formation occurs extracellularly or where the cells are damaged so much that their membranes no longer provide a barrier to the diffusion of materials, PG synthetase inhibitors would prevent the appearance of PGs For example, in our experiments with strips of rabbit jejunum, it seems likely that PGs are probably formed during cell breakdown and their leakage from these damaged cells could not be expected to be inhibited by steroids, although their formation and therefore their leakage is inhibited by indomethacin It has also been shown that steroids did not affect PG levels in an inflammatory exudate *in vivo*[14], that is, another situation where there is cell necrosis But Ferreira *et al*[15] found a similar result in perfused spleen where cell damage would seem unlikely,


Fig 4 The venous effluent from the fat pad from a female New Zealand White rabbit (3 4 kg) was superfused over a single CR The tracing is arranged and labelled as in Fig 3 In the first panel calibrating doses of PGE_2 of 5–10 ng ml^{-1} were given IBB When $ACTH_{1-24}$(1 μg min^{-1} for 5 min) was infused close-arterially to the fat pad a substance which caused a contraction of CR equivalent to 5–10 ng ml^{-1} PGE_2 was released into the venous blood In the second panel, hydrocortisone (500 nmol) was infused close-arterially to the fat pad for 15 min immediately before $ACTH_{1-24}$ (1 μg min^{-1}) This time there was no release of contractile substance 1 5 h elapsed between doses of $ACTH_{1-24}$

although the perfusions with Krebs solution and dextran might have caused some alterations in the cells On the other hand, during lipolysis there is no damage to the fat cells and the release of PGs from these cells is therefore probably an active process rather than leakage It is this 'active transport' which seems to be inhibited by corticosteroids It seems likely that this effect on subcutaneous adipose tissue might well account for some anti-inflammatory effects of corticosteroids in skin, in particular their local vasoconstrictor activity[16] The inhibition of PG release may well have further implications on the mode of action of corticosteroids on inflammatory cells and the cells of other systems like those of the reproductive tract

Such a hypothesis needs confirmation by experiments with isolated cells First it would be required to show that isolated fat cells synthesise PG when stimulated and that its release is inhibited by anti-inflammatory steroids It would also be interesting to examine the effect of steroids on the release of PGs from cells which play an obvious role in inflammatory reactions, such as mast cells, leukocytes and platelets

Until now there has been no report of a transport mechanism for the release of PG from cells, formation being synonymous with release But some investigations have indicated that there might be an active transport mechanism for the uptake of PGs[17,18] After injection of ^{3}H-labelled PG radioactivity was found to be concentrated in some tissues In addition, PGs were found to be rapidly taken up into lungs but the parent compounds and metabolites were released slowly On the other hand, there have been many reports of the membrane stabilising effect of anti-inflammatory steroids like hydrocortisone[19] It is not clear precisely what is meant by 'stabilisation' but it might well be involved in the inhibition of PG release

Inhibition of PG synthetase by non-steroid anti-inflammatory drugs may not only be the basis of their anti-inflammatory activity but may also be the cause of their main side effect–gastric-irritation If PGs mediate functional vasodilatation in the gastric mucosa as has been suggested[20], PG synthetase inhibitors would probably produce areas of ischaemia leading to necrosis As anti-inflammatory steroids also produce gastric ulceration, it

is possible that they act in the gastric mucosa too, by inhibiting the release of PG

Another instance where the inhibition of PG release by anti-inflammatory steroids might explain their action is in their effect in controlling fever It has been suggested that pyrogenic fever is caused by release of PGs in the anterior hypothalamus[21,22] In addition, it has been shown that PG synthetase inhibitors reduce or prevent the release of PGs into the cerebral ventricles and reduce fever[23,24] The release of PGs in the hypothalamus may well be mediated through a similar sort of transport mechanism as that which seems to be present in adipose tissue It would therefore be interesting to examine the effect of corticosteroids on PG release in the brain during fever since it is known that certain kinds of fever are alleviated by these agents

We thank M A Palmer and J Chang for technical help and the Medical Research Council for supporting this research

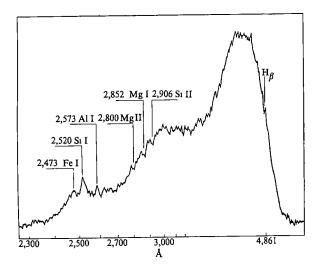
letters to nature

Silicon-rich stellar envelope?

DURING an analysis of Orion-2 data derived from a space astrophysical experiment[1], we came across a hot star with a gaseous envelope, SAO077308, of B1e type and nearly ninth magnitude It is interesting because of an extremely strong emission line at 2,520 Å occurs in its ultraviolet spectrum Following a series of attempts, the identification of this line with the resonance sextet of neutral silicon (mean wavelength 2,520 Å) seems probable The components of this sextet, of almost equal strengths, are 2,507, 2,514, 2,516, 2,519, 2,524 and 2,528 Å, the second of these lines is resonant, the others quasi-resonant in the sense that the lowest levels of these lines are located quite close to the ground level, up to 0 01–0 03 eV This identification cannot be taken as final and needs further examination Irrespective of possible closer definitions, however, the very presence of the emission line itself in the spectrum of this star is significant Regardless of the true nature of the chemical element to which this line belongs, the problem of an anomalous abundance of this element cannot be overlooked

Here we report the further somewhat conventional examination of the abnormal abundance of silicon in the envelope of the star SAO077308

The emission line at 2,520 Å is the strongest in the spectrum of SAO077308 at least in the range from 4,000 Å to 2,300 Å, one can see its unusual strength in the densitometric recording of the spectrum of this star in Fig 1 (the spectral resolution is nearly 15 Å at 2,500 Å) To establish the anomalous nature of the line in the spectrum of this star, a comparison with the spectrum of another well known emission star, ζ Tau, of almost the same spectral class, has been made This is shown in Fig 2 by collating the densitometric recordings of the same parts of both spectra near 2,500 Å

A few spectral images with an exposure time of 7–8 min (frame F23) have been obtained for the star SAO077308 The spectral pictures of ζ Tau were obtained from Orion-2 with an exposure time of nearly 5 s (F4), that is, in conditions considerably more favourable than in the case of SAO077308, bearing in mind the inevitable deterioration of the quality of the spectrograms during long exposures as a result of the


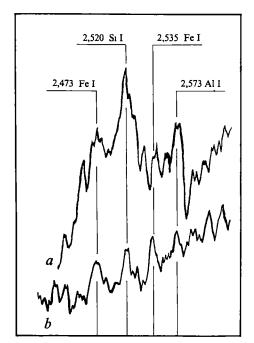


Fig 1 Densitometric recording fiom the ultraviolet spectra of emission star SAO077308 in the range of wavelengths from 5,000 Å to 2,300 Å The strongest emission line 2,520 Si I is visible

accidental disturbances of the guide system of Orion-2 Nevertheless, the line at 2,520 Å is sharply distinguished compared with nearby emission lines in SAO077308, but this line has the same intensity as those of nearby emission lines in the spectrum of ζ Tau The alternative assumption that this difference may be the result of the anomalously small abundance of iron (2,473 Fe I, a resonance doublet) and aluminium (2,573 Al I, a resonance triplet) in SAO077308 seems unlikely

It is difficult to determine the relative abundance of silicon in the envelope of the star SAO077308 as compared to ζ Tau, in view of the different conditions in which the spectral images were taken A very approximate estimate shows that the relative abundance of silicon in the envelope of SAO077308 must be at least 3–4 times, and perhaps a whole order of magnitude, larger than in the envelope of ζ Tau

To what degree the discovered abnormal abundance of

Fig 2 Comparison of two densitometric recordings from the spectras of the stars SAO077308 (a) and ζ Tau (b), near 2,500 Å, from which the anomalous intensity of 2,520 Si I in the case of SAO077308 is clear

silicon is characteristic, not only of the gaseous envelope of the star SAO077308 but also of the photosphere itself, is difficult to specify without additional data To achieve this, it is necessary to look for the absorption lines in the spectrum of the star under examination by means of ground based astrophysical observations and to compare those lines with their analogues in the spectrum of the comparsion star

Ionospheric mid-latitude trough and the abrupt scintillation boundary

THE mid-latitude trough[1,2] in electron density and the equatorward limit of small-scale F-region irregularity structure apparent in the scintillation of satellite and radio star signals, the scintillation boundary[3,4], are both features of the transition region between the high and mid-latitude ionospheres There are broad similarities between the morphology and statistical behaviour of the trough and the irregularity boundary[5-7] and, although the individual behaviour of the scintillation boundary and the mid-latitude trough may be related to particle precipitation patterns or plasmapause movements, there is a definite local time variation in their mean relative latitudinal positions when simultaneous observations of the two phenomena are analysed[8] We have examined this variation in more detail, using data from simultaneous observations of trough and scintillation boundary positions

Some 530 recordings of passes of the ionospheric beacon satellite BE-B (1964-64A) taken at Aberystwyth (52 42°N, 4 05°W) were selected from the available records for the years 1966 to 1968 inclusive The sample analysed comprised those records which showed irregular Faraday fading rates, indicating steep gradients in total electron content, or a sharp transition from zero to full scintillation of the 40 MHz signal indicating the presence of a clear scintillation boundary Reduction of the 40 and 41 MHz records by means of the differential Faraday technique yielded the variation of total electron content with invariant latitude, for an assumed ionospheric height of 350 km, over the approximate range 45° to 63° These plots of total electron content were used to determine the trough latitude, for the purposes of the analysis this was taken to be that corresponding to the minimum electron content recorded in the trough The invariant latitude, at 350 km, of the scintillation boundary was also determined The definition of the boundary used, a mean between zero and full modulation of the signal, was of the 'abrupt' type[9], with 95% of the sample having widths less than 3°, the width being the latitudinal range over which the scintillation depth varied from zero to full modulation of the 40 MHz signal

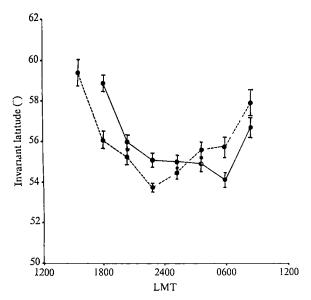
The results (Fig 1) show the contrast between the diurnal behaviour of the trough and scintillation boundary latitudes as a function of time The trough was first observed at ~59°Λ at 1900 LMT, falling rapidly in latitude to ~55°Λ at 2300 LMT and then more slowly to reach a minimum ~54°Λ at 0600 LMT, subsequently it returned very rapidly to higher latitudes A separate study of the gradients of the trough walls indicates that this apparent movement to higher latitudes is a filling of the equatorward margin of a stationary trough formation by solar electromagnetic radiation produced ionisation as dawn advances, rather than a true poleward motion of the trough as a whole In contrast to trough behaviour, the scintillation boundary has been observed at all times of the day, it


Fig 1 Variations of the latitude of the mid-latitude trough and the scintillation boundary as functions of local mean time The solid line represents the trough, the dashed line the scintillation boundary The points plotted represent median values for each time interval, using only data for which the planetary magnetic index, K_p, was less than four The bars denote the standard errors of the median values

is found at 59 5°Λ at 1600 LMT, falling steadily to a minimum at 53 5°Λ by 2300 LMT and retreating more slowly to reach ~58°Λ by 0900 LMT These results are in broad agreement with the mean latitudinal differences in trough and scintillation boundary positions reported previously[8] It now seems that the differences in the relative behaviour noted earlier, based on simultaneous observations, also occur in the absolute statistical variation of these phenomena, furthermore the clear differences in the diurnal behaviour of the trough and the scintillation boundary can explain these results

We conclude that the mid-latitude trough and the scintillation boundary, although both features of the high to mid-latitude ionosphere interface, are essentially independent having distinct diurnal behaviour patterns It must therefore be supposed that the immediate causative mechanisms, whether in terms of particle precipitation, plasmapause behaviour, electric field effects or some more complex process involving plasma waves, are also essentially unrelated

The movement of the scintillation boundary, reaching minimum latitude around local midnight, is similar, although displaced towards the equator, to that of the edge of the auroral oval closest to the equator It is possible that an energy source at E-layer altitude, within the auroral oval, acts by means of electric fields or perhaps plasma waves to cause the observed irregularities which lead to scintillation It does not seem that the trough can be related directly to reported particle precipitation patterns, but its movement shows certain similarities to that of the plasmapause, at least in the midnight to post-dawn sector But the present results do not reveal any motion of the trough which can be related to the 'dusk bulge' in plasmapause position We therefore conclude that one-to-one correspondence between trough and plasmapause movements may not be maintained at all times

Interaction of a photon with a gravitational field

IT is usual to analyse the behaviour of photons in gravitational fields as if they were point particles which travel along geodesics But by taking into account the finite spatial extent of the photon I show that it could interact with the transverse gradient of the gravitational field to give a deflection additional to the well known gravitational deflection of General Relativity I postulate that this deflection, even though it is extremely small, could be the basis for a much more important effect in which the photon can decay into three photons (or possibly (E H Derrick, personal communication) several photons with one or more gravitons) If such a mechanism is possible it would appear as a decrease in photon energy and could be of astrophysical importance in explaining many of the anomalous redshifts that have been observed[1,2]

In some situations the secondary photons which are expected to have very low energies may be observed as low frequency radio waves

For a classical electromagnetic wave its linear momentum **p** and its angular momentum **L** are given by the two volume integrals

$$\mathbf{p} = \int \varepsilon\mu\mathbf{N}d\tau \qquad (1)$$

$$\mathbf{L} = \int \varepsilon\mu\mathbf{r}\times\mathbf{N}d\tau \qquad (2)$$

where **N** is the localised Poynting vector ($\mathbf{N}=\mathbf{E}\times\mathbf{H}$)

Moller[3] has shown that in General Relativity for the description of electromagnetic radiation a weak stationary gravitational field may be considered as a refractive medium with $\varepsilon\mu=1/c^2/(1-2\chi/c^2)$ where χ is the gravitational potential Clearly this description would be valid for many other theories of gravitation which predict the deflection of light by a massive body Now in a region of space which is large compared to the possible extent of a photon but small compared to variations in the gravitational field, the gravitational potential can be expressed as $\chi=\chi_0+\nabla\chi$ **r**, where **r** is vector centred in the region

$$\mathbf{p}=\left[1-(2\chi_0/c^2)\right]\mathbf{p}_0-(2/c^2)\int(\nabla\chi \ \mathbf{r})\mathbf{N}d\tau \qquad (3)$$

where $\mathbf{p}_0$ is the momentum in a region containing no field and the first term on the right is the usual gravitational redshift, which is of no further concern here Using the vector triple product expansion the second term can be expanded to give

$$\int(\nabla\chi \ \mathbf{r}) \ \mathbf{N}d\tau = \int(\nabla\chi \ \mathbf{N}) \ \mathbf{r} \ d\tau - \int\nabla\chi\times(\mathbf{r}\times\mathbf{N})d\tau \qquad (4)$$

applying these equations to a circularly polarised photon which has circular symmetry about its trajectory the first term on the

right of equation (4) is zero and equation (2) can be substituted in the second term to give

$$p=[1-(2\chi/c^2)]p_0-(2/c^2)\ \nabla\chi\times L \qquad (5)$$

Since a photon has angular momentum parallel to its trajectory equation (5) predicts an additional deflection orthogonal to both the photon trajectory and to the gradient of the gravitational field (the vector taking opposite sign for right handed and left handed polarisation) Thus for a photon that just grazes the edge of the Sun there is no change between the initial and final directions but there is a small lateral displacement For a photon of wavelength λ this is $2GM\lambda/\pi R$ where G is the gravitational constant, M is the mass of the Sun and R is its radius The separation between right handed and left handed polarisations of a source at the Sun is twice this value and corresponds to an angular separation of $1\ 5\times10^{-11}$ arc s for $\lambda=37$ mm This is very much smaller than a recent[4] upper limit of 2×10^{-3} arc s

The angular momentum may be calculated by substitution in equation (2) but in this case the term proportional to the gradient of χ is zero because of the circular symmetry about the trajectory of the poynting vector N. This leads to the 'paradox' that the photon spin is no longer parallel to the photon trajectory as defined in equation (5) One could imagine the reference trajectory to be defined by the photon spin and the last term in equation (5) to be the result of a perturbation caused by an interaction with the gravitational field Havas[5] has shown that if there is a momentum transfer, as occurs here, there is no known reason why the photon cannot split up into three or more photons It is the conservation of spin, momentum and energy which gives the photon the characteristics of a single particle I therefore postulate that a photon can interact with a gravitational field to produce two or more secondary photons It seems reasonable to assume that the rate of energy loss per unit path length resulting from the production of secondary photons is proportional to the magnitude of the transverse momentum given by equation (5), and to make the proportionality constant dimensionless the path length is measured in wavelength units Alternatively, one could argue that the distance between interactions is that which would give a lateral displacement of the order of a wavelength and each interaction produces on average an energy loss proportional to the energy of the primary photons Both arguments lead to the same equation for the energy loss, namely

$$(1/E)\partial E/\partial l = - (K/c^2)|\nabla\chi\times n| \qquad (6)$$

where l is the distance measured along the photon trajectory, K is a dimensionless constant and n is a unit vector parallel to the photon trajectory This decay process can be likened to the removal of a tidal strain set up in the photon by the gradient of the gravitational field and it must therefore compete with any other process that could remove the strain In particular if there is a refractive medium present the excess momentum could be transferred to the medium without the decay process occurring In order to estimate the constant K this postulate can be used to explain the anomalous redshift[1] observed in solar emission lines coming from the limb of the Sun Then by integrating equation (6) the redshift may be expressed as an effective velocity v where

$$v=(KGM/cR)\ ((1-\cos\theta)/\sin\theta) \qquad (7)$$

where θ is the angle between the line of sight and the solar radius at the point of observation

Since the experimental observations are subject to an unknown additional constant the 25 velocities given by Adam[1] in his Fig 6 were fitted by the least squares method to give

$(0\ 962\pm0\ 083)[(1-\cos\theta)/\sin\theta]+(0\ 416\pm0\ 065)$ km s^{-1}

Then equating the first coefficient to the constant in equation (7) gives $K=1\ 51\pm0\ 13$ Although the r m s residual (0 05 km s^{-1}) is small, the experimental scatter is too large to confirm the functional form of equation (7)

Since the secondary photons will have frequencies lower than the plasma frequency of the solar corona there will be virtual emission with all the energy loss being used to heat the corona Integration of equation (7) shows that the energy loss to the solar corona measured per unit area of the photosphere is $(KGM/cR)/(\pi/2-1)\ F$, where F is total radiation flux density of the primary photons For the Sun with $F=6\ 41\times10^7$ W m^{-2} the loss to the corona is 117 W m^{-2} (with $K=1\ 5$) or a total power of $7\ 08\times10^{20}$ W At the solar minimum the estimated loss[7] to radiation and the solar wind is 200 W m^{-2}, however, allowance must be made for conduction losses to the chromosphere, values for which vary from[6] 50 W m^{-2} to an order of magnitude greater[7] Athay[8] has argued that this conduction loss may not be a genuine loss but that the energy is returned to the corona by mass motions of the chromospheric filaments In any case these low energy photons could be an important energy source for the solar corona

I thank Professor B Y Mills and Dr A J Turtle for discussions This work is supported by grants from the Australian Research Grants Committee, the Sydney University Research Grants Committee and the Science Foundation for Physics within the University of Sydney

Is the Earth tide phase lag unaffected by anelasticity?

THE dynamics of the Earth–Moon system raises the question whether the bodily tides or ocean tides in the Earth–Moon system produce most of the energy dissipation which is necessary to account for the secular retardation of the rate of rotation of the Earth Macdonald[1] has shown that a phase lag of 2° of bodily tides is enough to account for the whole change, and in principle this phase lag could be obtained from earth tide observations In practice, however, the determination of the phase lag of Earth tides is extremely uncertain, since the true value of the delay is influenced by the lag of recording instruments and by several disturbing effects Parussky[2] found that the mean value of the phase lag of solid Earth tides in Europe and in Asia is approximately equal to that of mentioned above, but the individual values are so much different one from another that the averaging is rather uncertain The study reported here indicates that all of the phase lag derived from Earth tide observations may be instrumental in origin

Miller[3] investigated in detail the possibility of dissipation in shallow seas His results hint that shallow seas are responsible for two-thirds of the dissipated energy, this numerical value, however, is so uncertain that as little as one-third or as much as

100% of the dissipated energy may be attributed to the shallow seas

I have obtained the Earth tide phase lag in a different way, computing the phase delay in case of a supposed model of the internal structure of the Earth and of its rheological characteristics The phase lag of crustal deformations has been computed using Molodensky's[4] theory As a starting point I used the homogeneous equations for the deformations of an elastic Earth of spherical symmetry[4] leading to a set of six linear differential equations In this equation system six unknown functions occur, these being proportional to the radial and tangential components of the displacement vector, to stress, to the tide generating potential and to its derivatives, respectively For example, one of the functions sought for and denoted by H satisfies the following connection with the U_r radial component of the displacement vector

$$U_r = H_n(a^{n-1}/r^n)/(W_n/g)$$

where a is the radius of the Earth, r is the distance from the centre of the Earth to the point of interest, g is acceleration due to gravity, n is the degree of harmonic development of the tidal potential W Introducing complex expressions of the shear modulus and of the unknown functions we have

$$\bar{\mu} = \mu_o(1+im) = \bar{\Phi}_j = \Phi_j + i\Phi_j^* = j = 1,2, \quad ,6, \quad (1)$$

and we obtain for the imaginary parts of the corresponding functions an inhomogeneous differential equation system taking into account the effect of anelasticity too In equation (1) μ_o represents the real part of the shear modulus, $i = \sqrt{-1}$, m is some chosen function and Φ_j denote the functions sought for The bulk modulus is taken here as being a real number This means that energy dissipation in compression is much less than in shear Solving the homogeneous differential equations relating to the real parts of the functions being sought we can compute the values of the real parts of Love numbers The imaginary parts can be obtained using the method of variation of constants, after having obtained the solution of the problem relating to the deformations of ideally elastic Earth

Full details of the method are published elsewhere[4,5], here I restrict myself to the description of results of the computations

I assumed the Earth model of Bullen and Haddon[6] denoted as model B_2 I also assumed that rheological features of the Earth can be characterised by the Knopoff–Lomnitz body, that is, the Q dissipation function does not depend on the frequency of oscillations Furthermore, it is known that in case of a Knopoff–Lomnitz body function m figuring in equation (1) is connected with Q by

$$m = Q^{-1}$$

The radial variation[7] of the function Q is given in Table 1 Solving the equations of the deformations of the elastic Earth gives the values of the Love numbers the values included in Table 2 These values are in good agreement with those obtained from observations On the basis of the processing of a 50,000-d long series of Earth tide measurements, Melchior[8] gives the following values for k and h

$$k = 0\ 316 \pm 0\ 010,$$
$$h = 0\ 637 \pm 0\ 016$$

After solution of the problem relating to the ideally elastic Earth, I turned to the solution of that dealing with deformations

Table 1 Radial variation of dissipation function Q

Depth (km)	Q
0–38	450
38–300	100
300–1,000	300
1,000–2,898	1,000

Table 2 Computed values of the second and third order Love numbers

n	h	l	k
2	0 6335	0 0882	0 3228
3	0 2983	0 0150	0 0970

of an inelastic globe, using the Q profile given in Table 1 The imaginary parts of the Love numbers obtained are almost zero Consequently, the phase lag of tidal deformation—which can be given, as a matter of fact, as the ratio of the imaginary and real parts of Love numbers—vanishes, and for practical purposes we have no phase lag For example, the computed value of the phase lag of gravimetrically obtainable δ factor is only 1–2 These results suggest that at present the solid Earth tides do not play a significant role in the deceleration of the Earth

It is difficult to say to what extent the computed phase lag values might be in accordance with observational results, since the determination of instrumental lag is rather uncertain The instrumental lag of recording apparatuses can be computed mathematically or it can be determined experimentally using some artificial gravity oscillation But in both cases an insufficient knowledge of parameters and physical characteristics of the instrument makes the exact determination of the accurate instrumental lag rather doubtful

Age differences between Archaean cratons of eastern and southern Africa

ARCHAEAN greenstone belts have commonly been correlated on the basis of similarities in their stratigraphic successions[1] Conclusive radiometric tests of these correlations have rarely been made, because of the difficulty of dating the rocks of the greenstone belts themselves, and because of uncertainties in their relationships to the more easily dated granitoid rocks with which they are normally associated We report here radiometric evidence from eastern Africa, which clearly contradicts previous lithostratigraphic correlations between the Tanzanian and Kaapvaal Cratons by establishing a minimum age difference between the uppermost parts of their respective greenstone belt successions

In Table 1 the stratigraphy of the greenstone belts of the Tanzanian Craton (see Fig 1) is compared with those of the Rhodesian and Kaapvaal cratons The Kavirondian and Nyanzian systems, confined to the northern part of the Tanzanian Craton, are particularly well exposed near the Tanzanian–Kenya border towards Lake Victoria There is no direct evidence that the Dodoman is older than the Nyanzian[2], only the presence of metamorphosed ultrabasic rocks in its type area[3] supports the analogy with the Sebakwian and Lower Onverwacht suggested in Table 1

The Kavirondian and Nyanzian systems were shown by Cahen and Snelling[4] to be older than about 2,550 Myr Subsequently, Old and Rex[5] published a 3,100 Myr Rb–Sr isochron age for the Masaba granite, south-eastern Uganda, which they considered a minimum age for the Nyanzian Field relationships suggest that the granite may be post-Kavirondian[6], which means that the greenstone belts in eastern Africa would be comparable

Table 1 Comparison of some African greenstone belts*

Tanzanian Craton	Rhodesian Craton	Kaapvaal Craton	Lithology	
Kavirondian System (Unconformity)	Shamvaian System (Unconformity)	Moodies Group (Unconformity)	Sedimentary Group coarse grits, conglomerates and shales

in age to the very ancient rocks of the Swaziland System[7-10] (All Rb–Sr ages are calculated here with $\lambda_{Rb} = 1\,39 \times 10^{-11}\,yr^{-1}$, to facilitate comparison with published data on southern Africa)

We have dated pre and post-Kavirondian granites in western Kenya by the whole-rock Rb–Sr isochron method We have also reanalysed the samples of Masaba Granite studied by Old and Rex[5], and have obtained very different results from those authors Sample localities are shown on Fig 2

Two distinct phases of magmatism bracket the Kavirondian system The Mumias Granite cuts post-Kavirondian structures in the Kakamega region, and has produced a distinct thermal aureole in the Kavirondian sediments to the north This granite is contiguous with the Kitosh Batholith of Kenya, which becomes the Buteba Granite in Uganda[5] The Migori G2 granite, the only body for which there is good evidence for a pre-Kavirondian age, intrudes the Nyanzian but is nowhere seen in contact with the Kavirondian Its pre-Kavirondian status[11] is based on its petrographic similarity to some of the well-rounded boulders contained within a basal Kavirondian conglomerate

Fig 1 Geological setting of Tanzanian Shield (Inset map after T N Clifford)

overlying the Nyanzian a few kilometres north-east of the G2–Nyanzian contact (Fig 2) The Masaba granite has an uncertain relationship with the Nyanzian and Kavirondian systems, but its eastern boundary seems to truncate Nyanzian–Kavirondian contacts[6]

Although the samples of Migori G2 are petrologically more varied than the very uniform boulders from the Kavirondian conglomerate, KEN 167 and 168 are porphyritic quartz monzonites which are indistinguishable in thin section from the boulders The post-Kavirondian granites, also quartz monzonites, contain abundant biotite or chlorite, and rare hornblende, whereas the pre-Kavirondian samples are characterised by abundant hornblende

Analyses were performed at the Universities of Leeds (Migori G2, Kavirondian boulders, and reanalyses of Masaba), Texas (MA 100–103, analysed by S DeLong) Toronto and Carleton University Concentrations of Rb and Sr were determined by isotopic dilution at Leeds and by X-ray fluorescence elsewhere, with an estimated precision of ± 1 5% (1σ) Strontium isotope ratios have a precision of ± 0 03% on critical samples (Migori G2), and 0 4–0 05% on the remainder Numerous inter-laboratory comparisons showed no systematic differences

Fig. 2 Sample localities Ma, Masaba Granite, Bu, Buteba Granite, Mu, Mumias Granite, Mi, Migori G2, Kc, Kavirondian conglomerate, T, Tertiary volcanics Small Kavirondian outcrops are omitted

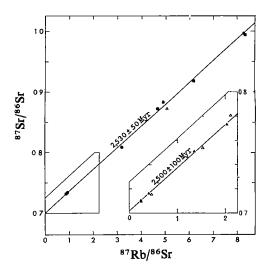
*$^{87}Sr/^{86}Sr$ determined at Leeds, Rb and Sr at Carleton

Analytical data are presented in Table 2 and Figs 3 and 4 The post-Kavirondian samples, including Masaba, give ages of about 2,500 Myr (Fig 3) The main differences between our data on the Masaba granite and those of Old and Rex[5] lie in the Sr isotope ratios, which they apparently overestimated systematically Our new analyses on the original Masaba samples (pre-fixed RO) are consistent with the results obtained by De-Long on MA 100–103 We consider the latter to be the more reliable, the samples were collected specifically for geochronological analysis, and they yield an isochron age of 2,500 ±80 Myr, with an initial $^{87}Sr/^{86}Sr$ (R_i) ratio of 0 7024 ± 0 0013 The other post-Kavirondian granite, Mumias-Buteba, yields an isochron age of 2,530 ± 50 Myr (R_i = 0 701 ± 0 003) consistent with the original data[5] for these samples Deviations from linearity in both isochrons suggest a measure of geological error, and the uncertainties quoted are estimates based on McIntyre's models 2–4 and York's model 1 (ref 12)

Our minimum age for the Kavirondian system, 2,530 ± 50 Myr, is similar to that given previously[4] A maximum age is obtained from the Rb–Sr isochron on Migori G2 (Fig 4), which gives 2,800 ± 120 Myr (R_i = 0 7013 + 0 0007) with no significant geological error The boulders do not yield an isochron, but they plot sufficiently near to the data on G2 to support the hypothesis that they were derived from that body, the discrepancies can reasonably be ascribed to the effects of weathering There are no strong reasons to suspect the isochron age of G2 to be other than the date of emplacement

The Kaapvaal counterpart of the Kavirondian System, the Moodies Group, is intruded by the Kaap Valley Granite, dated at 3,310 ± 40 Myr by the U–Pb method[9] A possible older limit for the Moodies Group, 3,500 ± 200 Myr, is given by an Rb–Sr mineral isochron[10] on a basaltic komatiite from the underlying Onverwacht group Thus, there is an age difference in the range 500 ± 100–1,000 ± 200 Myr (a length of time comparable with the whole Phanerozoic), between the Moodies Group and the Kavirondian System


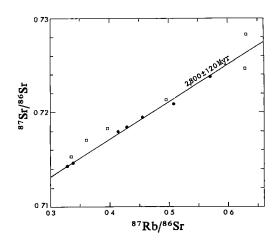


Fig. 3 Rb–Sr isochrons for post-Kavirondian granites ●, Mumias, ■, Buteba, triangles, Masaba (closed symbols used for isochrons) Isochron calculations were made using the method of McIntyre and York[12] Uncertainties are 1σ (67% confidence) Mean square of weighted deviates (MSWD) = 7 2 (Mumias) and 5 5 (Masaba)

No granites older than Migori G2 (2,800 ± 120 Myr) have been found in the Tanzanian Craton[13-15], and nothing unequivocally younger than 2,500 ± 100 Myr In the Kaapvaal Craton the granitic rocks were emplaced over a much longer period, and are divided into two suites on geochemical grounds[16] Granites of the older suite, dated at 3,400–3,000 Myr, can perhaps be considered to be geochemically analogous to the granites of the Tanzanian Craton The 'younger plutons', all of which postdate the greenstone belts, have ages of 2,800–2,500 Myr, but possess no obvious analogues in eastern Africa in the appropriate age range (1,900–2,200 Myr) Further radiometric and geochemical measurements on the granites of the Tanzanian Craton are in progress, and will allow a more precise comparison between the Archaean histories of eastern and southern Africa

We thank the Director of the Mines and Geological Department, Nairobi, for permission to sample from western Kenya, and the manager and staff of Macalder Mine for assistance Comments were provided by H Allsopp, C Anhaeusser, R A Cliff and D H Rayner Figure 1 was drafted by R C Boud

Numerical test of Palásti's conjecture on two-dimensional random packing density

RANDOM packing and random space-filling problems have received frequent attention[1-5] In one dimension, this topic is usually called the car-parking problem[6-10] Palásti[11] generalised the parking problem to two dimensions and conjectured that the random packing density in the two-dimensional case is equal to the square of that in the one-dimensional case Here we provide a thorough check on her conjecture and confirm its validity

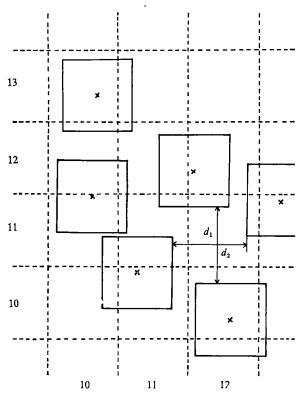
The procedure of two-dimensional random packing in Palásti's sense is as follows Consider a rectangle T_{xy} with vertices $(0,0)$, $(x,0)$, $(0,y)$, (x,y) where $x,y>1$ Fill the rectangle at random by unit squares whose sides are parallel to the coordinate axes The centre of filling squares is assumed to follow a uniform distribution over the unfilled portion of the rectangle If a unit square overlaps any of the previously placed squares or intersects with the boundary of T_{xy}, then it is discarded The process continues until the remaining space is inadequate for a unit square Let $M(x,y)$ denote the total


Fig 1 Diagram illustrating the filling procedure Dotted meshes represent unit square sections into which T_{xy} is subdivided Unit squares whose sides are solid lines express cars For example, the sections (10,13) and (11,11) belong to type I and type II, respectively The section (12,11) is of type III since d_1 and d_2 are greater than unity When (12,11) experiences 150 discardings of cars and still remains unfilled, we classify it in type III*

number of unit squares placed in T_{xy} and $m(x,y)$ indicate the expectation of the random variable $M(x,y)$ Palásti[11] proved that there exists

$$\lim_{x\to\infty, y\to\infty} m(x,y)/xy$$

and conjectured that the limit is equal to $c^2 \simeq 0\ 5589$ where

$$c = \int_0^\infty \exp\left[-2\int_0^t (1-e^{-u})/u\, du\right]dt \simeq 0\ 7476$$

This is just the limit of the mean random packing density in one dimension[6] Furthermore, she made Monte Carlo experiments for the four cases of $xy = 5\times15, 10\times15, 15\times15, 20\times15$, which always produced a value of 0 56 Solomon[12] reported similar experiments with results ranging from 0 50 to 0 55 In both cases, however, the size of the rectangle T_{xy} seems too small to test Palásti's conjecture stringently We have devised

* Another series of ten trials
† Only one trial

a computer program by which a Monte Carlo simulation of this problem can be made even for relatively large T_{xy}

For simplicity we restrict ourselves to the rectangle T_{xy} with x and y integers We subdivide T_{xy} into unit square sections whose number is xy To avoid confusion between a unit square section and a filling unit square, we shall hereafter call the former a 'section' and the latter a 'car' Instead of picking a centre point of a car at random in T_{xy}, choose a section with equal probability and then choose a centre of a car in that section During the course of packing, we classify sections into three categories (Fig 1) A section of type I contains a centre point of a car already placed It is obvious that sections of this sort cannot be occupied by centres of cars again A section of type II is defined as an empty section to which no centres of cars can be assigned In other words, the arrangement of cars inserted in the neighbouring sections prevents the type II section from including a centre point of a car Sections that belong neither to type I nor to type II are termed type III sections At the first stage, all sections are of type III As the procedure goes on, however, some of them change to type I or type II sections Type III sections left unchanged still experience repeated discardings of cars Those sections which have encountered 150 discardings of cars are excluded from the group of type III and renamed type III* sections The iteration proceeds until no sections of type III remain in T_{xy} The number of type I sections gives a lower bound of $M(x,y)$, and the total number of type I and type III* sections yields an upper bound The difference of these bounds was about 1 5% Furthermore, careful examination of type III* sections enables us to evaluate $M(x,y)$ with an error of at most 0 1%

Table 1 shows the results of our computer simulations together with the data of Palasti and Solomon Sample means and standard deviations over ten trials are listed there Our results seem to be in better agreement with those of Solomon than with those of Palasti As the size of T_{xy} increases, the mean packing density approaches $c^2 \simeq 0\ 5589$ When $xy = 100 \times 100$, this value is estimated as 0 5593, which is very close to c^2 Assuming that $M(x,y)$ is asymptotically normally distributed as in the one-dimensional case[9,10], we have a 95% confidence interval of $(0\ 5593 \pm 0\ 0013)$ The validity of Palasti's conjecture is thus confirmed numerically

Detonation of fuel coolant explosions

In certain circumstances the mixing of a hot liquid and a cooler, vaporisable one leads to an explosive rate of vapour production Such explosions have occured in foundries when molten metals and water mix[1], and when liquid natural gas is spilt on to water[2], they may also occur in liquid-cooled nuclear reactors under accident conditions It seems likely[3,4] that in these events an initial disturbance causes motions which fragment some of the material and so allow rapid heat transfer, this produces

explosive expansion and further fragmentation, and so the reaction propagates through the medium We give here a simple one-dimensional model of a system in which the two liquids are initially coarsely mixed, and show that there is the possibility of an extremely violent thermal explosion, the structure of which is analogous to that of a detonating chemical explosion

Consider a strong shock front progressing steadily through the coarsely mixed material (Fig 1), we assume (and justify below) that close to the front the flow velocities are sufficient to cause fine fragmentation of the hot material and rapid heat transfer The front leaves behind a mixture which attains thermal equilibrium at high pressure, in so doing the material expands and drives the front forward

Applying the equations of conservation of mass, momentum and energy to the material entering and leaving the front[5] we deduce that the possible states (U_2, P_2, V_2) of the material leaving the front are related to the pressure P_1 specific volume V_1 and internal energy U_1 of the material entering the front by

$$\tfrac{1}{2}(P_1 + P_2)(V_1 - V_2) = U_2 - U_1$$

This, together with the equation of state for the material leaving the front $U_2(P_2, V_2)$, defines a unique relationship between the possible values of P_2 and V_2 (called the Hugoniot or shock adiabatic)

From the theory of detonation[5] it can be shown that for a specific set of initial conditions, there is only one state (point O in Fig 2a), for the material behind the front which ensures that the explosion is stable In this state the velocity of the material leaving the front is just sonic with respect to the front—this is called the Chapman–Jouguet (C–J) condition Sonic choking at the C–J plane enables the explosion front to propagate independently of the motion in the region behind it

The explosion propagates with a velocity which is greater than the speed of sound in the medium ahead of the front The pressure and density both rise at the shock front in the 'von Neumann spike' (point N in Fig 2a), and the velocity in the frame of the front falls from the shock velocity to a low value (Fig 1) Behind the shock, as fragmentation and energy transfer occur, the velocity increases, reaching the local speed of sound at the C–J plane Pressure and density both fall in this region, along the straight line of constant mass flux NO in Fig 2a

Behind the C–J plane the material expansion continues The form of the solution in this region is 'self similar', that is the pressure and velocity profiles are always the same shape but their scale increases linearly with time Thus the expansion rates in this region fall inversely with time, and for times much longer than the heat transfer timescale equilibrium will be maintained throughout, and the expansion will be adiabatic

By analogy with the terminology for chemical explosions, we call a thermal interaction which propagates stably behind a shock front a 'detonating thermal explosion' Because the explosion must satisfy the C–J condition, we can predict the propagation velocities and pressures without a detailed knowledge of the fragmentation and energy transfer processes, assuming only that energy transfer is complete at the plane a_1 which the C–J condition is satisfied (see, for example, ref 6) Figure 2b shows the shock adiabatic for a system consisting of equal volumes of tin, water and steam The tangent from the initial point, $P_1 = 1$ bar, $V_1 = 0\ 37$ g cm^{-3}, meets the curve at a C–J point of pressure ~ 1 kbar The propagation velocity

$$v_1 = V_1 \sqrt{[(P_2 - P_1)/(V_1 - V_2)]} \sim 3 \times 10^4 \text{ cm s}^{-1}$$

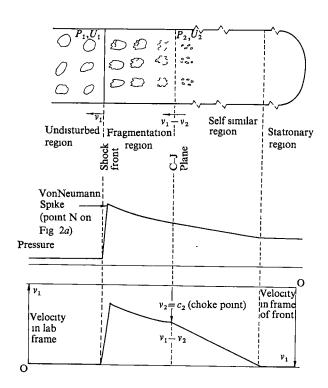
If there is little or no vapour initially present the Hugoniot curve remains more or less unchanged, but the point from which the tangent is drawn moves to a lower specific volume so that the pressure of the C–J state increases considerably The propagation velocity and the velocity differential causing fragmentation are also increased by the absence of vapour

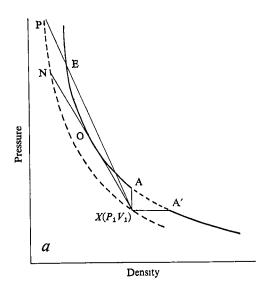
The model as so far outlined does not demonstrate that a detonation will occur, merely the conditions which it will fulfil if it does To demonstrate the realisability of such an explosion we must consider the fragmentation processes behind the front

In a detonating chemical explosion, the leading edge of the reaction front is a shock in the unreacted material, the compression raises the temperature of the material passing through it to such a level that combustion occurs close behind the shock We consider that the structure of a detonating thermal explosion may be similar, a simplified picture (Fig 1) is that the leading edge of the reaction region is a shock in which the vapour blankets are collapsed causing some degree of mixing and allowing efficient heat transfer to begin The steep pressure gradient at the shock front accelerates the materials entering it at rates dependent on their densities, so causing velocity differentials between the residual vapour, coolant and fuel If these velocity differentials are sufficiently large, fragmentation will occur before velocity equilibrium is re-established Such mechanisms for the breakup of drops have been observed in chemical detonation of two-phase systems where the fuel is in droplet form in a gaseous oxidising atmosphere[7]

We may use the data of Simpkins and Bales[8] on the breakup of liquid drops behind shock fronts to examine this event in more detail They showed that a drop of radius r_0, density ρ' in a flow of velocity u, and density ρ would break up in a time t given by

$$(\rho/\rho')^{\frac{1}{2}}ut/r_0 \simeq 44B_0^{-1/4}$$

Here B_0 is the Bond number, given by


$$B_0 = (\rho'gr^2)/\sigma = \tfrac{3}{8}C_DWe = (3u^2r_0 C_D)/8\sigma$$


where C_D is an effective drag coefficient (~ 2) and σ is the surface tension of the drop We compare the breakup time t with that required to achieve velocity equilibrium, namely

$$t' \simeq (8/3)(\rho'r_0)/(\rho u C_D)$$

The breakup time must be shorter than this for successful

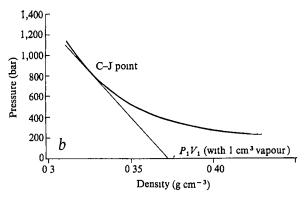
Fig 1 Geometry and schematic pressure and velocity profiles of a one-dimensional explosion


Fig 2 *a*, Schematic shock adiabatic Solid curve, reacted material, dashed curve, unreacted material *b*, Shock adiabatic for an initial mixture of equal volumes of tin at 1,000 °C, water at 100 °C and steam

fragmentation For tin drops of 1 cm diameter in water this condition is satisfied if the Bond number is greater than $\sim 10^4$ The differential velocity, u, is initially greater than v_1-v_2 (Fig 1), where $v_1-v_2 = \sqrt{[(P_2-P_1)(V_1-V_2)]} \sim 10^4$ cm s^{-1} (Fig 2*b*) Thus Bond numbers are greater than 10^5, and breakup by Taylor instability is achieved in typically $\sim 2\times10^{-4}$ s, ~ 10 cm behind the front The liquid drop will break into particles a micrometre or so across ($\rho u^2r/\sigma \sim 8$), and so the time for heat transfer will be much shorter than that for breakup Thus, a short distance behind the front energy transfer will be complete and a homogeneous equilibrium state will be produced These equations, though derived for motion down a long tube, should apply in any explosion if the reaction front is plane on a scale of many times its thickness so that all flow velocities are normal to it Single-phase chemical detonations have reaction fronts which are only a few tenths of a millimetre wide so that detonations can occur even in very small regions without external constraint On the other hand, two-phase detonations, whether chemical or thermal, have relatively long reaction lengths True one-dimensional detonation can only occur in constrained geometries, or regions of coarse intermixing which are large compared with the reaction length

We show now that the experiments so far performed in which large efficiencies have been achieved have approached the conditions necessary for detonating thermal explosions

Consistently high pressures (up to 600 bar) have been observed when columns of water are impacted into molten materials in strong tubes[9] It has been observed that material is excavated to a depth of about one tube width by each successive bounce of the column, and that the largest pressure peak is usually produced on the second impact If material which was

excavated on the first bounce is coarsely distributed over a few tube diameters at the bottom of the column, then the pressure pulse provided on second impact may trigger a detonating thermal explosion in this rather short (~ 5 cm) but roughly homogeneous and constrained medium. Experiments in which longer initial distributions of material were produced would provide a good test of the model.

We have observed explosions of quite high efficiency between Freon-22 and hot water[10]; on a foundry scale efficient interactions in metal–water systems have also been reported. In both cases there is photographic evidence for a degree of intermixing of the two components before explosion, though it is probable that in neither case is the characteristic dimension of the system much larger than the reaction length. Such explosions are thus intermediate in character between those in very constrained geometries and those in unconstrained stratified media.

Experiments in horizontally stratified and unconstrained metal–water mixtures have provided direct evidence for explosion propagation[4]. The reaction region is observed to propagate at only moderate velocity ($\sim 3 \times 10^3$ cm s^{-1}) along the fuel-coolant interface, and pressures of a few tens of bars are generated. These interactions do not fulfil the conditions for a one-dimensional detonating explosion; there is little premixing of tin and water, and the reaction front is necessarily of a size comparable with its width, so that sideways flow out of the front is very important. Accordingly, vapour generation is not suppressed, and the speed of sound in the front will be low. But it seems possible that for reasons of stability similar to those applying to a one-dimensional detonating explosion, the Chapman–Jouguet condition also holds for these two-dimensional explosions. Thus, because of the low speed of sound at the front, material will leave the front rather slowly and so the propagation itself will be slow; the low propagation velocities, and hence low efficiencies, seen in our small-scale experiments may also be characteristic of larger-scale explosions in unconstrained stratified media. But the first slow passage of the reaction front over a pool of metal may not cool all the available metal and could leave behind a coarsely mixed region through which a second, more efficient, explosion could propagate; this is indeed consistent with the photographic evidence of our larger tin–water interactions.

Although further work is necessary for a full quantitative theory of two-dimensional explosions, the present one-dimensional model is applicable to large scale events in, say, nuclear reactors. The SPERT 1D reactor was destroyed by an explosion which occurred when one third of the fuel was melted in an overpower transient. The high fraction of vapour in the core (~ 30%) at the time of the explosion presents difficulties for most explanations of the large pressures generated (~ 250 bar), see ref. 11), but these are easily understood on our model.

Fuel melting could also arise in fast reactors under fault conditions, and our calculations[12] show that pressures of the order of 15 kbar could be produced from large scale events involving sodium and molten uranium dioxide.

Fall of liquid metal into water

THERE is a possibility of explosions under a wide variety of conditions[1-6] when liquids are rapidly mixed. When molten tin is poured from a crucible into water in defined conditions, a rapid explosive interaction takes place producing a sponge-like mass of debris[7-9]. We have repeated these experiments using an apparatus which provides small (~ 0.25 g) and reproducible single drops of molten tin, and have been able to determine quantitatively the dynamics of the interaction by a photographic technique. Using a metal temperature of ~ 570 K and water at room temperature metal drops were produced which entered the water in a straight vertical line but were then observed to deviate suddenly and sharply from their course without losing their pear-like shape. This metal temperature was just below that necessary to produce explosive interactions for the given water temperature.

We have photographed the fall of drops of molten tin at 570 K, and mercury and carbon tetrachloride at room temperature, into tap water at room temperature, using stroboscopic illumination. The path of a falling drop is clearly visible, both in the air and below the water, and the velocity may be determined from the image spacing. Although mercury and carbon tetrachloride fall in vertical straight lines to the first order (Fig. 1), molten tin drops

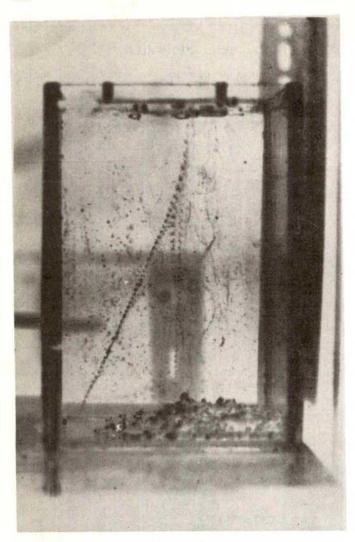
Fig. 1 A carbon tetrachloride drop falling from a height of 2 cm into water. Both liquids were at 293 K, and the drop was photographed in a stroboscopic light at 1,500 flashes min^{-1}. No significant deviation can be seen.


Fig. 2 Molten tin drops at 570 K falling from a height of 23 cm into distilled boiled water at 293 K. The drops were photographed in a stroboscopic light at 9,500 flashes min⁻¹. A significant deviation can be seen.

which takes place between stable film boiling and transition boiling. In less than 0.25 ms the vapour shell is explosively destroyed giving rise to a regime of boiling described as pulsation boiling, which consists of a thin oscillation vapour film. This then progressively changes to nucleate boiling from the front of the sphere to the back, with a pulsating vapour ring separating the nucleate boiling zone from the remaining thin vapour film. If the transplosions or the pulsating vapour rings occur in a similar fashion on molten tin drops, they could perhaps provide an explanation for the considerable momentum found to be imparted during the quenching process.

This work was carried out for the Sub-Committee on Continuous Casting of the Joint Standing Committee on Health, Safety and Welfare in Factories, and financed by the Department of Employment.

(Fig. 2) initially fall in vertical straight lines, but after a few centimetres in the water deviate from this straight line by up to $\frac{1}{3}$ rad.

It has been suggested[7-9] that fragmentation of the molten tin is linked with the collapse of a vapour blanket surrounding the molten metal during the change from stable film boiling to transition boiling. Using a model for the collapse of a vapour bubble developed by Plesset and Chapman[10], Buchanan and Dullforce[7] predict the velocity and dimensions of a slug of water resulting from the collapse of a bubble of initial radius R_m, which then penetrates the liquid metal initiating the first cycle of a fragmentation process. From our photographs, using simple particle dynamics, it is possible to find the direction and magnitude of momentum imparted to the tin drop. Assuming that this momentum results from the collapse of a single vapour bubble adjacent to the tin drop, R_m can be evaluated. Values of the momentum imparted lay between 4 and 12 g cm s⁻¹, and the momentum was directed upwards at angles to the vertical between 0.87 and 1.22 rad. Corresponding values of R_m were between 0.25 and 0.35 cm. These seem too large for single bubble collapse to be a complete explanation for an initiation of the fragmentation process, at least for molten tin drops of radius 0.15 cm.

Work has been carried out[11] on quenching hot, solid metal spheres by moving them at a constant speed (of a similar value to that of our tin drops) through a tank of water. A phenomenon termed a "transplosion" is described,

Strain enhanced dissolution effects in the corrosion-fatigue failure of metals

IT has been suggested[1] that yield assisted dissolution, which occurs during the corrosion fatigue of high carbon steels in aqueous sodium chloride solutions, may be responsible for the initiation of cracking. Furthermore, it is likely[1] that at low stresses the process of crack initiation largely determines the overall corrosion-fatigue life. It now seems that these significant dissolution effects can be produced and observed in metals subjected to strain cycling in corrosive solutions.

We have studied the anodic dissolution of mild steel, aluminium and stainless steel, during cyclic plastic deformation in aqueous electrolytes, in order to simulate on a macroscopic scale the local conditons that occur at stress concentrations during corrosion fatigue. Specimens held under potentiostatic

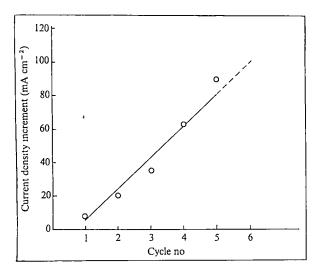
Fig. 1 Dissolution transients in 18/8 stainless steel, strain cycled in 3.7 M H_2SO_4 at 1,042 mV (normal hydrogen electrode—n.h.e.)


Fig 2 The variation of dissolution transient magnitude with cycle number at a potential close to the active–passive transition, using 18/8 stainless steel in 3 7 M H_2SO_4 at 262 mV Strain, $-0 05$ to $+0 05$

control in the electrolyte were subjected to square wave strains in the range $\pm 0 02$ to $\pm 0 05$ at strain rates of $\sim 0 30$ s^{-1} These strain levels were chosen to provide a sufficient number of slip steps on the surface of the metal to give dissolution effects large enough to be measured In practice, overall strains of this magnitude are unlikely to be encountered even at stress concentrations Even when small local plastic strains occur, however, the emergent slip steps will behave chemically in a similar manner

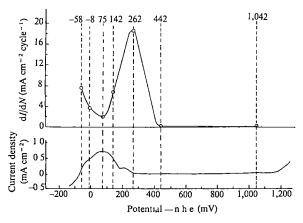
Dissolution transient currents were observed during both tensile and compressive strain reversals The transients reached peak values during the application of the strain or at the position of maximum strain, and decayed during the constant strain portion of the strain cycle (Fig 1) The magnitude of the transients, their position relative to the strain cycle and their decay characteristics have been found to depend on several factors, including the potential of the metal surface, the magnitude of the strain reversal, the strain rate and the tendency for surface films to form


Fig. 3 The change of dI/dN relative to the anodic polarisation curve for 18/8 stainless steel in 3 7 M H_2SO_4

A particularly interesting type of behaviour was observed with 18Cr–8Ni (18/8) stainless steel in 3 7 M H_2SO_4 where repeated strain cycling at active and just passive potentials caused a progressive increase in the magnitude of the tensile dissolution transients The initial transient at all potentials was found to be $< 10 mAcm^{-2}$, at potentials close to the active–passive transition, however, the transients were found to grow by an order of magnitude

within six or seven strain cycles (Fig 2) Assuming that dissolution was concentrated on emergent slip steps at the metal surface these transients represent a local increase of $> 1,000$ in the dissolution rate The rate of increase of the peak value of the current transients per cycle, dI/dN, varies with potential for a cyclic strain of $\pm 0 05$ (Fig 3) It is evident that dI/dN reaches maximum values over a limited potential range coincident with the active–passive transition region, this effect has also been observed at strain levels below $\pm 0 05$ Dissolution effects occurring beyond 10 or 15 cycles have not been investigated because of experimental difficulties in continued cycling at high strain levels It cannot, therefore, be assumed that dI/dN will remain constant during subsequent cycling

If, in corrosion fatigue, stress concentration effects are sufficiently high to induce local plastic deformation on the surface of the metal then the observed dissolution behaviour is likely to occur and could assist crack initiation by a combination of reversed slip and dissolution[2] The evidence suggests that for stainless steel in H_2SO_4 the maximum contribution of dissolution to the initiation of cracking should occur at the active–passive transition Corrosion-fatigue data on 18/8 stainless steel in H_2SO_4 at controlled potential is not available It is interesting to note, however, that Spahn[3] has found the minimum corrosion-fatigue properties of a 13% Cr stainless steel in H_2SO_4 occur at potentials in the active–passive range, that is, at potentials equivalent to those where we observe dI/dN to reach a maximum value

Tough fibrous composites

GORDON and Jeronimidis[1] and Atkins[2] have noted that increased fracture toughness in fibrous composites can be obtained by an enhanced decoupling of the fibre–matrix interface Gordon[1] has pointed out that in the case of wood (natural cellulose), the decoupling of the 'reinforcing elements' from the rest of the structure is stress dependent and the cells in the vicinity of the fracture face can extend by about 20 per cent before breaking, absorbing a great deal of energy in the process The failing strain of the material as a whole is, however, about 1% Atkins[2] pointed out that increased works of fracture can be obtained in boron fibre expoxy resin composites by arranging for a distribution of strongly and weakly bonded interfacial regions along the fibres During crack propagation the weakly bonded regions allow greater lengths of fractured fibres to be pulled out of the matrix with a concomitant increase in the work of fracture The tensile strength of the composite system is not affected significantly but the overall failing strain is again limited by the failing strain of the reinforcing fibres to about 1%

It has been pointed out[3,4] that the fracture toughness of fibrous composites can be enhanced by a stress controlled decoupling mechanism and, moreover, that fibre fracture can thus be prevented Very large tensile deformations are thus rendered possible as continuous reinforcing elements are pulled through the composite structure The design and behaviour of experimental non-fracturing reinforcing elements has been reported[5-7,12] and the enhanced work of fracture of sheet metal reinforced with such elements has been observed[8-10]

Not only do such systems possess fail-safe characteristics, because of the non-fracturing nature of the reinforcing fibres, but the reinforcing phase is completely insensitive to stress concentrations Because of this, these systems can absorb very much more mechanical energy without fracturing than the toughest work-hardening metal alloys in circumstances where the metal would suffer localised failure[11] That is, of course, the normal situation when sheet metal structures are subjected to localised loading by the impact of a missile or by any other means Prototype systems based on the stress-controlled decoupling principle are under investigation as potential energy absorbing components of motor vehicles (R S Millman and M J Chappell, unpublished)

Studies have been made of the energetics of crack growth in metal plates loaded in tension under fixed grip conditions and reinforced by non-fracturing elements[10] The fracture mechanics of these composite structural systems is quite different from those of other materials because the primary reinforcing phase is completely crack insensitive and also inhibits crack growth in the metal plate Within a specified envelope of conditions, unstable crack growth in the metal plate is not energetically possible, whatever the length of the crack Within these specified conditions the work of fracture of the composite system, calculated in the conventional way, becomes, in effect, infinitely large

It is interesting to speculate whether analogous stress controlled decoupling mechanisms could be made to operate at the molecular level on the cross links between the molecular chains of polymeric systems

Organochlorine residues in Antarctic snow

DDT is a useful model compound for studying the circulation of a toxic pollutant in the global environment[1,2] An understanding of this process could in future be related to potentially more hazardous materials Present models of the dynamics of DDT circulation can account for only a small fraction of the amounts of DDT and DDE which are known to have been released into the environment Major unknowns include the extent to which the atmosphere and oceans act as reservoirs and the transfer rate of these residues from the atmosphere to the oceans where, according to present ideas, they may be removed from circulation by transfer to the abyss[3] Such atmospheric and oceanic transport mechanisms may carry pollutants into the ecologically protected area of Antarctica and it is necessary to assess the extent to which this is occurring and the relative importance of alternative input routes The atmosphere has been assumed to play the major role in the transport cycle but there is a lack of supporting data We report here levels of DDT and metabolites

in Antarctic snow which suggest that the role of the atmosphere in the transport of DDT may have been overemphasised

Measurements of global background levels are hampered by contamination problems at the very low concentrations found[4], by the proximity of local sources of emission, and by interference from other more dominant organic components (as in oceanic measurements) Studies in the interior of Antarctica largely overcome the last two problems Subzero temperatures throughout the year combined with negligible biological activity ensure minimal chemical alteration or diffusion of trapped pollutants after deposition of the snow The year and season of deposition of a particular snow sample may be established by investigation of the stratigraphy of the snow section from which it was taken The present study forms part of an attempt to establish upper limits of concentration of organochlorine residues in contemporary Antarctic precipitation

Representative snow samples from the previous 5–10-yr accumulation were collected during December 1969 on a journey of 450 km inland from the British Antarctic Survey's Halley Bay station (75°31'S, 26°42'W) Sampling procedures were designed to reduce contamination to a minimum by repeatedly trimming large snow blocks before packing them for transport The snow was returned to England in the frozen state, wrapped in pre-cleaned aluminium foil and sealed in steel containers

Samples for analysis were obtained by continued trimming of the snow blocks in a glove box under purified nitrogen at -10 °C Analyses were carried out in a closed glass system[13] under purified nitrogen The system allowed melting, meltwater transfer, and extraction and concentration steps to be carried out in sequence so that at no stage did the samples contact a laboratory atmosphere Continuous cyclic liquid–liquid extraction was used to transfer the organochlorine components in 1 l aliquots of meltwater into 20 ml hexane The hexane solution was subsequently concentrated to 20 µl Meltwater samples, to which had been added radiolabelled pp'DDT at the 1×10^{-12} g g^{-1} level, were used to check the efficiency ($>90\%$) of these procedures Extracted components were identified without cleanup using a Pye 104 gas chromatograph with electron capture detection and 3 m × 3 mm glass columns packed with 1 5% OV-17/QF-1 and 2% SE-30 on 100–200 mesh Chromosorb G Identification of DDT was confirmed by treating the extract with alkali, which eliminated the DDT peak and enhanced the DDE peak Detection limits, which were imposed by incidental contamination, were 3×10^{-14} g g^{-1} water for both DDT and DDE

The data reported here were obtained from 10 snow samples representative of accumulation laid down between 1965 and 1969 at two sites, 360 and 400 km from the coast, where possible interference from oceanic components was minimal Results from two duplicated samples agreed within experimental error (10% at 1×10^{-13} g g^{-1} to 50% at 2×10^{-14} g g^{-1}) Peaks coincident with pp'DDT and pp'DDE occurred in all samples studied The total concentration of DDT and its metabolites (DDT-R) ranged from 0 1 to 2 0 × 10^{-12} g g^{-1}, however pp'DDE was consistently more abundant than pp'DDT by a factor of 1 3 to 1 8 There was no evidence for families of other components corresponding to polychlorobiphenyls (PCBs) in the 50–60% chlorine composition range, which are widespread in the northern oceanic areas[5] and have been reported in birds which range north of the Antarctic Convergence[6]

Our data contrast with earlier measurements[7] made on snow from Plateau Station, Antarctica where some of the samples were reported to contain 40×10^{-12} g g^{-1} of pp'DDT alone These figures are comparable with average measurements made in England over the same period[8] It is evident that studies more widely based both in time and space are required in Antarctica

Higher levels of DDE than DDT have also been reported in some English rainwater samples[8], particularly outside the spraying season when DDT levels were relatively low This could be explained simply by evaporation of the more volatile metabolite DDE from deposited DDT which has undergone microbial degradation The increased DDE/DDT ratio indicated by the Antarctic samples could point to further photodegradation of

DDT vapour in sunlight[9] during atmospheric transport The very low background levels add further weight to Cramer's[2] suggestion that perhaps too much emphasis was placed on the atmosphere as a reservoir and transporter of DDT in an earlier model described by Woodwell[1] in which 60×10^{-12} g g^{-1} was considered to be a global average for precipitation Further sources of chemical[14] and biological degradation must be sought

Previous studies[6,10-12] of animal species which remain closely associated with the Antarctic continent throughout their life cycle (Emperor penguins, Adelie penguins, crabeater seals and snow petrels) have yielded lipid analyses of total DDT-R ranging from 0 to 200×10^{-9} g g^{-1} The average content of all samples so far studied is approximately 90×10^{-9} g g^{-1} Taking an initial value of 1×10^{-12} g g^{-1} DDT-R in Antarctic precipitation, an enrichment factor (concentration in animal/concentration in environment) of about 90,000 is obtained This is compatible with values found elsewhere in the environment[3] The implication is that the animal species which remain close to the Antarctic continent are in equilibrium with the surrounding air and natural water It is not necessary to invoke a passage up the food chain of pesticide residues from oceanic nutrients drawn southwards across the Antarctic Convergence

The extremely low levels of PCBs in our snow samples (5×10^{-14} g g^{-1}) agree with data[8] from Adelie penguins and snow petrels, in which the ratio of DDT-R/PCBs is much greater than that found in species which range north of the Antarctic Convergence, despite the marked increase in DDT-R in these species[6,12] These results indicate that the Antarctic environment is much more strongly shielded from penetration by PCBs than by DDT-R This would tend to argue against the idea that, at least on a global scale, the atmosphere is the predominant mode of transport for PCBs

Mutation affecting taste perception in *Drosophila melanogaster*

ANALYSIS of mutant organisms can elucidate by contrast the development of the normal phenotype and this approach can be used to break down behavioural characteristics into their embryological and physiological components Taste in insects is a characteristic suitable for such a study Genetic analysis of taste in *Drosophila melanogaster* can complement the electrophysiological and anatomical information on taste organs of flies obtained mainly from *Calliphora* and *Phormia* The taste organs of flies are located predominantly on the labella at the tip of the proboscis, and on the tarsi On each half labellum of *Drosophila* there are 36–42 taste bristles on the surface and some 25 taste pegs between the pseudotracheae All but five or six bristles are penetrated by the dendrites of four chemoreceptors (the remaining ones having two dendrites), while there is only one chemoreceptor in each interpseudo-

tracheal peg Each taste organ is also provided with a mechano-receptor neurone (R. F , Bleiser-Avivi and J A , in preparation) Of the four dendrites penetrating to the pore at the tip of the taste bristles in *Phormia*[1-3], one is a water sensor, one reacts to sugars and two react to salts[4-6]

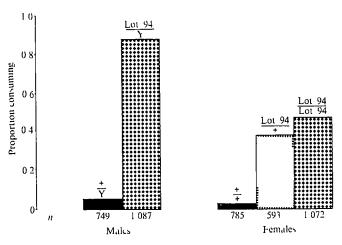
The normal fruit fly responds to stimulation of its taste organs by a vigorous extension (or retraction) of the proboscis which may be followed by consumption of the solution offered A standard testing procedure was developed 4-5-d-old flies were put into funnels covered with a nylon net, they were starved and desiccated for 3 h at 28 °C and then the funnels with the flies were transferred to Petri dishes containing a cotton wool pad soaked with a test solution to which a red food colouring was added The flies were allowed to consume the solution through the net for 20 min (at 28 °C) The proportion of flies with red coloured intestines expressed the reaction of the flies to the taste of the solution Wild type *Drosophila* consume a 0 1 M sucrose solution but reject it when 1 M NaCl is added


Fig 1 Proportion of flies consuming the test solution (1 M NaCl+0 1 M sucrose) under standard conditions 4-5-d-old flies, 3 h starvation and desiccation at 28 °C, 20 min feeding at 28 °C +, The normal allele of the Lot-94 salt-tolerant mutation (in the heterozygous females it was carried over the In(1)FM6, $y^{31d} sc^8 dm B$ chromosome) *n*, Number of flies tested

Mutations were induced by feeding young males of the wild-type Qiryat-Anavim (QA) stock with a 0 2% ethylmethanesulphonate +1% sucrose solution for 24 h The treated males were mated to yellow, attached-X females F_1 progeny were scored for salt tasting with a standard screening solution of 1 M NaCl +0 1 M sucrose About 3% of wild-type males consume this solution normally All males with red intestines were mated individually to attached-X females and cultures in which a high proportion of the male progeny consumed the screening solution were maintained The suspected X-chromosome mutations to tolerance to the taste of salt were designated 'Lot'[7] Three Lot mutations have been characterised so far[8] One, Lot-94, was mapped to the left of *f*, at 55 5–56 0 on the X-chromosome (J A and Baker, in the press) Homozygous females of this mutation were less insensitive to NaCl solutions than the mutant males This might be only partly the result of the generally greater reluctance of females to consume any solution under our experimental conditions No clear conclusion on the dominance of Lot-94 could be reached, since in some heterozygous combinations it reacted like a partial-dominant mutation (Fig 1), while in others it was completely recessive (see controls in Table 2) Another mutation, Lot-114, probably allelic to Lot-94, was completely recessive in all combinations tested The third mutation, Lot-235, is a recessive mutation at another locus

Response to labellar and tarsal stimulation was tested separately to find out whether the Lot-94 mutation affected both sites QA and Lot-94 flies were fixed in rows on a double-

Table 1 Response of wild-type (QA) and mutant (Lot-94) males to 0 1 M sucrose (Suc) and to 1 M NaCl+0 1 M sucrose (Mix)

Tergites 2 and 3	0 27	0 52	0 63	38 6	5 4
Non-gynandromorphic sibs (controls)	0 09		0 86		

The proportion of 532 gynandromorphic flies that consumed 1 M NaCl+0 1 M sucrose solution under standard experimental conditions is given, and the distance in sturt units between the focus of Lot-94 and the reference foci (Af) and between left and right foci of Lot-94 (ff′) was calculated according to Hotta and Benzer[12], assuming that the mutant focus is submissive to the normal focus
*Fate map distances change slightly and proportionally if corrected for consumption of non-gynandromorphic siblings

sided tape on a microscope slide Solution of sugar or mixed salt and sugar was applied from a capillary to alternating flies in the row, by touching their labellum or tarsi The proportion of flies that extended their proboscis was registered In other experiments, the labellum was touched and the length of time that the flies consumed the solutions was recorded (Table 1) There were no differences in the response to sugar between QA and Lot-94 when either the labellum or the tarsi were stimulated Lot-94 flies were significantly less sensitive to salt when consumption time was measured Reduced salt sensitivity was also indicated by extension of the proboscis on touching the labellum with salt solution On the other hand, touching the tarsi with salt solution elicited less proboscis extension in the Lot-94 than in the wild-type QA flies This indicates that tarsal reaction is not the decisive component of the flies' response in our standard testing procedure Getting and Steinhardt[9] postulated the existence of different intermediate neurones for the labellar and tarsal taste receptors in *Phormia* The difference in labellar and tarsal response to salt in the mutant Lot-94 of *Drosophila* is consistent with this finding

The behavioural pattern of a genetic mosaic depends on whether the genotype of the focus essential for the relevant phenotype is mutant or normal In order to produce mosaics for Lot-94, females heterozygous for the unstable ring X-chromosome R(1)2, w^{vc} were mated to y w sn $Lot-94/y^+Y$ males[10] In 25% of these heterozygous embryos, the unstable X-chromosome was lost in an early cleavage division, turning them into XX/XO gynandromorphs Yellow cuticle (y), white eyes (w), singed bristles (sn), sex combs and male genitalia served to detect sectors of XO cells These sectors were also hemizygous for the Lot-94 mutation Since less than half of the gynandromorphs were mutant with respect to their taste response, the mutant focus was assumed to be submissive to

the normal The focus of the mutant was located in the gynandromorphs on the basis of the assumption that the closer a cell was to the focus in the blastoderm, the higher the probability of agreement between their genotypes[11,12] The focus of Lot-94 was closer to that of the antenna than to that of the proboscis (Table 2) The only significant maximum likelihood estimate[13] obtained so far, places the focus 31 sturts (see ref 12 for definition) away from the proboscis and 6 sturts from the midline This does not exclude the possibility that the focus of Lot-94 for taste perception of the labellum is located at a different site from that of the tarsi The focus of Lot-94 was tentatively located midventrally, in the area of the blastoderm giving rise to the brain Thus Lot-94 is a mutation of a perception centre, affecting the recognition of salt, with no detectable effect on that of sugar

We thank Mrs S Baker for her help, and Dr John Merriam for running our gynandromorph data on his computer program

Iridovirus and cytoplasmic polyhedrosis virus in the freshwater daphnid *Simocephalus expinosus*

AN iridovirus and a cytoplasmic polyhedrosis virus have been found as the cause of disease in the freshwater daphnid, *Simocephalus expinosus*, collected in Florida (Fig. 1). Although both types of virus were originally reported from insects[1-3] and are now well known insect virus types[4], neither has been reported before from the Crustacea. Iridoviruses have been reported from other invertebrates and from some vertebrates[5], however, cytoplasmic polyhedrosis viruses have been reported only from insects.

Daphnids infected with iridovirus were first collected during April 1972 from two woodland ponds, approximately 7 miles apart, near Gainesville, Florida. One pond was sampled periodically during each season of 1972, 1973 and 1974. *S. expinosus* seemed to be present only during the spring. During each sampling period, infected specimens were collected until the middle of June, after which host populations declined. The incidence of infected daphnids was never greater than 1%. All specimens were examined against a black background with a fluorescent light. Frankly infected daphnids were opalescent while apparently healthy specimens were grey and translucent.

For electron microscope studies, daphnids were dissected and fixed in 3% glutaraldehyde in 0.1 M phosphate buffer for 3 h, postfixed in 1% osmium tetroxide for 2 h, dehydrated, and embedded in an Epon–Araldite mixture, using standard methods. Examination of ultrathin sections of daphnids infected with iridovirus revealed virions throughout the adipose and glandular tissues, in the epidermis and associated endocuticle, and occasionally in nerve tissue. No virions were observed in muscle or gut epithelial tissues. Virus morphogenesis was restricted to the cytoplasm of infected cells. There was marked degradation of cellular organelles in advanced stages of the disease. Although large numbers of virions accumulated in the cytoplasm of many infected cells, paracrystalline arrays of virions, common in many iridovirus diseases, were not observed.

Structurally, virions were icosahedral and morphologically very similar to other virions of the iridovirus group[5]. Cross sections through mature virions indicated a dense central core (diameter about 96 nm), surrounded by at least one unit-membrane envelope which in turn was surrounded by the capsid. In most virions an amorphous layer of approximately 12 nm was observed between the envelope and the dense central core. The edge-to-edge and point-to-point diameters of mature virions were about 136 nm and 154 nm, respectively. From these measurements, an average fivefold rotational axis diameter of about 140 nm was calculated, using the icosahedral virus model of Mattern[6]. The virus tentatively has been designated iridovirus type 20, conforming with the interim nomenclature system for iridoviruses proposed by Tinsley and Kelley[6].

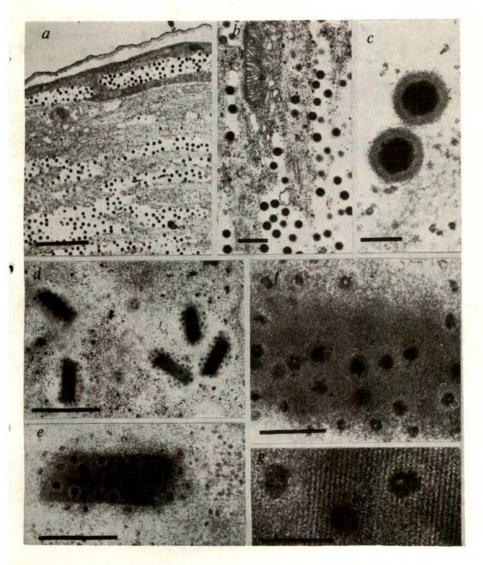
The cytoplasmic polyhedrosis virus (CPV) was discovered during ultrastructural examinations of daphnids infected with iridovirus. This virus was only observed in the cytoplasm of the midgut epithelial cells. The occlusion bodies were pleiomorphic,


Fig. 1 Electron micrographs demonstrating iridovirus (*a–c*) in a portion of the postabdomen and cytoplasmic polyhedrosis virus (*d–g*) in midgut (caecum) epithelial cells of the daphnid *Simocephalus expinosus*. *a*, Virions in epidermal and adipose tissue (bar=3 μm); *b*, virions in the cytoplasm of an adipose cell (bar=500 nm); *c*, section through two mature virions illustrating the dense core and unit membrane interior to the capsid (bar=100 nm); *d*, oblong polyhedral occlusion bodies in the cytoplasm of a cell (bar=1 μm); *e* and *f*, developing occlusion bodies. Note the virions with electron translucent centres toward the periphery of the occlusion bodies (*e*, bar=400 nm; *f*, bar=200 nm). *g*, Virion cores in an occlusion body (bar=100 nm). Note the crystalline lattice of the occlusion body in (*f*) and (*g*).

the smaller ones ($900 \times 300 \times 300$ nm) being brick-shaped polyhedra while the larger forms (up to 2 μm) were spherical. Virion morphogenesis was different in that unlike other CPVs the virions apparently matured only in close proximity to developing occlusion bodies. Unoccluded virions were frequently observed with electron translucent centres. Occluded virions near the periphery of developing occlusion bodies also occasionally contained electron translucent centres, whereas those occluded within the central areas of large occlusion bodies had uniformly dense cores typical of unoccluded and occluded virions in other CPVs. The virions were icosahedral and approximately 60 nm in diameter. Because the capsid and occlusion body protein were similar in electron density and could not be easily distinguished, this figure should be considered tentative. The virion cores, which were quite distinct, were about 38 nm in diameter.

Couch[8] reported a baculovirus, another type of virus found commonly in insects, in the pink shrimp, *Penaeus duorarum*. The observations reported here, in conjunction with Couch's report, demonstrate that virus types generally considered to be insect viruses, namely, baculoviruses, cytoplasmic polyhedrosis viruses, and iridoviruses, also have as their natural hosts members of the Crustacea. This is not to imply that insect viruses infect Crustacea, but rather that these virus groups have a broader taxonomic distribution than is generally realised. These findings indicate the need for further research directed toward determining the kinds of viruses which occur in Crustacea and other invertebrates. This is important especially because several pathogenic insect viruses are being considered as biological control agents. Knowledge of the distribution of virus types and their specificity in invertebrates will provide valuable background information for the implementation of biological control programmes involving insect viruses.

Enzyme synergistic for insect viruses

A GRANULOSIS virus (GV) and a nuclear-polyhedrosis virus (NPV) of the armyworm, *Pseudaletia unipuncta*, form a synergistic association in which the infection of the NPV is enhanced[1]. The synergistic factor responsible for the enhancement (56-fold) occurs in the protein of the inclusion body (capsule) that surrounds the particle of GV[2,3]. This factor is present in detectable quantities in one strain of GV (Hawaiian) but not in another (Oregonian)[4,5]. It has been purified by Sephadex gel filtration and seems to be a simple or conjugated protein[3]. We now report that the synergistic factor has properties of an enzyme and can enhance not only the NPV and GV of the armyworm but also other insect viruses. Earlier studies[1,2] had shown that the synergistic factor was heat labile. It became inactive when heated at 85 °C for 10 min (ref. 1). The viral activity, on the other hand, was destroyed at 75 °C for 10 min.

The synergistic factor seemed to be an enzyme because

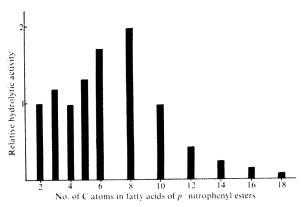
it catalysed the hydrolysis of *p*-nitrophenyl esters of fatty acids and was inhibited by metallic ions. Tests for hydrolysis of the soluble substrates (esters of two to four carbon atoms) were made in a mixture containing the synergistic factor at 1 mg ml⁻¹, 5% *iso*propyl alcohol, 0.5 mM of the *p*-nitrophenyl ester, and 0.0025 M HCl-Tris buffer, pH 9.0 the pH of optimal hydrolysis. The mixture was held at 25 °C for 30 min, and the amount of product released was measured in the spectrophotometer at 410 nm, the wavelength of the peak absorption for *p*-nitrophenol. In the case of the insoluble substrates (esters of five or more carbon atoms), gum arabic at a final concentration of 1% was added as an emulsifier to stabilise the suspension. The mixture was agitated for 3 min in a sonicator. Subsequently, the treatment was essentially the same as for the soluble substrates, except that after incubation at 25 °C, chloroform was added, and the mixture was shaken for 3 min and centrifuged at 3,000 r.p.m. for 15 min to remove the residual insoluble substrate. The supernatant was collected and read at 410 nm. The controls, which consisted of the esters of the fatty acids, were examined concurrently with the treatments containing the synergistic factor.


Fig. 1 Hydrolysis of fatty acids by the synergistic factor of a granulosis virus. The hydrolysis of *p*-nitrophenyl acetate is given a value of one. The synergistic factor was isolated and purified as follows. The GV capsules were dissolved largely by treatment for 3 h with 0.02 M NaOH at 4 °C, after which the insoluble material was removed by centrifugation at 20,000 r.p.m. for 1 h. The supernatant was dialysed against 0.01 M phosphate buffer, pH 8.0 and then concentrated in a collodion bag under reduced pressure at 4° C. The concentrate was fractionated by filtration through a Sephadex G-200 gel at 4 °C, and the various components separated were examined with a Beckman DB-GT spectrophotometer at 280 nm. There were six peaks, and each was tested on fifth-instar armyworm larvae for its enhancing capacity as before[2]. The synergistic factor occurred in the second peak fraction, which was concentrated at 4 °C in a collodion bag under reduced pressure and dialysed at 4 °C against 0.001 M phosphate buffer, pH 8, for 16 h. The dialysate was applied to a 1.5 × 5 cm hydroxylapatite column which had been equilibrated with 0.001 M phosphate buffer. The column was washed with 0.001 M phosphate buffer and the synergistic factor was eluted with 0.005 M phosphate buffer, pH 8. The eluate gave a single protein band in disc acrylamide gel electrophoresis using a 7.5% gel in a medium of 8 M urea and glycine buffer, pH 8.7.

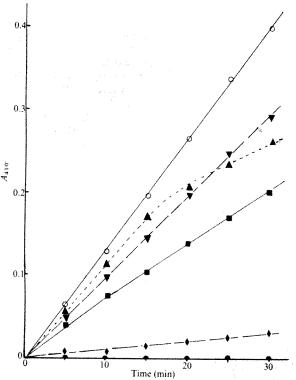
In the controls, hydrolysis of the esters of fatty acids occurred also, but at a slower rate than in the presence of the synergistic factor. The results given in Fig. 1 are the differences between the controls and those obtained with the synergistic factor. The relative activity (with *p*-nitrophenyl acetate arbitrarily given a value of 1) of the synergistic factor increased as the carbon atoms in the chains of the fatty acids increased from two to eight, but possibly with a slight dip in activity with butyrate (four carbons). There was a gradual reduction in the hydrolysis of esters with 10 to 18 carbon atoms. Accordingly the synergistic factor catalyses the hydrolysis of synthetic esters of fatty acids.


Fig. 2 Effect of metallic ions on the hydrolysis of p-nitrophenyl butyrate by the synergistic factor of a granulosis virus. ○, Control; ▼, Mn; ▲, Mg; ■, Ca; ◆, Cu; ●, Hg.

The optimum pH for the hydrolysis of p-nitrophenyl caprylate by the synergistic factor was studied at various pH using the following buffers: 0.05 M phosphate buffer for pH 6.0, 7.0 and 7.5; 0.05 M Tris-HCl buffer for pH 8.0, 8.5, and 9.0; 0.05 M carbonate buffer for pH 9.5, 10.0, and 11.0. The quantity of released p-nitrophenol was measured in the spectrophotometer at 410 nm. The peak in hydrolytic activity occurred at pH 9.

Since enzymes are often inhibited by metallic ions, the synergistic factor was exposed to five different salts of metals and its activity on p-nitrophenyl butyrate was examined. The salts were $MnCl_2$, $HgCl_2$, $CuSO_4$, $CaCl_2$ and $MgCl_2$, at 1 mM. These metals inhibited to varying degrees the hydrolysis of the butyrate by the synergistic factor (Fig. 2). Copper markedly inhibited and mercury completely inhibited hydrolysis.

The synergistic factor after exposure to these five metallic ions was tested for its enhancing capacity on NPV in the armyworm. After treatment with mercury, the enhancing capacity was destroyed; however, treatment with other metals had little or no effect on enhancement.

Before the isolation of the synergistic factor, our tests indicated that the GV was synergistic for the NPV of the armyworm but not for other insect viruses. But, when the synergistic factor was purified and concentrated and fed together with the GV (Hawaiian and Oregonian strains) of the armyworm, with the NPV and GV of the cabbage looper (*Trichoplusia ni*), and of the beet armyworm (*Spodoptera exigua*), it enhanced the infection of these viruses.

The inclusion bodies, such as the polyhedra of the NPV and of the cytoplasmic polyhedrosis virus (CPV), the capsules of GV, and spherules of poxvirus, are generally believed to protect the virus particles occluded within them from the adverse effects of the environment. The presence of the synergistic factor within the capsule of the GV suggests another function, that of enhancing the infection of the virus.

Although the shapes of inclusion bodies, such as the polyhedra of NPV[6-9] and of CPV[8,10-13] and the capsule of GV[14], are apparently determined by the virus, the origin of these proteins, whether virus- or host-directed, has not been established. The origin of the enhancing enzyme (synergistic factor) is still to be determined, but its detectable presence only in the Hawaiian GV strain suggests that it is a virus-directed protein*.

Recently, the use of chemical insecticides has been encouraged less than before, primarily because of pollution of the environment, the development of resistance in insect pests, the adverse effect on insect parasites and predators, and the conversion of minor pests to major economic pests. One of the areas receiving increasing interest is microbial control where pathogens, such as viruses, bacteria, fungi and protozoa, are used for the control of insect pests. In as much as the synergistic factor enhances not only the NPV of the armyworm but also other insect viruses, it is potentially important in microbial control of insect pests.

Experimental viral labyrinthitis

CONGENITAL and acquired deafness and acute and chronic vertigo are often attributed to viral infections of the inner ear. Direct demonstration of natural or experimental infection of the membranous labyrinths of the cochlear and vestibular systems has not been practicable, however, because these structures are encased in the dense temporal bones. Evidence that viral infections can cause deafness and vertigo in man is based largely on epidemiological observations and on a limited number of temporal bones examined months or years after the acute event. Temporal bones from patients with deafness associated with mumps, measles, cytomegalovirus and rubella have shown a cochlear–saccular degeneration suggesting that endolymphatic structures may have been infected[1-4]. Except for cytomegalovirus infections, which cause characteristic histopathological changes[4], there are no previous studies of acute viral infections of the inner ear in patients or experimental animals.

We have now studied the pathogenesis of acute viral infections of the inner ear in newborn hamsters, whose temporal bones are not calcified at birth. This made possible the use of fluorescence microscopy to localise infection at a cellular level after direct intralabyrinthine or intracerebral viral inoculations. The distribution of inocula was first localised by the injection of India ink. Following intracerebral inoculation, carbon

particles reached the cochlear scala tympani from the subarachnoid space through the cochlear aqueduct, which is patent in rodents[6]. Carbon particles were seen in perilymph but not endolymph. A few particles also reached the perineural and perivascular spaces of the cochlear modiolus through the internal auditory canal. Direct intralabyrinthine inoculations were performed percutaneously using a microsyringe with a 30-gauge needle. Volumes of 0.005 ml could consistently be introduced through the temporal cartilage into the labyrinth. Injections of India ink showed that carbon particles were variably distributed into the endolymph, perilymph or both.

Three viruses were studied. The mouse-adapted neurotropic (NWS) strain of influenza A virus[7], prepared as a 10% homogenate of infected mouse brains, had an infectivity of $10^{5.6}$—50% lethal doses (LD_{50}) per ml determined by intracerebral inoculation of newborn hamsters. The hamster-adapted Kilham strain of mumps virus[8], grown in Vero cells, had an infectivity of $10^{6.2}$—50% tissue culture doses (TCD_{50}) per ml. The hamster-adapted neurotropic strain of measles virus (HNT)[9], prepared as a 10% homogenate of infected suckling hamster brains, had an infectivity of $10^{6.3}$—LD_{50} per ml determined by intracerebral inoculation of newborn hamsters. Virus pools were diluted 1 : 10 in balanced salt solution, and 0.005 ml of these dilutions was inoculated into each labyrinth or 0.02 ml

was inoculated intracerebrally.

30 min. Rhodamine was used as a counterstain. After final washings, the sections were mounted in neutral glycerol and examined by fluorescence microscopy.

Influenza A virus inoculated by either intracerebral or intralabyrinthine routes resulted in a similar pattern of infection. Immunofluorescent staining demonstrated viral antigen in the loose mesenchymal cells of the cochlear aqueduct and scala tympani 1–4 d after inoculation (Fig. 1a). Eighth nerve ganglion cells in the cochlear (spiral) ganglia and vestibular (Scarpas) ganglia also showed specific fluorescence. No viral antigen was found in endolymphatic structures.

In contrast, mumps virus infected endolymphatic structures. This infection was most consistent after intralabyrinthine inoculation but occasionally some endolymphatic cells contained antigen after intracerebral inoculation. Nine to 12 d after inoculation, cells in both layers of Reisner's membrane, the stria vascularis, and the organ of Corti contained mumps virus antigen (Fig. 1b). Specific fluorescence was also seen in cells of the macula of the saccule and adjacent endolymphatic membrane. Again neurones in both the cochlear and vestibular ganglia stained specifically, but no viral antigen was seen in perilymphatic structures.

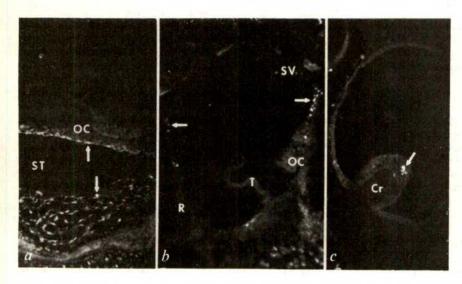
Measles virus inoculated by either route infected both


Fig. 1 Micrographs of hamster inner ears stained with fluorescent antibodies. *a*, Cochlea 1 d after intracerebral inoculation of influenza A virus. The arrows indicate the location of specific fluorescence in the loose mesenchymal cells of the perilymphatic scala tympani (ST) below the immature organ of Corti (OC). ($\times$ 78). *b*, Cochlea 11 d after intralabyrinthine inoculation of mumps virus. The arrows indicate the location of viral antigen in the organ of Corti (OC), stria vascularis (SV), and Reisner's membrane (R), but not in the tectorial membrane (T) ($\times$ 78). *c*, Semi-circular canal 3 d after intralabyrinthine inoculation of measles virus. The arrow shows viral antigen in the crista (Cr) ($\times$ 78).

Newborn hamsters were observed for signs of illness following intracerebral or intralabyrinthine viral inoculation. Since hamsters do not have functioning inner ears before day 20 (ref. 10), no clinical signs of inner ear disturbance could be observed. Animals inoculated by either route also developed encephalitis 3–4 d after inoculation of influenza or measles virus and 9–13 d after inoculation of mumps virus. Litters inoculated with diluent remained well and were killed at appropriate times for controls.

After the animals had been killed, optimal preservation of inner ear structure and viral antigens was achieved by using saline perfusion followed by perfusion of cold 95% ethanol. The skinned head, with jaw removed, was fixed in 95% ethanol for 24 h at 4 °C, dehydrated in graded steps of cold 100% ethanol, cleared in cold xylene and embedded in paraffin wax according to the method of Sainte-Marie[11]. Serial horizontal sections of the head including both inner ears were cut on a rotary microtome. At various levels of the inner ears adjacent sections were taken for histological examination and immunofluorescence studies. The paraffin sections were stored at 4 °C until processed for fluorescent antibody staining. The paraffin was removed by washing in consecutive cold xylene, alcohol and saline baths. Sections were then overlayed with virus-specific guinea pig antisera or with control non-immune sera for 30 min. Sections were then washed in saline and overlayed with fluorescein-conjugated rabbit anti-guinea pig γ globulin for

perilymphatic cells and cells in the organ of Corti and crista. Three and four days after inoculation, loose mesenchymal cells in the cochlear aqueduct and scala tympani of the cochlea contained viral antigen. Measles antigen in membranous labyrinth was limited to cells in the organ of Corti and crista of the semi-circular canals (Fig. 1c). The cells of the surrounding endolymphatic membrane were not involved. Again neurones of the cochlear and vestibular ganglia stained specifically.

Sections of saline-inoculated control animals showed no specific fluorescence when stained with viral antisera, and sections of all virus-inoculated animals were negative when stained with non-immune antisera.

Histological examination of sections stained with haematoxylin and eosin showed only minimal inflammatory responses elicited by influenza and mumps virus. Measles virus, however, caused giant cell formation in the spiral ganglia and occasionally in the organ of Corti.

These studies have demonstrated the feasibility of infecting inner ear structures in an experimental animal either by direct inoculation into the labyrinth or indirectly from the subarachnoid space through the cochlear aqueduct. Endolymphatic structures are, however, more readily infected using percutaneous intralabyrinthine inoculation. Preservation of the delicate membranous structures of the inner ear as well as preservation of viral antigens has been possible using paraffin embedding following cold alcohol fixation.

These initial studies have shown that cells of the inner ear differ in their vulnerability to viral infections. Each virus caused a different pattern of infection: influenza virus infection was limited to perilymphatic structures, mumps virus to endolymphatic cells, and measles virus involved both perilymphatic cells and the organ of Corti and the crista. All three viruses infected ganglion cells of the eighth cranial nerve. It is significant that both measles and mumps viruses infected endolymphatic structures or cells in the organ of Corti, since an endolymphatic labyrinthitis has been implicated as the original cause of damage in patients with deafness associated with these two virus infections[1-3].

Effect of electric fields on growth rate of embryonic chick tibiae in vitro

NUMEROUS investigators have reported work on the stimulation of bone growth by electric currents in the microampere range, with varying degrees of success. Such work, along with the various tentative theories of the underlying mechanisms, have been summarised by Bassett[1], and some quantification of the effect has been attempted[2,3]. Hambury et al.[3] concluded that the necessary crudity of the surgical techniques involved, and the overriding effects of the trauma militated too severely against accurate quantification of the electrically-stimulated bone growth, and proposed[4] that in vitro experiments might yield more definitive results. They also concurred with other workers that if electric currents do influence bone growth, then so should electric and magnetic fields, and Norton[5] has already performed work in this area in vivo, using chickens. We report that the gross development of embryonic chick tibiae grown in vitro is affected by a pulsed, transverse electric field, but that no significant changes were observed when a static, non-varying field was used.

Between one and three bones were placed in each of eight Petri dishes, four of the dishes being subjected to a 1,000 V cm⁻¹ electric field, and four being placed between the inactive plates of a second control apparatus (see Table 1 for detailed method). Each bone was measured before and after a 9 d incubation period. The ratio of the final to the initial bone length was calculated for each bone, giving the fractional increase in length in each case. Also, the experiments were systematised so that the two ratios obtained for the bones from each embryo could be related and compared. Where bones distorted somewhat, the lengths of the longitudinal median lines were measured incrementally. Table 1 gives the results in terms of the fractional increase in length

The 8–9-d-old embryos were aseptically decapitated, and extracted and the tibiae carefully excised. Each bone was then placed on a thin siliconised cellulose acetate mat supported by a 3 mm thick sponge of similar material, both items being chemically clean and sterile. Each assembly, consisting of a sponge, mat and two or three bones was placed in a 35 mm disposable polystyrene Petri dish containing sufficient medium to thoroughly soak the sponge without immersing the bone. The bones must be allowed free exposure to the incubator atmosphere of CO_2-air (5:95). Chemically-defined BGJ-b nutrient medium[6] was used, as described previously. In particular, the medium was changed every 2 d by gently removing the cellulose mat and placing it on a new sponge in a new Petri dish. This enabled most of the metabolic by-products of the preceding 2 d to be removed in the interstices of the sponge, the mat to which the bones adhered being too thin to retain more than a very small portion of these products. The bones were incubated for 9 d at 37 °C, after which they reached their maximum length. This period was defined by trials in which the length of each bone was measured and plotted against time until the graph became horizontally asymptotic. These measurements were made outside the Petri dishes using a micrometer scale mounted on a dissecting microscope eyepiece. After excision, one bone from each embryo was placed in a Petri dish inserted between the plates of the apparatus applying the electrical field. The other bone was placed in a dish within a similar, but inactive, apparatus as control. Both sets were placed in the same incubator. The apparatus for applying the field consisted essentially of two circular stainless steel plates, 12.7 cm in diameter, and held 1.4 cm apart by a Perspex framework. A Keithley model 244 high voltage power supply was used to apply 1,400 V across the plates, so that a uniform invariant field of 1,000 V cm⁻¹ existed between them, the lower plate being grounded. A Plexiglass disk, 3 mm thick, drilled with four holes 38 mm in diameter, was used to slide the four 35 mm Petri dishes into the space between the stainless steel plates. In the fully operating system, an interlock microswitch was incorporated into the incubator so that the opening of the door switched off the power supply. The stainless steel plates of the second apparatus, containing the controls, were short-circuited and grounded.

of each bone subjected to the field, compared with that for each corresponding control bone from the same embryo. The ratio of each pair of fractional increases is also included. Further, a 'one-tail' *t* test was applied to each batch, and also to the complete series. This shows that there is no significant difference between the test and control bone fractional increases.

A second series of experiments was carried out using a 1,000 V cm^{-1} field pulsed at approximately 1 pulse s^{-1} using a high voltage relay driven at this pulse repetition rate by a unijunction transistor circuit. The live (upper) plate was alternately connected to the $-1,400$ V supply and to ground by this means, so that a good square wave of approximately 1 : 10 mark–space ratio was obtained. Table 2 shows that for batch A, the chances that the pulsed electric field had no effect were no more than 0.5%; and for batches C and E, were no more than 2.5%. These results can therefore be considered significant, whereas those for batches B and D could not, being more than 10 and 25%, respectively. The 'one-tail' *t* test was also applied to the entire series taken as a whole (Table 2). The overall confidence limit was less than 0.5%, clearly very significant.

Bones were photographed in their Petri dishes at the end of each test to provide a record of their macroscopic appearance, then fixed in neutral formalin for 3 d. After manual processing, they were embedded in paraffin wax and sectioned longitudinally. The sections were then fixed to

glass slides by means of a glycerin–albumin mix and dewaxed in a hot air oven. They were then regressively stained with haemotoxylin, counterstained with eosin, and examined with an optical microscope. This did not reveal any differences between test and control slides; nor did a macroscopic inspection of the photographs reveal any differences in growth patterns.

We propose to grow further batches and perform more comprehensive tests including cell counts, wet and dry weight measurements and DNA content analyses, and to determine the effect of variation in field strength, frequency, waveform, and the spatial relationship of the field to the bone.

If our trials are significant, it can be concluded that there is present in the embryonic bone a transducer mechanism which allows the electric field to interact directly and modify (at least) the growth rate. Since the bones are in a pre-osseous phase, this mechanism clearly cannot be related to any properties of hydroxyapatite, thus ruling out at least one mechanism, the collagen–hydroxyapatite semiconductor interface[1]. In addition, because only pulsed electric fields (as opposed to invariant fields) have an effect, it is likely that repeated cycles of charge separation are involved. This is equivalent to applying very small pulsed currents, and since such currents can also be induced by pulsed magnetic fields, a series of experiments using such fields has been initiated. Note that Bassett *et al.* have reported that pulsed magnetic fields do modify bone growth patterns *in vivo*[7].

We thank Mr H. J. Hambury of Swansea, who first suggested the use of bone cultures in the context of our work, and Professor C. A. L. Bassett of the Columbia University Orthopaedic Centre, for his encouragement and advice.

Left-handed to right-handed helix conversion in *Salmonella* flagella

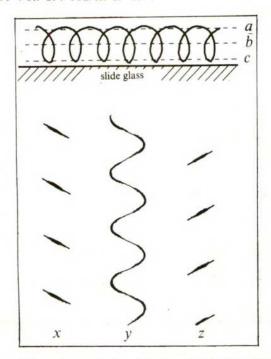
ALTHOUGH bacterial flagella can assume various helical configurations[1-3], the 'normal' and 'curly' configurations are encountered most frequently in nature. In *Salmonella*, normal and curly flagella have helical pitches of about 2.3 and 1.1 μm, respectively[4]. Macnab and Koshland[5] observed that normal flagella of living *Salmonella* were left-handed helical filaments, as shown for *Proteus* and *Bacillus*[6]. Flagella with this handedness and rotating counterclockwise (looking in the direction of travel), would cause helical waves to propagate distally and provide forward thrust[7-9]. Normal flagella can transform reversibly into the curly type when physiological conditions, such as *p*H, are varied[10,11]: this has been termed biplicity. Asakura *et al.*[12], using *Salmonella* strain SJ670 and others, found that reconstituted flagellar filaments also could be transformed reversibly, although they could not control this transformation completely. SJ670 is a motile strain that produces


Fig. 1 The optical method used for the determination of helical handedness. For explanation, see text.

the difficulty of photographing individual filaments, assuming that the helical form of individual filaments changed little with association. The optical system consisted of an Ushio 100 W mercury arc lamp, and a Nikon SKR microscope equipped with an Olympus d.c. condenser (numerical aperture 1.2–1.33), an Olympus Apo 40 × objective (numerical aperture 1.0), Nikon 20 × eyepiece and a Nikon EFM camera. In this system, there are no beam reflections and therefore micrographs are real, not mirror images.

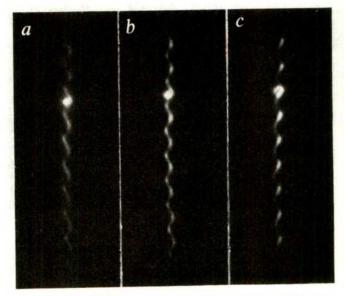
The method used for the determination of helical handedness can be understood by considering a bundle of left-handed helical filaments, lying on the surface of a slide glass (Fig. 1). If parts of the bundle near planes a, b and c are illuminated successively and focused by raising the specimen stage discontinuously, then images of types x, y and z will be obtained in succession. If a bundle of right-handed helical filaments is examined, images of types z, y and x will be observed, corresponding to planes a, b and c, respectively.


Fig. 2 A set of micrographs obtained for a bundle of normal-type filaments (SJ670) at pH 7.0. Micrographs (a), (b) and (c) were obtained by successively raising the specimen stage. The scale represents 5 μm.

normal flagella. On the other hand, the mutant SJ30 isolated by Iino[13] produces flagella which are stable in the curly configuration in various conditions. The mutation is in the structural gene for the flagellar protein subunit, flagellin, and the mutant cannot swim normally but appears to tumble continuously. Now, using SJ670 and SJ30, we have found that, whereas the normal configuration of flagella is a left-handed helix, the curly configuration is a right-handed helix.

Flagellins were purified from the two strains and polymerised into flagellar filaments as before[12]. Flagellins of SJ670 and SJ30 repolymerised into normal and curly filaments, respectively, which were used in the experiments. We also used curly filaments obtained by copolymerising flagellins of SJ670 and SJ30 at a protein ratio of 9:1[14]. Other curly filaments used were composed of SJ670 flagellin at pH 4.2, for we have found that such filaments are transformed reversibly when the pH changes from 7.0 to 4.2. (Full details will be reported elsewhere.)

If flagellar filaments are suspended in a medium containing methylcellulose (about 0.5% w/v), they associate into bundles visible by dark-field light microscopy, and heterogeneous in thickness (as judged by brightness) and overall length. They are helix-shaped, however, with a pitch equal to that reported by Pijper et al.[4] (Table 1). We have determined the helical handedness of bundles, because of

Figure 2 shows a set of micrographs obtained for a bundle of normal filaments. Clearly the bundle had a left-handed helical form. From this and many other observations we confirmed that normal flagella are left-handed helical filaments. In contrast, curly filaments of each kind examined were found to have a right-handed helical form (Fig. 3). Previously normal and curly configurations of flagella were believed to have the same helical handedness[3,14]. It is important that helical handedness is reversed when filaments transform from normal to curly when the pH changes, for this means that the same protein can form filaments with left or right-handed helical symmetry.

Others have argued that in a genus such as Salmonella and Escherichia, in which the cells are peritrichously flagellated, each organism swims by rotation of the left-handed helical flagella in a counterclockwise sense and tumbles by reversal of the sense of flagellar rotation[7-9]. This argument is based on the observations of the manner in which tethered bacteria swim. We observed that bacteria of SJ30 tethered on to the surface of a slide glass also spin counterclockwise. Therefore, it is likely that in SJ30, the right-handed helical flagella are rotating counterclockwise, giving rise to reverse thrust and continuous tumbling. At a recent meeting (First International Congress of the International Association of Microbiological Societies, Tokyo, September

Table 1		Four specimens examined			
Flagella	pH	Concentration of added NaCl	Helical pitch* (μm)	Type	Helical handedness
SJ670	7.0	0.01 M	2.35	Normal	Left
SJ670	4.2	0.3 M	1.13	Curly	Right
SJ30	7.0	0.01 M	0.99	Curly	Right
9:1 Copolymer of SJ670 and SJ30	7.0	0.01 M	1.04	Curly	Right

Each sample solution was prepared as follows. To a flagella solution containing 0.1 mg ml⁻¹ protein, 0.01 or 0.3 M NaCl, 5 mM citrate and 10 mM Na$_2$HPO$_4$ was added 2 N NaOH or HCl to give pH 7.0 or 4.2, and then the solution was mixed with an equal volume of a solution containing 1% methylcellulose and 0.01 or 0.3 M NaCl.
* Experimental errors were less than 5%.

Fig. 3 Two sets of micrographs obtained for bundles of curly-type filaments: SJ670 (wild type) at pH 4.2 (top) and SJ30 curly mutant at pH 7.0 (bottom). In each set, micrographs (*a*), (*b*) and (*c*) were obtained by successively raising the specimen stage. The scale represents 5 µm.

1974), R. M. Nacnab reported that during bacterial tumbling induced by high intensity blue light[5], or during spontaneous tumbling in uncoordinated mutants, normal filaments were transformed to the curly configuration. Also, in spite of the findings that reversal of rotation occurs during tumbling[7-9], wave propagation was always observed to proceed distally. From these observations he predicted that transformation from normal to curly by hydrodynamic forces was accompanied by a left-handed to right-handed helix conversion, in agreement with our observations. Macnab's finding suggests that the conversion from normal to curly (left-handed to right-handed) configuration of flagella plays a role in the mechanism of tumbling and therefore tactic responses.

It is well known that when peritrichously flagellated bacteria swim in a medium containing methylcellulose, the flagella attached to each cell associate into bundles each with the appearance of a rotating helix. We have found that reconstituted flagellar filaments also associate into bundles in the presence of methylcellulose, though the nature of inter-filament interaction is not well understood. Asakura and Oosawa[15] pointed out that if a macromolecular substance (in this case, methylcellulose) is added to a suspension of large particles (flagellar filaments), an attractive force appears between particles, even when there is no specific interaction between macromolecule and particle. This force is of entropic origin, since the volume which the added macromolecules can occupy is increased to some extent if the particles aggregate. This kind of force may be involved in the inter-filament interaction.

Prevention of induced leukaemia in mice by immunological inhibition of adenohypophysis

THE theoretical and technical approach to an immunological inhibition of the adenohypophysis (AH) has been discussed in previous work[1,2]. It has been shown that heterologous antibodies against mouse or rat AH have high organ-specificity and affinity for acidophilic cells of the anterior pituitary gland producing growth hormone. The possible application of such an immune intervention in the prophylaxis and therapy of hormone-dependent or hormone-sensitive tumours has been suggested[1] and experiments have demonstrated that hormone-dependent mammary carcinoma in rats can be prevented by anti-AH serum treatment[3].

Further, the thymus is primarily involved in experimental leukaemogenesis in mice and thymectomy prevents or delays the onset of leukaemia induced by X rays or chemical carcinogen[4,5]. In view of the extraordinary sensitivity of the thymus to hormonal change in general and especially to that of growth hormone[6], we suggested that inhibition of cells of the AH secreting growth hormone (or prolactin) might effect lymphoid cell turnover in the thymus and therefore influence the onset of leukaemia[1]. Recently, endocrine derangements have been found in SJL/J mice, a strain characterised by a very high incidence of spontaneous reticulum cell neoplasms (RCN), and this observation prompted the present investigation on the role of hormone in leukaemogenesis[7]. We have therefore investigated the effect of anti-AH serum in mice treated with different leukaemia-inducing agents.

Three groups of C57BL/6 inbred female mice (50 d old) received four doses of 170 rad wholebody irradiation at weekly intervals. At 34 d after the first irradiation, group 1 was injected intraperitoneally with 0.5 ml of sterile sheep anti-C57BL/6 AH serum, prepared and titrated as described previously[1,8]. Group 2 was inoculated with the same amount of normal sheep serum (NSS) and group 3 was untreated. The same quantities of anti-AH serum or NSS were sub-

Table 1 Effect of anti-AH serum on lymphosarcoma induction by X rays in C57BL/6 mice

Host treatment	Lymphosarcoma incidence	Average latent period (d)
Anti-AH serum	6/19 (31%)	245
NSS	19/22 (86%)	201
—	11/14 (78%)	198

sequently inoculated 48, 66, 96, 175 and 210 d after the first irradiation.

Using previously described techniques[9], three groups of SJL/J female mice (50 d old) were administered by stomach tube five doses of the carcinogen 7,12-dimethylbenzan-thracene (DMBA) at weekly intervals. A dose of 0.1 ml of the DMBA solution (1 mg DMBA) in polyethylene glycol 400 was given at each feeding. At 31 d after the first feeding, one group was injected intraperitoneally with 0.5 ml anti-AH serum, one group was injected with the same quantity of NSS and one group was untreated. At 34, 48, 71, 93, 118, and 142 d after the first DMBA feeding, further doses of 0.5 ml anti-AH serum or NSS were injected. Because of the danger of anaphylactic shock in SJL/J mice, which are exceedingly susceptible to sensitisation with heterologous proteins, increasing doses (0.2; 0.4 ml of serum diluted 1:10; 0.1 ml undiluted serum) were

Table 2 Effect of anti-AH serum on lymphosarcoma induction by DMBA in SJL/J mice

| Host treatment | Lymphosarcoma | | Reticulum cell neoplasms | | Other tumours |
	Incidence	Average latent period (d)	Incidence	Average latent period (d)	
Anti-AH serum	12/39 (31%)	227	8/39 (20%)	299	2/39 (5%)
NSS	27/35 (77%)	134	2/35 (5%)	320	1/35 (2%)
—	9/15 (60%)	161	2/15 (13%)	253	3/15 (20%)

given respectively 3, 2 and 1 d before the final dose of 0.5 ml anti-AH serum or NSS.

Both treatments of either X rays in C57BL/6 mice[10] or DMBA in SJL/J mice[9] induce high incidences of lymphosarcomas. Both X rays and DMBA had no effect on the development of spontaneous RCN. Tables 1 and 2 show that inoculation with anti-AH antibodies during and after treatment with carcinogenic agents drastically reduced the incidence of lymphosarcoma in both experimental models. Further, the antiserum prolonged the average latent period for the development of the disease. On the other hand, treatment with anti-AH serum (Table 2) did not influence development of RCN in SJL/J mice.

Many direct and indirect data support the hypothesis that host factors of endocrine character are of primary relevance for development of systemic neoplasia[7,11]. Our data support this contention by demonstrating that immunological inhibition of the adenohypophysis influences both the incidence and time of onset of lymposarcoma in mice.

The mean latent period for spontaneous RCN is beyond 400 d and that for lymphatic leukaemia in DMBA-treated SJL/J mice is 130–170 d. The low incidence of RCN in the experiment with SJL/J mice (Table 2) probably results from the fact that the experiment was terminated after one year. Anti-AH serum does not influence incidence and does not delay onset of spontaneous RCN in SJL/J mice (W. P. and N. H-G., unpublished), thus pointing out the remarkable selectivity of action of anti-AH serum for lymphosarcoma. Both organ-specificity and potency of the anti-AH antibodies can undoubtedly be enhanced by further studies. It is therefore most astonishing that such a striking reduction in incidence of leukaemia was obtained in both experimental models in view of the relatively empirical dosage of the antibodies. It will be of particular interest to determine whether this distinctive kind of immune intervention will be similarly effective in preventing naturally occurring leukaemia, such as that in AKR mice. These data encourage new approaches to therapy of lymphatic leukaemia by 'immunological hypophysectomy'.

Oxygen dissociation properties of human embryonic red cells

THERE are three stages in the development of human haemoglobins. In the smallest embryos studied the embryonic haemoglobins, Hb-Gower 1, Hb-Gower 2 and Hb-Portland are the main haemoblobins found[1], but foetal haemoglobin (Hb-F) is also present in gradually increasing amounts. By about the 30 mm (crown–rump (CR) length) stage, Hb-F amounts to about 50% of total haemoglobin and after 50 mm it forms over 90% of total pigment. Adult haemoglobin (Hb-A) is already present by week 8 of gestation but this does not exceed 10% of total haemoglobin until week 30; after this it gradually increases until at term it forms between 10% and 30%. After birth, Hb-F is rapidly replaced by Hb-A and at 6 months Hb-F is less than 10%, while at one year it forms less than 2% of total haemoglobins. The oxygen dissociation properties of adult haemoglobin and of foetal haemoglobin have been studied in great detail. Foetal blood has a higher oxygen affinity than adult blood; this helps the transport of oxygen across the placenta and ensures that the steep part of the oxygen dissociation curve corresponds to foetal tissue oxygen tensions, thus maximising the release of oxygen. The oxygen affinities of the human embryonic haemoglobins have so far not been studied because the amounts available have been extremely small. Here we describe the oxygen dissociation properties of human embryonic red cells which were found to be similar to those of foetal red cells.

Cord blood samples were taken from embryos and foetuses obtained from terminations of pregnancy carried out for unrelated maternal indications. Great care was taken to avoid contamination by maternal blood and the electrophoretic patterns obtained confirmed that this was not a problem. The red cells were washed three times in isotonic NaCl and the oxygen dissociation curves of the red cells suspended in isotonic phosphate buffers pH 7.13 (or pH 7.46) at 37 °C were measured[2]. In the method used the saturation of the haemoglobin with oxygen is measured spectrophotometrically using the second sample position of a Unicam SP 1800 or SP 800(0) recording spectrophotometer. Because of the small amount of cells the absorbance scale expansion was used. First the haemoglobin was deoxygenated using a vacuum and the spectrum recorded, then a measured amount of air was let into the tonometer and after equilibration at 37 °C the spectrum was again recorded. This procedure was repeated until the haemoglobin was fully saturated with oxygen. The partial pressure of oxygen P_{O_2} in the tonometer and the percentage saturation of haemoglobin

Fig. 1 In this figure the amino acid composition of peptides from the ζ-chain determined by Capp *et al.*[8] are arranged to give a postulated sequence corresponding to that of the known α chains[9]. It can be seen that the fit is very good except at positions 90 and 114 which are external and position 107 in the $\alpha_1\beta_1$ contact. E, External; I, Internal; haem, haem contact; (LYS) in brackets in the postulated sequence assumed to be present from tryptic cleavages seen. Amino acids found in known α chains: Caps—common, lower case and brackets—rare. ↓, Tryptic cleavages. The positions of the various residues in the haemoglobin molecule are from the data of Perutz and his coworkers (for refs see ref. 7).

with oxygen were then calculated[3]. The use of the second sample position of the Unicam SP 1800 (SP 800(0)) recording spectrophotometers allows the direct recording of spectra of intracellular haemoglobin with minimal loss of precision as a result of light scattering.

Oxygen dissociation curves were obtained from the red cells from six embryos with a CR length of less than 35 mm. In these cells the embryonic haemoglobins amounted to between 30 and 50% of total haemoglobin. Similar studies were carried out on red cells obtained from several foetuses (Table 1). The oxygen affinities of the embryonic red cells do not differ from those of foetal red cells in the conditions used, the P50 (partial pressure of oxygen at 50% saturation of haemoglobin with oxygen), Bohr shift and haem–haem interactions being very similar. In order to exclude the presence of high or low affinity components the partial pressures of oxygen necessary for 20 and 80% saturation were also compared and found to be identical. These studies therefore show no difference in the oxygen dissociation properties of embryonic red cells compared with foetal red cells and further studies are necessary to elucidate the physiological significance of these haemoglobins.

Table 1 Comparison of the oxygen affinity of human embryonic* and foetal red cells suspended in isotonic phosphate buffers

Red cells suspended in isotonic buffer pH 7.13	Embryonic red cells (6 samples)	Foetal red cells
p20 mmHg	13–17	12–16
p50 mmHg	25–30	22–27
p80 mmHg	38–46	38–46
Haem–haem interactions (n value†)	about 2.5	about 2.6 normal adult red cells
In isotonic buffer pH 7.46	(4 samples)	
p20 mmHg	7.5–9.5	9–10.5
p50 mmHg	18–20	17.5–18
p80 mmHg	29–32	27.5–28
Bohr shift	−0.43 to −0.49	−0.42 to −0.52

*Cells from embryos with a crown–rump measurement of less than 40 mm and containing more than 30% embryonic haemoglobins.
†The slope of the line log $y/(1-y)$ against log P_{O_2} where y is the fractional saturation with oxygen as a measure of the haem–haem interactions.

As haem–haem interactions are thought to require a pair of different chains (such as $\alpha_2\beta_2$) in each haemoglobin molecule and do not occur in haemoglobins consisting of one type of chain only (such as Hb-β_4 or Hb-γ_4), our finding that the haem–haem interactions of embryonic haemoglobins were normal argues against the presence of a major haemoglobin species containing one type of chain only, as previously suggested for Hb-Gower 1 (ref. 4). Studies of the embryonic haemoglobins have shown that there are two types of embryonic globin chains, ε-chains and ζ-chains. The ε-chain is found in Hb-Gower 2 in combination with α-chains, Hb-$\alpha_2\epsilon_2$. The other embryonic chain, the ζ-chain, is found in combination with γ-chains in Hb-Portland, $\zeta_2\gamma_2$ (ref. 5), and in combination with β-chains, Hb-$\zeta_2\beta_2$ (ref. 6), and it has been suggested that the ζ-chain is an α-type chain[7]. Comparison of the composition of some tryptic peptides from the ζ-chain with that of other mammalian haemoglobin α-chains (Fig. 1) confirms this idea. Previously it has been shown[4] that Hb-Gower 1 contains ε-chains but not any α^A-chains. Our observation that the haem–haem interactions are the same in embryonic red cells as in foetal or adult red cells indicates that Hb-Gower 1, which forms a large haemoglobin component in the former, must contain α-like chains as well as ε-chains. It is, therefore, suggested that it consists of ζ-chains combined with ε-chains: Hb-$\zeta_2\epsilon_2$.

Note added in proof: The peptide described by Capp *et al.*[8] from their ζ-chain preparation from Hb-Portland which could not be fitted to the α-chain sequence (Fig. 1) appears to correspond to the first part of the additional peptide found[10] attached to the

C-terminal end of the α-chain in Hb-Icaria present in some cases of α-thalassaemia.

Residue no.	142	143	144	145
Hb Icaria	LYS	ALA	GLY	ALA
Postulated additional peptide from ζ-chain	LYS	ALA	GLY	ALA
Residue no.	146	147	148	149
Hb Icaria	SER	VAL	ALA	VAL
Postulated additional peptide from ζ-chain	SER	LEU	THR	THR

It is not clear however whether this peptide is present in all samples studied (that is, those from α-thalassaemia as well as those from normal embryos).

Progesterone antagonism of the oestrogen receptor and oestrogen-induced uterine growth

PROGESTERONE has long been considered an antagonist of oestrogen action[1]. The delicate balance and interactions between these ovarian hormones are essential for many reproductive functions. Early studies in chick oviducts and uteri of rats and mice have shown that the simultaneous administration of progesterone and oestrogen resulted in inhibition or modification of oestrogen-induced growth of these target organs[2-5]. One possible mechanism by which progesterone could be antagonistic to oestrogen is by suppressing the quantity of cytoplasmic oestrogen receptor. It is generally held that the mechanism by which oestrogen, O, stimulates uterine growth depends on the binding of O to cytoplasmic receptors, R_c, to form R_cO complexes[6]. These R_cO complexes are translocated to nuclear sites where they probably stimulate nuclear events that cause the uterus to grow[7]. Translocation and nuclear accumulation of receptor–oestrogen complexes, R_nO, are accompanied by a concomitant decrease in the quantity of R_c (ref. 8). During the period when R_c is reduced, the uterus is insensitive to additional exogenous oestrogen[9]. Gradually R_c is replenished by processes which may involve reutilisation and/or resynthesis[8]. Work from our laboratory indicates that the mechanism of action of non-steroidal oestrogen antagonists resides in their inability to stimulate the replenishment of the cytoplasmic oestrogen receptor, R_c, thereby rendering oestrogen responsive tissues less sensitive to oestrogen[10,11]. The possibility that progesterone might also act as an oestrogen antagonist by reducing the amount of oestrogen R_c has been suggested[12,13]. In this report, we demonstrate that progesterone does decrease the quantity of oestrogen receptors by interfering with the replenishment of R_c and that this decrease results in a reduced sensitivity of uterine tissue to oestrogen.

To establish the effect of progesterone on the quantity of oestrogen receptor, it is necessary to use assay techniques that permit the measurement and distribution of total receptor[14,15]. The ^{3}H-oestradiol exchange assay, as developed in this laboratory and elsewhere[15,16] enables us to make such measurements.

Table 1 Effect of progesterone on various uterine growth parameters and concentration of cytoplasmic oestrogen receptor

Pretreatment	Uterus (day 4)			Cytoplasmic receptor (day 4)	
	Wet weight (mg ± s.e.m.)	Protein (mg ± s.e.m.)	DNA (μg ± s.e.m.)	pmol per 100 mg protein	pmol per mgDNA
a (OL)	92.6 ± 4.5	8.81 ± 0.41	679.7 ± 17.8	27.1 ± 2.3†	3.52 ± 0.31†
b (OL + P)	69.0 ± 2.3†	8.20 ± 0.57*	744.5 ± 26.1†	13.2 ± 4.9†	1.47 ± 0.05†

Immature rats were treated with hormones as described in Fig. 1 and uterine wet weight, protein and DNA content were determined on day 4 by the methods of Lowry *et al.*[24] and Ceriotti[25]. The values represent the mean ± s.e.m. from six to eight experiments with six animals per experiment.
*No significant differences between a and b
†Significant differences ($P < 0.01$) between a and b

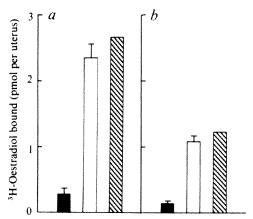
Immature female Sprague–Dawley rats (22 d old) were purchased from Texas Inbred Mice Co. and housed in a controlled environment with 14 h of artificial light between 0700 and 2100. All rats received two daily subcutaneous injections of 2.5 μg oestradiol 17-β in 0.5 ml of saline containing 1% ethanol. The pretreatment with oestradiol was done to increase the sensitivity of the uterus for progesterone, presumably through the effect of oestrogen on increased synthesis of the progesterone receptor[17,18], and to maximise the translocation of


Fig. 1 The effect of progesterone on the quantity of oestrogen receptor in the rat uterus. Two groups of immature rats were given 2.5 μg of oestradiol for 2 d as described in the text. Group a received another injection of oestradiol on day 3 while group b received oestradiol plus progesterone. On day 4 the quantity of oestrogen receptor was determined in the nuclear (■) and cytoplasmic (□) fractions as described in text. The total (///) amount of receptor (■ + □) is also shown. The data represent the mean ± s.e.m. from six to eight experiments with 6 animals per experiment.

the R_cO complex to the nucleus. On the third day rats were divided randomly into two groups. Animals in group A were injected with 2.5 μg of oestradiol in 0.5 ml of saline and 0.2 ml of sesame oil. Animals in group B were injected with 2.5 μg of oestradiol plus 2.5 mg of progesterone dissolved in 0.2 ml of sesame oil. In both groups, the sesame oil or progesterone in oil was injected at a separate subcutaneous site and did not affect the adsorption of oestradiol. On day 4 uteri were removed and analysed for cytoplasmic and nuclear receptor by the ³H-oestradiol exchange assay[15,16].

Progesterone treatment caused a significant reduction in the

amount of cytoplasmic oestrogen receptor in the uterus on day 4 (24 h after the injection, Fig. 1 and Table 1). A reduction was also observed in the amount of R_nO present in the nuclear fraction although these quantities in either group are small and hence have little influence on the total amount of receptor (Fig. 1). Antagonistic effects of progesterone are also observed at this time by the reduced wet weight of the uterus (Table 1). But, the decrease in the quantity of R_c does not result from a general depressive action of progesterone on uterine protein synthesis, since the decrease can still be observed when the data are expressed as sites per mg protein (Table 1).

Since it has been shown that progesterone does not interfere with the ability of oestrogen to cause the translocation of the RO complex from the cytoplasm to the nucleus[15], the reduced R_c 24 h after progesterone treatment probably results from the blockade of the replenishment process. To test this possibility the quantity of R_c was determined at various times after treatment with oestrogen (O), or oestrogen plus progesterone (O + P) (Fig. 2). These data show that the level of R_c is depleted immediately after injection of oestrogen plus progesterone and that replenishment occurs during the next 24 h. In the case of oestrogen plus progesterone, the level of R_c does not exceed the quantity present 24 h earlier. In contrast, oestrogen alone results in a significant increase above control level. This antagonistic influence of progesterone is dose-dependent and specific for progestational hormones (data to be reported elsewhere).

The reduction in the quantity of cytoplasmic oestrogen receptor following progesterone treatment should make the uterus less responsive to oestradiol. To assess this possibility animals were treated with oestradiol or oestradiol plus progesterone as described in Fig. 1 and on day 4 all animals were injected with 2.5 μg of oestradiol. The wet weight, dry weight and protein content of the uterus were examined 24 h later. Oestrogen treatment increased wet and dry weight in both OL and OL + P pretreatment groups when compared with saline injected controls (Table 2). But the ability of oestradiol (OL) to increase uterine weight was significantly depressed ($P < 0.01$) in the OL + P pretreatment group when compared with OL pretreatment group (Table 2). This was also true for the protein content of the uterus (OL pretreatment group, 10.7 ± 0.2 mg per uterus; OL + P pretreatment group, 8.7 ± 0.3 mg per uterus). No appreciable difference among treatment groups was observed, however, for saline-injected controls. These data indicate that the antagonistic effect of progesterone is correlated with its depressive effect on the quantity of cytoplasmic

Table 2 Antagonism of oestrogen uterine growth by progesterone

Pretreatment (day 3)	Treatment (day 4)	Uterine weight			
		Wet weight (mg ± s.e.m.)	% Saline control	Dry weight (mg ± s.e.m.)	% Saline control
a (OL)	OL	151.0 ± 20.0*	228	23.0 ± 1.3*	195
	S	66.1 ± 2.9†	100	11.8 ± 0.5†	100
b (OL + P)	OL	89.0 ± 4.0*	155	17.6 ± 0.6*	166
	S	57.3 ± 2.3†	100	10.6 ± 0.4†	100

Immature rats received hormone treatment as described in Fig. 1. On day 4 they were injected with 2.5 μg of oestradiol (OL) or saline (S) and the uterine weight was determined on day 5. The values represent the mean ± s.e.m. of five experiments with six rats per experiment.
*Significant differences between pretreatment groups ($P < 0.01$).
†No significant differences between pretreatment groups.

oestrogen receptor. When considered in the light of the results from Figs 1 and 2, these data suggest that progesterone decreases cytoplasmic R_c and thereby reduces the sensitivity of the uterus to subsequent oestrogen action.

The antagonistic effects of progesterone on uterine weight and protein content probably reflect the ability of progesterone to redirect the manner in which certain uterine cell types will respond to oestrogen. Histological examination of the uterus on day 5 indicates considerable changes in the epithelial and stromal elements of the uterus (data not shown). In the OL + P pretreatment group, the height of the luminal epithelium is greatly reduced and the surface area of the lumen is expanded. In addition, the quantity of stroma seems to be reduced although the quantity of myometrium is only slightly affected. Thus, progesterone may reduce the amount of R_c in certain cell types and not in others, thereby differentially controlling the action of oestrogen.

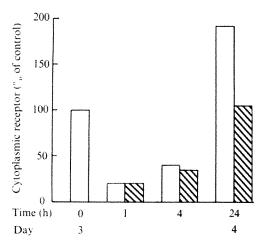
Several reports have suggested that progesterone has a depressive effect on the cytoplasmic oestrogen receptor. The cytoplasmic fraction of human uterus binds more oestrogen during the follicular phase than during the luteal phase of the menstrual cycle[19,20]. The ability of the rabbit uterus to bind oestrogen has also been shown to decrease during pseudopregnancy and


Fig. 2 The effect of progesterone on the oestrogen-induced depletion and replenishment of the cytoplasmic oestrogen receptor. Immature rats received 2.5 μg of oestradiol for 2 d and on the third day they were injected with either oestradiol (□) or plus oestradiol and progesterone (////). The quantity of cytoplasmic oestrogen receptor was determined at 1, 4, and 24 h after injection. The values represent the mean of three experiments with four animals per experiment.

increase subsequent to lutectomy[21]. Thus, in conditions when the concentration of progesterone in the blood is high, the oestrogen binding capacity of the uterus is decreased. Brenner *et al.*[13], made similar observations with the monkey oviduct. In the above studies indirect methods or methods that do not permit the evaluation of the quantity and distribution of total receptor were used. The methods we used permit this evaluation and demonstrate conclusively that progesterone can decrease the quantity of cytoplasmic oestrogen receptor. Also, this decreased quantity of R_c is correlated with a reduced or redirected ability of the uterus to respond to oestrogen.

It is known that oestrogens and progestins bind to separate cytoplasmic receptor molecules[22] and that the receptor-steroid complexes thus formed do not compete for the same nuclear sites[15,23]. Therefore, it seems that progesterone or the progesterone-receptor complex influences the replenishment of the cytoplasmic oestrogen receptor by interfering with its resynthesis or recycling, thereby reducing the quantity of oestrogen R_c in the uterus. This concept, that progesterone can reduce the quantity of oestrogen receptors and thereby reduce or modify

the ability of a tissue to respond to oestrogen, is basic to the elucidation of the progesterone-oestrogen interactions during various reproductive states.

Immunoperoxidase staining of α-bungarotoxin binding sites in muscle endplates shows distribution of acetylcholine receptors

α-BUNGAROTOXIN (αBT) and similar toxins are specific ligands for the nicotinic acetylcholine (ACh) receptors in skeletal muscle[1,2] fish electric organ[3-5] and retina[6] and other parts of the central nervous system[7,8]. Fluorescent[9,10] and autoradiographic[1,11,12] methods have been used to visualise the αBT binding sites in muscle and electric organ. We report here an αBT-immunoperoxidase staining method for light and electron microscopy, which is relatively convenient and has high resolution. We have used this method to study the distribution of ACh receptors in skeletal muscle.

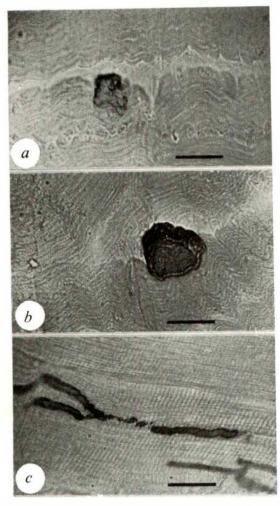
Mouse diaphragms or frog (*Rana pipiens*) sartorius muscles were agitated gently for 1.5–2 h with 5×10^{-8} M αBT in either F14[13] tissue culture medium with 10% foetal calf serum at 37 °C in a 5% CO_2 atmosphere (mouse), or frog Ringer solution with 2 mg ml^{-1} bovine serum albumin (BSA) at room temperature (frog). Controls were either incubated without αBT or preincubated for 10 min with 10^{-3} M decamethonium (a specific inhibitor of αBT binding) followed by 5×10^{-8} M αBT with 10^{-3} M decamethonium. The tissues were then washed extensively in incubation medium without αBT or decamethonium (the last washes without serum or BSA), fixed for 90 min at 0–4 °C in a solution containing 2% paraformaldehyde, 0.01 M $NaIO_4$, 0.075 M lysine and 0.037 M phosphate buffer, final pH about 6.9 (ref. 14), cut in pieces, washed in 0.1 M sodium phosphate buffer, pH 7.1 (PB), cryoprotected by soaking in 5% dimethylsulphoxide in PB, and quick frozen. For electron microscopy, cryostat sections 20 μm thick were fixed to gelatin-coated plastic dishes with vapours of


Fig. 1 *a*, αBT-immunoperoxidase-stained endplate in mouse diaphragm. *b*, Acetylcholinesterase-stained endplate in a parallel section. *c*, αBT-immunoperoxidase-stained endplate in frog sartorius muscle. Bright field photomicrographs. Reference bars represent 20 μm.

8% paraformaldehyde at 40 °C, washed with PB, and treated at room temperature as follows: (1) 60 min in rabbit anti-αBT (ABT), 29 μg ml⁻¹, in PB with 0.1 mg ml⁻¹ BSA (PB-BSA); (2) 30-min wash with PB-BSA; (3) 60 min in a horseradish peroxidase conjugate of the IgG fraction from goat antiserum to rabbit IgG (AR-HRP), 13 μg ml⁻¹ in PB-BSA. (ABT was purified from rabbit antiserum to αBT by affinity chromatography on a Sepharose-αBT column. One milligram of ABT precipitated 22 μg of αBT in a precipitin test. AR-HRP was made from the IgG fraction of goat antiserum to rabbit IgG (Miles) by conjugation with horseradish peroxidase (RZ-3.2, Worthington) according to the two-step method of Avrameas and Ternynck[15], except that the conjugation step was done at *p*H 9.0. The conjugate had an A_{403}/A_{280} of 0.49, thus approximately a 1.2 molar ratio of peroxidase to IgG.) Antibody-treated sections were washed extensively with PB-BSA and PB, refixed in 2% glutaraldehyde in PB, washed, and stained for 30 min at room temperature with 3,3′-diaminobenzidine (DAB, 0.1 mg ml⁻¹) and 0.001% H_2O_2 in 0.05 M Tris-HCl, *p*H 7.6 (ref. 16), washed for up to 3 h, postfixed in 1% OsO_4 in PB for 45 min, then dehydrated and embedded in Epon. Except where stated, thin sections were not poststained with uranyl acetate or lead citrate. This omission preserved the high contrast between the DAB reaction product and the tissue background. For light microscopy, cryostat sections 12 μm thick were dried on to glass slides and treated as above, omitting OsO_4 treatment, cleared and mounted under coverslips; alternate sections were stained for acetylcholinesterase[17].

As seen by light microscopy (Fig. 1), the αBT-immunoperoxidase stain was limited to the muscle endplates. The observed patterns of staining resembled the characteristic paths of nerve endings in these species as delineated by silver or gold impregnation. In mouse diaphragm (Fig. 1*a* and *b*) the immunoperoxidase stain gave the endplate the appearance of convoluted strands but the cholinesterase stain was less restricted, filling the endplate region. In frog sartorius, however, both immunoperoxidase (Fig. 1*c*) and acetylcholinesterase stains followed the paths of the nerve endings. Omission of αBT or either antibody from the staining procedure completely eliminated endplate staining. Compounds known to interact specifically with nicotinic ACh receptors were assayed for their effects on αBT-immunoperoxidase staining. Cryostat sections of untreated mouse diaphragm 10 μm thick were incubated for 10 min at room temperature with a 10⁻³ M concentration of one of the following: *d*-tubocurarine, carbamylcholine (with 10⁻⁵ M eserine), nicotine, or decamethonium, in phosphate buffered saline[18] with BSA (2 mg ml⁻¹), and then incubated 30 min more with the addition of 5×10^{-7} or 5×10^{-8} M αBT. The sections were then washed, fixed, and immunoperoxidase stained as described above. All the ligands markedly reduced endplate staining at both concentrations of αBT and all were more effective at the lower concentration. Decamethonium was the most effective blocker, virtually eliminating endplate staining at 5×10^{-8} M αBT concentration. The ability of these ligands to block the staining reaction at the concentrations used is consistent with the known pharmacology of the binding of αBT and similar toxins to ACh receptors[2-5]. These pharmacological results, together with the immunochemical controls mentioned, show the αBT immunoperoxidase stain to be highly specific for nicotinic ACh receptors. Staining of the same specificity was also obtained in diaphragms fixed in paraformaldehyde before freezing, sectioning and incubation with αBT.

Electron microscopy (Fig. 2) confirmed the restriction of staining to the endplate (Fig. 2*a*) and revealed a non-homogeneous distribution of stain within the endplate (Fig. 2*b* and *f*). The heaviest staining was on the muscle plasma membrane at the 'tops' of the postsynaptic folds, with little or no stain at the 'bottoms' of the folds. Some of the stain was on the presynaptic plasma membranes. This was less intense than the postsynaptic stain. A qualitatively similar distribution of stain was seen in the diaphragm of a mouse killed by intravenous injection with 10 μg of αBT. Staining was almost eliminated by the presence of 10⁻³ M decamethonium during αBT incubation (Fig. 2*d*) and completely eliminated by omission of αBT (Fig. 2*c*).

The presence of some presynaptic ACh receptors cannot yet be ruled out by this method; however, it seems that either specific antigen–antibody complex or DAB reaction product originally attached to postsynaptic ACh receptors was translocated and later fixed to the presynaptic membranes. This was most clearly shown by the presence of stain on any structure located directly opposite a site of strong postsynaptic membrane staining. These structures included Schwann cell processes (Fig. 2*b* and *f*), and the muscle basement membranes in the synaptic cleft (Fig. 2*f*) or in denervated muscle (A. N. Bender, S. P. Ringel, B. W. Festoff, W. K. Engel, Z. V. and M. P. D., unpublished), as well as the presynaptic nerve membrane. This spreading of stain could also account for the staining of the membranes in the relatively shallow folds of the frog endplates (Fig. 2*f*).

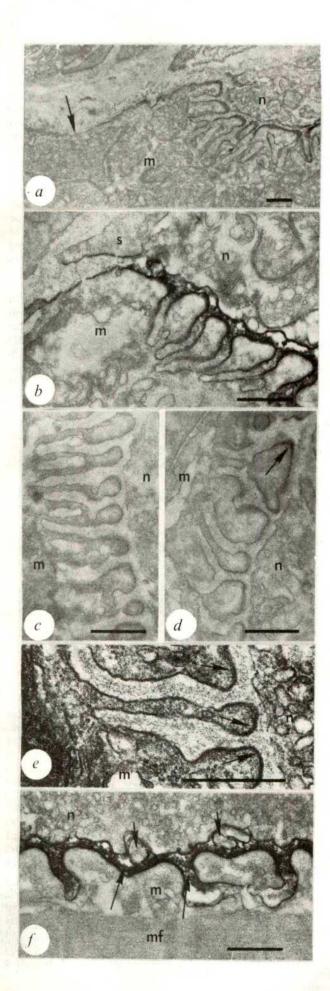
It is clear that most, if not all, of the muscle ACh receptors are restricted to that region of the postsynaptic plasma membrane which is nearest to the nerve ending and is contiguous with the postsynaptic dense material normally seen in thin sections poststained with uranyl acetate and lead citrate (Fig. 2*e*). This is in agreement with the results of electron microscope autoradiography with radioactive


Fig. 2 Mouse diaphragm (*a-e*) and frog sartorius muscle (*f*) endplates stained by the αBT-immunoperoxidase method after various treatments. *a*, αBT-treated. The endplate is stained, but the nearby muscle plasma membrane (arrow) and other structures are not. *b*, αBT-treated. Most of the stain is on the muscle plasma membrane at the tops of the postsynaptic folds. There is some stain in the synaptic cleft and on the nerve and Schwann cell plasma membranes. *c*, Control incubated without αBT. There are no stained structures. *d*, Decamethonium and αBT-treated. There is little or no stain (arrow) on the muscle and nerve plasma membranes. *e*, Control incubated without αBT. This thin section was poststained with uranyl acetate and lead citrate. Note the postsynaptic dense material (arrows). *f*, αBT-treated (frog sartorius). The staining pattern resembles that in mouse. Note the staining of Schwann cell processes (short arrows) and of the basement membrane (long arrows). Reference bars represent 0.5 μm. n, Nerve ending; m, muscle; mf, myofibril; s, Schwann cell process.

αBT[12]. The postsynaptic distribution of ACh receptors revealed by the αBT-immunoperoxidase method also corresponds to that of the 80–120-Å membrane particles observed in freeze-fractured[19-20] and in thin-sectioned[21] muscle.

The αBT-immunoperoxidase method offers high resolution of the ultrastructural distribution of nicotinic ACh receptors and should be useful for light and electron microscopic evaluation of the distribution of ACh receptors in the central nervous system where structural and functional complexity pose serious obstacles to neurophysiological methods of receptor analysis. Our preliminary results with chicken retina indicate that the method will indeed be useful in examining the central nervous system.

We thank Drs M. Nirenberg, T. Reese, J. Heuser and M. Dubois-Dalq for advice and criticism and Mrs A. Ling for technical assistance.

Putative neurotransmitters in clonal cell lines

THE regional distribution of putative neurotransmitters in the mammalian central nervous system (CNS) has been studied often (for example, refs 1–4). Although in some cases neurotransmitter synthesis has been correlated with nervous function, its distribution among different cell types has not been assayed. For example, the distribution of the putative neurotransmitters taurine and γ-aminobutyric acid (GABA) between nerve and glia has not been established using *in vivo* preparations. Another approach is to use clonal cell lines derived from the CNS, for their cellular homogeneity facilitates the assay of pool sizes of neurotransmitters and free amino acids in identified cells. Such determinations have been made with fibroblasts[5-7].

The expanding collection of clonal cell lines from the CNS[8-11] and other tissues (for example, refs 12-14) presents the opportunity to extend this approach. We describe here the free amino acid pools of some cell lines from the CNS and other tissues which exhibit differentiated phenotypes. We have found that although several specific differences exist between cells from different tissues, there is a strong similarity between different cell types of common embryological origin.

We used the rat nerve cell lines B35, B50, B65, B103 and B104, and the rat putative glial cell lines B11, B12, B15, B23, B28, B49, B82, B90, B92 and B108 (ref. 11), and two other lines of glial origin, C6 (ref. 8) and RN2 (ref. 15). Additional clonal cell lines examined were: smooth muscles BC_3H1 (ref. 16) and A10 (B. Kimes and B. Brandt, submitted); skeletal muscle L6 (ref. 13); plasmacytoma C1 and lymphomas S1A and S49 (ref. 14); neurblastoma clones C1 (ref. 10) and N18 (ref. 17); melanomas[18] B78 (non-pigmented) and B559 (pigmented); hepatoma H35 (ref. 19); growth hormone and prolactin-producing pituitary cells GH_3 (ref. 20); adrenal cortical line Y1 (ref. 12), and the fibroblast cell line 3T3 (ref. 21). All cells were grown in modified Eagle's MEM containing 10% foetal calf serum[11].

Early stationary phase cultures, 2 or 3 d after cessation of net cell division, were used exclusively for the determination of free amino acids, for cells at this stage of the growth cycle usually express maximum morphological and biochemical differentiation[22,23]. Cell viability was greater than 95% as measured by the uptake of fluorescein dibutyrate[24].

Free amino acids were extracted from cells washed four times in phosphate buffered saline (PBS, 150 mM sodium chloride, 10 mM sodium phosphate, pH 7.3, 2 mM calcium chloride, 0.5 mM magnesium chloride) according to a modification of the trichloroacetic acid (TCA) procedure of Saifer[25]. Frozen cell pellets were homogenised at 0 °C with 20 volumes of 6% TCA using a Duall tissue grinder and centrifuged at 12,000g for 20 min. The procedure was repeated on the TCA precipitate, and the two supernatants were combined. A third extraction of the TCA precipitate yielded no more detectable free amino acids (less than 3% of the combined previous two extracts). The TCA was then extracted four times with 3 volumes of ethyl ether, the aqueous extract was lyophilised and dissolved in the starting buffer for the amino acid analysis. Amino acids were analysed with a Beckman amino acid analyser, Model 121, equipped with an automatic integrating device and run with an expanded elution profile[26]. More than 40 amino acids and related compounds are resolved by this procedure. Since cell volume and protein per cell varies with chromosome number and growth phase (for example, ref. 27), the data are expressed as residues of a particular molecule per 1,000 residues of resolved free amino acids and related compounds.

GABA, glutamic acid, glycine, aspartic acid, taurine, (reviewed, for example in refs 28-30) and β-alanine[31] are putative neurotransmitters in the CNS. Although little is known about their relative distribution between nerve, glia and other differentiated cells, clonal cell lines can be used to study their synthesis and/or accumulation. Table 1 shows the relative concentrations of the putative CNS transmitters in several cell types. There is little statistical difference between the GABA content of nerve and glial cells, although individual nerve lines contain much more GABA than observed in any glial line. The former is also true with the other putative neurotransmitters. The GABA pools do not necessarily correlate with glutamic acid decarboxylase activities[11,23], for the retention of amino acids was assayed, not synthetic ability. The only qualitative difference between cell types was the lack of detectable GABA and β-alanine in muscle and fibroblast cells.

Table 1 Relative concentrations of putative CNS neurotransmitters in clonal cell lines

Cell line	Cell type	GABA	β-ALA	GLU	ASP and ASPN	GLY	TAU
				Relative concentration (residues per 1,000 free amino acids ± s.d.)			
B35	Nerve	7.1±0.3 (3)	35±6 (3)	203±6.5 (3)	53±5 (3)	235±17 (3)	207±19.7 (3)

Serum		<0.1	3.5	80.6	60.5	59.3	16.7
Medium		<0.1	<0.1	<0.1	<0.1	8.4	<0.1

Free amino acids were extracted from cells by TCA precipitation and chromatographed on an amino acid analyser. Serum and medium samples were treated in an identical manner. The sum of the aspartic acid and asparagine peaks are given. Where indicated, the data are presented as the mean ± (s.d.) for n determinations using different cell preparations. Abbreviations: GABA, γ-aminobutyric acid; β-ALA, β-alanine; GLU, glutamic acid; ASP, aspartic acid; ASPN, asparagine; GLY, glycine; TAU, taurine.

Of the remaining amino acids, there were no significant differences between the different cell types. Finally, several unidentified, ninhydrin-reacting compounds eluted at times which did not correspond to the standards. For example, cells contained compounds which eluted between DL-O-phosphoserine and O-phosphoethanolamine, and between urea and hydroxyproline. These compounds never individually constituted more than a few residues per thousand, and were found in similar amounts in all cells.

The relative concentrations of free amino acids described in the nerve and glial cell lines are in general agreement with those published for whole brain (for example, ref. 25), although there are exceptions. For example, the concentration of glutamic acid was the highest of the free amino acids in whole cerebral tissue[25] and the nerve and glial cell lines (Table 1), but the concentration of aspartic acid was significantly higher in the brain than the cell lines (Table 1). Such discrepancies are, however, to be expected since the multiplicity of cell types found *in vivo* may not have been represented among the clonal cell lines.

Table 1 shows that cells derived from neuroectoderm contained detectable amounts of GABA and β-alanine, although the mesodermally derived muscle and fibroblast cells did not. Thus nerve, glia, melanocytes and neuroblastoma clones had qualitatively similar free amino acid pools distinct from those of muscle and fibroblast cells. It has been shown that nerve and glial cells share a number of additional traits distinct from muscle, such as acetylcholine and catecholamine synthesis, GABA uptake, S100 and 14-3-2 protein synthesis, and a morphological response to cyclic nucleotides[11,32,33]. Other cell types, such as those derived from lymphoid tissue, the adrenal cortex and the anterior pituitary, also contained both GABA and β-alanine (Table 1). Thus GABA and β-alanine were excluded from most mesodermal tissues as opposed to being uniquely associated with nervous tissue. The apparent exception was the adrenal cortical clone, which is thought to be of mesodermal origin, but contained GABA (Table 1). The functional similarity between cells of the immune and nervous systems has, however, been pointed out repeatedly (for example, ref. 34). In addition, GABA has been found in other tissues in smaller amounts than in the nervous system and may serve a metabolic role (for example, ref. 35). Since no GABA was detected in the culture medium, cells containing GABA probably synthesise it. Although it is likely that these cells also synthesise β-alanine, this is not proven, for serum contained this compound (Table 1) and it may be concentrated. It should be noted, however, that cells contain both GABA and β-alanine, or neither, probably because glutamic acid decarboxylase can use both aspartic and glutamic acids as substrates to produce β-alanine and GABA, respectively[36].

H₁ and H₂ histamine receptors on *Aplysia* neurones

WE have found two types of histamine receptor on neurones of the mollusc *Aplysia* corresponding to those already known in mammals. The presence of these specific receptors is consistent with the suggestion that histamine acts as a neurotransmitter.

Histamine, originating primarily from mast cells, is an important pharmacological agent in the regulation of smooth muscle and visceral functions in mammals[1]. Two types of histamine receptor, H₁ and H₂, have been described. Activation of H₁ results principally in smooth muscle contraction and is blocked by pyrilamine and several other compounds. H₂ mediates stimulation of gastric secretion, increases in heart rate and inhibition of uterine contraction, and its response is blocked by burimamide but is insensitive to H₁ blocking drugs[2,3].

Although it seems likely that histamine functions as a neurotransmitter in the central nervous system (CNS), there is no definitive evidence for this. Some cortical neurones of the cat respond to iontophoretic histamine by both depression and excitation[4], and a relatively high proportion of hypothalamic

Fig. 1 Responses of an unidentified neurone from the left pleural ganglion to 1,000-nC pulses of histamine. Trace 1 is the intracellular recording and trace 2 indicates the iontophoretic pulse. Pyrilamine was dissolved in seawater and perfused over the ganglion. Na⁺ replacement was made with Tris⁺ as previously described[14].

neurones is excited by histamine[5]. It has been suggested, on the basis of postdegenerative changes in local histamine concentrations, that histaminergic pathways run through the medial forebrain bundle[6]. Histamine affects sympathetic ganglia, but it is not clear whether it functions in this system as a neurotransmitter or simply modulates other transmitter systems[7,8].

Previous work on an invertebrate (*Helix*) nervous system has demonstrated that both excitatory and inhibitory responses can be recorded when histamine is added to the bath and that both kinds of response are blocked by pyrilamine[9]. We have extended these observations, applying the drug iontophoretically, testing both H_1 and H_2 blocking drugs and determining which ionic conductances are changed by histamine.

Histamine is present in most identified neurones of *Aplysia* in concentrations of 10^{-6}—10^{-5} M (ref. 10). Weinreich *et al.*[11] have found two small neurones in the cerebral ganglion containing histamine in concentrations as great as 4×10^{-4} M. While surveying for the presence of receptors for several amines, we have found two types of response to histamine, the pharmacological sensitivities of which correspond to those of mammalian H_1 and H_2 receptors.

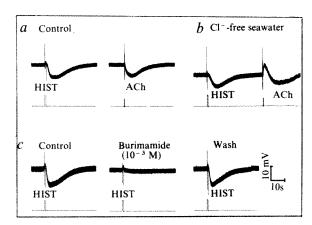
Experiments were performed on pleural, pedal, cerebral and abdominal ganglia of *Aplysia californica* removed from the animal and maintained under flowing artificial seawater in a Lucite chamber. As before[12], neurones were penetrated with double-barrelled glass pipettes for recording and electrical stimulation. Putative neurotransmitters were applied iontophoretically, through a five-barrelled glass pipette controlled by an electronic unit which delivered constant charge rather than current. Histamine was placed in one of the barrels at a concentration of 1 M, pH 3.5.


Fig. 2 Response of an unidentified cerebral neurone to histamine (HIST) and acetylcholine (ACh), 500-nC pulses. For (*b*) the preparation was perfused with a solution in which all Cl⁻ salts were replaced by isosmotic acetate salts. Burimamide was dissolved in seawater and perfused over the preparation.

Receptors for histamine were found on only a small fraction of neurones, and when present appeared both on the cell body and in the neuropile. All receptors were specific for histamine and showed no sensitivity to acetylcholine, dopamine, octopamine, phenylethanolamine or noradrenaline. Figure 1 shows the response of an unidentified neurone in the left pleural ganglion to a 1,000-nC pulse of histamine. After a very short latency, histamine caused a marked depolarisation and increase in discharge. The threshold for response was 500 nC. Pyrilamine (10^{-3} M), an H_1 blocking agent, reversibly abolished the response after exposure for 10 min (Fig. 1*b*). After recovery to control, the ganglion was perfused with seawater in which all Na⁺ was replaced with Tris⁺, which is at least relatively impermeable in this preparation. As Fig. 1*c* shows, the response was totally blocked in Tris⁺ seawater. This and all other responses to histamine which we have observed have been associated with an increase in

membrane conductance. Because both the voltage shift and the conductance change were absent in Na⁺-free seawater, this response seems to be the result of an increase in only Na⁺ conductance. The absence of action potentials in Fig. 1*c* results from an independent Na⁺ requirement. All these manipulations were reversible (Fig. 1*d*). This response was unaffected by exposure to 10^{-3} M burimamide for 20 min.

Figure 2 is from studies on an unidentified cerebral neurone with a different type of response. Figure 2*a* shows that the neurone responded with a slow hyperpolarisation to 500-nC pulses of both histamine and acetylcholine. An increased membrane conductance was measured during both responses. When all Cl⁻ in the seawater was replaced by the impermeant anion acetate, the membrane potential increased by about 7 mV and, whereas the histamine response remained essentially unchanged, the acetylcholine response became biphasic. The biphasic response resulted because acetylcholine caused an early increase in conductance of Cl⁻ followed by a late increase in K⁺ conductance[13]. The Cl⁻ component was depolarising in acetate seawater because the Cl⁻ equilibrium potential was then more depolarised. Because the histamine response did not change in acetate seawater, we assume that it, like the late acetylcholine response, resulted from a conductance increase to K⁺. Burimamide, the H_2 blocker, reversibly abolished this response in less than 5 min, but pyrilamine (10^{-3} M) had no effect after exposure for 30-min.

All histamine responses recorded were sensitive to either pyrilamine or burimamide, but not both. Both depolarising and hyperpolarising responses were found sensitive to each drug. These observations suggest that in *Aplysia* there are two types of histamine receptor corresponding to the H_1 and H_2 receptors described for mammals[2,3], and that each receptor is coupled to either an Na⁺ or a K⁺ conductance mechanism. Although identification of a substance as a neurotransmitter is absolutely dependent on demonstration of its release on nerve stimulation, and this has not been shown for histamine in this population of neurones, the presence of sensitive and specific receptors is consistent with a neurotransmitter function of histamine.

Evidence for neuronal control of ion transport in chironomid larvae

THE role of anal papillae in the uptake of sodium and chloride ions has been established in the closely related culicid and chironomid larvae[1-6], but studies on the ultrastructure of these organs have been limited to the former group[7-9]. The sites of active ion transport are located on the apical membrane of the epidermal cells below the cuticle[5,8,10]. The mechanism by which ion transport is controlled in culicid larvae is most

probably hormonal[4,11] but there are indications that a different system operates in the chironomid larvae[12-14]. To investigate this possibility, the ultrastructure of the anal papillae of *Chironomus riparius* Meigen has been examined. Axons were clearly present suggesting that ion transport may be under neuronal control.

The basic structure of the anal papillae of larval *C. riparius* is very similar to that described in mosquito larvae (Fig. 1). The cuticle is thin, relative to that over much of the rest of the body, and its surface is thrown into complex waves. The apical membrane of the epidermal cells is deeply infolded and numerous mitochondria are located adjacent to the proximal limit of these folds. The basal membrane is also irregular, leaving channels penetrating almost to the limit of the apical membrane. A number of 'mitochondrial pumps' similar to those described by Copeland[7] in the corresponding region of *Culex quinquefasciatus* are situated among the intrusions of the basal membrane.

Two features distinguish the anal papillae of this chironomid species from those of mosquitoes. Tracheae and tracheoles are absent, but groups of axons are present in both the dorsal and ventral papillae of the chironomid. No axons have been reported in this region of any mosquito.

The examination of entire papillae, whether removed from the animal or not, did not reveal the presence of any nervous tissue. Similarly, conventional sectioning of wax-embedded papillae did not show any detail of the nerves. The use of silver staining on whole or sectioned tissue was also fruitless as the high concentration of Cl^- resulted in deposition of silver throughout the papilla[15]. The identification of axons has therefore been based exclusively on their appearance in thin sections examined in the electron microscope, where they are seen to contain microtubules, the diameter of which (about 20 nm) is compatible with that of typical neurotubules[16] (Fig. 1).

Fig. 1 The integument of the anal papilla of a larva of *C. riparius*, seen in thin section stained with uranyl acetate and lead citrate. Note the irregular membranes and small nerve. Distally, the individual axon in contact with the epidermis becomes invested in folds of the basal membrane. (×9,350)

The number of axons in each papilla is variable, but when sectioned transversely at their proximal end the number in each can be estimated. At this level there are usually twelve to fourteen axons in each of the ventral papillae and seven to ten in each dorsal papilla. As the degree of branching is unknown, closer estimates have not been attempted. The axons are grouped into two small nerves, diametrically opposed across the papilla, with occasional isolated axons separated from the main bundles. At this level in the papilla the axons are not always in contact with the epidermis. The source of the axons is not yet known.

Distally the number of axons or their branches is smaller, and individual axons can be seen penetrating the epidermis. They never seem to become intracellular but become closely

invested in folds of the basal membrane. Terminally, the axons increase in diameter and a swelling is formed that contains numerous vesicles, the diameter of which has been calculated as 80 ± 3 nm (ref. 17). The swelling is extracellular but located at the distal limit of the basal membrane near the mitochondria and apical membrane. No sense organs or cell bodies have been seen associated with these axons in the anal papillae and it is therefore presumed that they do not serve a sensory role.

The function of the axons and any transmitter which may be released from the vesicles at their termination is not yet known. If their existence, however, is related to Koch's observation that anticholinesterases inhibit net sodium transport[12], it may be concluded that the axons serve some role in the control of active ion uptake in the papillae of *Chironomus* larvae. As no axons have been reported in the papillae of mosquito larvae (nor could they be seen on examination of the published evidence) this conclusion would not contradict the idea of hormonal regulation of this activity in the mosquito *Aedes aegypti*[11]. Nevertheless, it would emphasise that parallels between ionic regulation in culicid and chironomid larvae should be drawn with great care. Certainly, there may be differences in the sodium transporting mechanisms located in the anal papillae of these groups.

Biosynthesis of γ-aminobutyric acid by isolated axons of cone horizontal cells in the goldfish retina

SPECIFIC proteolytic enzymes have been used to dissociate adult vertebrate retinae into single cells[1-3]. These methods facilitate the study of chemical and physiological properties of isolated, identified retinal cells. In particular, the synthesis of neurotransmitter candidates in a pure retinal cell type has been studied by drawing identified cells into a micropipette, incubating them with appropriate radioactive precursors, and analysing the presence of radioactive transmitters[1]. In the study reported here, this method was used to examine transmitter synthesis by horizontal cells. Cajal's internal horizontal cells[4] from the goldfish retina were used because they could be dissociated easily from the retina and identified readily. In addition, these cells have been shown to be connected to Cajal's external horizontal cells, and can therefore be considered as fusiform axon terminals of cone horizontal cells[5,6].

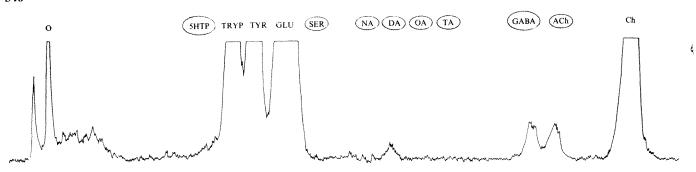
Before studying transmitters in dissociated cells, transmitter candidates synthesised by the whole goldfish retina were examined by the method of Hildebrand *et al.*[7]. As


Fig. 1 Radiochemical scanning of an electrophoretogram from a homogenate of goldfish retina incubated with ¹⁴C-labelled tryptophan, tyrosine, glutamic acid and choline chloride for 1 h. Two retinae (about 100 mg tissue weight) from an adult goldfish (*Carissius auratus*), were isolated and incubated with 1.0 ml of isotonic Leibovitz medium[8] (L-15, Grand Island Biological Co.) containing 10 μCi of each of methyl-¹⁴C-choline chloride (30 Ci mol⁻¹, Ch), L-U-¹⁴C-glutamic acid (255 Ci mol⁻¹, Glu), L-U-¹⁴C-tyrosine (54 Ci mol⁻¹, Tyr) and L-methylene-¹⁴C-tryptophan[7,9] (54.5 Ci mol⁻¹, Tryp). After 0.5 to 2.0 h of incubation at 24 °C, the retinae were homogenised with twice the tissue weight of formic acid (0.47 M)–acetic acid (1.4 M), and the homogenate was analysed by high voltage electrophoresis (6,000 V, 2 h) for the synthesis of ¹⁴C-ACh, GABA, DA, noradrenaline (NA), octopamine (OA), tyranine (TA), 5-hydroxytryptophan (5-HTP) and serotonin (SER). Scale: origin (O) to Ch is 72 cm.

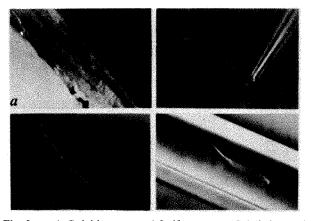
Fig. 1 shows, of all the transmitter candidates examined in this study, goldfish retinae synthesise only acetylcholine (ACh), γ-aminobutyric acid (GABA) and dopamine (DA). ACh and GABA synthesised were identified by specific enzymatic degradation[5,10] and ascending paper chromatography[11,12]. DA was also identified by paper chromatography[11]. Furthermore, significant activities of the


Fig. 2 *a*, A Golgi-impregnated fusiform axon (Cajal's internal horizontal cell) from the goldfish retina; *b*, an isolated fusiform axon from the goldfish retina; *c*, a fusiform axon drawn into a micropipette; *d*, a fusiform axon in a micropipette during incubation. (×175, Nomarski interference optics). The medium used for cell dissociation was modified L-15, made up of regular L-15 medium supplemented with glucose (2 g l⁻¹), ethyleneglycol *bis*(aminoethyl) tetraacetic acid (EGTA, 5 mM), penicillin (1,000 U ml⁻¹), streptomycin sulphate (0.5 mg ml⁻¹) and diluted to a tonicity of 250 mosmol, pH 7.2. In each experiment two to four goldfish retinae (100–200 mg) were incubated at 24 °C for 2 h with gentle shaking in 3.0 ml of sterile, oxygenated modified, L-15 medium containing crystalline papain (EC 3. 4. 4. 10) (1.0 mg ml⁻¹, 11.2 U mg⁻¹, Sigma). Retinae were then washed for 3 min with 5.0 ml modified L-15 medium and transferred to a conical tube containing 3.0 ml modified L-15 medium supplemented with 0.5% bovine serum albumin (fraction V, Sigma). Cells were dissociated by gently stirring and pipetting retinae up and down through a wide-bore Pasteur pipette. After the suspension had settled for 5 min, 2.0 ml was taken from the top fraction and filtered through a sterile gauze pad to remove cell clumps. The filtrate was then applied to a 40-ml velocity sedimentation chamber (made from a 50-ml plastic syringe) for cell separation[1]. Cells were separated by unit gravity at 24 °C through a linear gradient of 1–3% bovine serum albumin in modified L-15 medium. After 2–3 h of sedimentation, 2.0-ml fractions were collected and examined using a haemocytometer. A 0.1-ml sample of a fraction rich in these axons was spread on a glass slide. Under Nomarski interference optics (×256), single axons were drawn into a glass micropipette with a tip of inner diameter 6–8 μm attached to a micromanipulator (*c*). About 100 axons were drawn into each micropipette and used for chemical analysis.

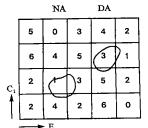
transmitter-synthesising enzymes choline acetyltransferase (EC 2. 3. 1. 6), glutamate decarboxylase (EC 4. 1. 1. 15), and tyrosine hydroxylase (EC 1. 14. 3a) in cell-free extracts of goldfish retina can be demonstrated (ref. 10 and D.M.K.L. unpublished).


To examine transmitter candidates synthesised by fusiform axons of cone horizontal cells[6] (Cajal's internal horizontal cells[4]) from the goldfish retina, a pure population of these axons was prepared by a modified cell dissociation and separation method[1]. By comparing the dimensions of the dissociated cells (Fig. 2*b*) with Golgi-impregnated fusiform axons of cone horizontal cells from the goldfish retina (Fig. 2*a*), isolated fusiform axons could be recognised easily and drawn into a glass micropipette individually (Fig. 2*c* and *d*) under visual observation. Figure 2 also shows that the isolated fusiform axons did not have nuclei, a finding consistent with earlier histological observations[13].

A hundred isolated fusiform axons were drawn into a micropipette, incubated with H³-labelled precursors and analysed for transmitter synthesis. Results of analyses from a typical experiment showed that these fusiform axons synthesised and accumulated GABA, but no detectable ACh and DA (Fig. 3).

These results did not show whether the level of GABA synthesis by these axons was significant compared with that in the whole retina. To obtain this information the enzymatic activity of glutamate decarboxylase in extracts of these axons was measured. A hundred fusiform axons were drawn into a micropipette and lysed by repeated freezing and thawing with dry ice. Both the glutamate decarboxylase and choline acetyltransferase activities in isolated axons and whole retinae were measured as described earlier[1,9,10]. After a 3 h incubation, radioactive products were separated and identified by two-dimensional paper electrophoresis and chromatography[11]. To calculate specific enzymatic activity, it is necessary to know the tissue weight of protein content. From microscopic measurements, the isolated fusiform axons used in this study had an average length of 100–200 μm and diameter of 3–6 μm. The specific activity of glutamate decarboxylase in these axons was calculated by assuming that an axon had a volume similar to a cylinder of radius 1.7 μm and 100 μm long, giving an approximate volume of 9×10^{-8} ml or a weight of 9.4×10^{-8} g per axon. On this basis the specific activity of glutamate decarboxylase in the isolated fusiform axons was 1.2 ± 0.4 μmol GABA formed h⁻¹ g⁻¹ wet weight, a value similar to that measured in the whole retina (1.0 ± 0.1, ref. 10). The specific activity of choline acetyltransferase in isolated fusiform axons (<0.05 μmol ACh formed h⁻¹ g⁻¹ wet weight) was below the sensitivity of this assay and was less than 5% of that

measured in the goldfish retina ($1\,8\pm0\,3$, D M K L , unpublished)

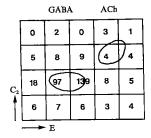
If GABA is to be considered a transmitter candidate in cone horizontal cells, the specific activity of glutamate decarboxylase in them should be substantially higher than that in the whole retina So, does the specific activity measured in isolated fusiform axons represent that in entire cone horizontal cells, which consist of both cell bodies and axons? Because isolated cone (external) and rod (intermediate) horizontal cell bodies could not be distinguished unequivocally, enzymatic activities in the cell bodies could not be measured directly Since in cone horizontal cells of the cyprinid retina, however, most of the structures characteristic of the chemical synapse have been observed on the cell bodies and not on the fusiform axons[3,14 15], the isolated axons used in this study probably contained very few synaptic endings (Fig 2) As glutamate decarboxylase has been shown to be very concentrated in presynaptic endings of neurones which presumably use GABA as a transmitter[16,17], the specific activity of glutamate decarboxylase in a cone horizontal cell complete with all its synaptic endings is probably much higher than that in an isolated


Fig 3 Two-dimensional analyses of radioactive transmitters synthesised by 100 fusiform axons incubated with purified methyl-³H-choline chloride (6 7 Ci mmol⁻¹), and L-³H-glutamic acid (generally labelled, 2 5 Ci mmol⁻¹) and L-3, 5-³H-tyrosine (25 Ci mmol⁻¹) for 8 h at 24 °C After incubation, cells were lysed by drawing 1 0 μl of 1 M HCl containing unlabelled precursors and transmitters into the micropipette Radioactive products were first separated by paper electrophoresis Regions corresponding to noradrenaline (NA) and dopamine (DA) were analysed further by ascending paper chromatography using a solvent system C₁ methylethyl ketone–propionic acid–water (200 65 55)[11] Regions corresponding to GABA and ACh were similarly analysed using another solvent system C₂ n-butanol–acetic acid–water (60 15 25)[11,12] Each chromatogram was dried, stained and cut into 1-cm squares Each square was placed in a scintillation vial containing 1 ml 0 01 M HCl for 1 h 9 ml of Aquasol was then added to each vial and the radioactivity was measured by scintillation counting[18] (25% efficiency) The values represent net c p m above a background of about 19 c p m

fusiform axon It is therefore reasonable to assume, on chemical and morphological grounds (Fig 2), that the specific activity of glutamate decarboxylase in intact cone horizontal cells of the goldfish retina is substantially higher than that in the whole retina

Lam and Steinman have shown that in the goldfish retina, a large amount of ³H-GABA is accumulated selectively by cone horizontal cell bodies and fusiform axons (Cajal's external and internal horizontal cells)[18] In addition, both the accumulation of ³H-GABA into these cells and the endogeneous level of GABA in the retina were influenced light stimulation of the retina[16,23] This study complements those results and shows that besides having a mechanism to accumulate exogenous GABA selectively, cone horizontal cells also possess the machinery to synthesis GABA These findings point to GABA as a transmitter candidate used by cone horizontal cells of the goldfish retina

I thank Professor Torsten N Wiesel for advice and encouragement I also thank Professors William K Stell and T Hastings Wilson for discussions, and Miss Shirley W Holbrook for preparing the figures This work was sup-

β-Adrenergic stimulation of cyclic AMP and protein kinase activity in the thyroid

THE demonstration that the sympathetic nervous system can have a direct effect on the thyroid[1], and the increasing clinical use of adrenergic blocking agents in thyrotoxicosis have reawakened interest in the effects of catecholamines on the thyroid We have therefore compared the effects of thyroid stimulating hormone (TSH) and isoproterenol, a β-adrenergic stimulator, on the activation of protein kinase within the thyroid by cyclic AMP We have also compared the inhibitory effects of the β-blocker propranolol, and the α-blocker phentolamine in this system We found that isoproterenol is stimulatory at concentrations as low as 10^{-8} M, and that l-propranolol, but not d-propranolol blocks this effect

Slices of calf thyroid were incubated and then frozen as before[2] Intracellular cyclic AMP was determined by the method of Steiner et al[3], and expressed per mg of protein in the homogenate Intracellular protein kinase activity in the frozen powdered tissue was determined as before[2] using a 2 mM EDTA/5 mM KHPO₄ homogenising buffer, pH 7 0, to which 0 5 mM 1-methyl-3-isobutyl xanthine and 200 mM NaCl had been added The ratio of the activity without added cyclic AMP to the activity found when 1 μM cyclic AMP is added during the assay reflects the degree of intra-

Table 1   Effect of TSH and isoproterenol on cyclic AMP and protein kinase activity

	Cyclic AMP (pmol mg⁻¹)	Activity ratio
Control	5 6±0 5	0 33±0 04
dl-Isoproterenol (5×10⁻⁵ M)	16 ±1 0*	0 63±0 03‡
TSH (50 mU ml⁻¹)	65 ±8†	0 99±0 04§
Isoproterenol +TSH	82 ±7	1 03±0 05

Means ±s e m , n = 4 The values for TSH alone are not significantly different from those when isoproterenol was added to TSH

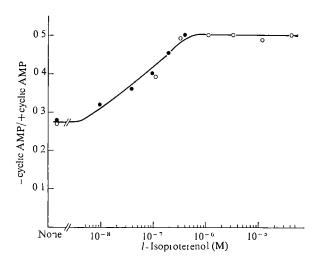
†P<0 01 compared with control and <0 01 compared with isoproterenol alone
‡P<0 025 compared with control
§P<0 001 compared with control and <0 01 compared with isoproterenol alone


Fig. 1 Dose–response Slices were incubated with various concentrations of *l*-isoproterenol for 10 min A 20,000*g* supernatant from tissue homogenate was assayed for its ability to incorporate ^{32}P from ATP into mixed calf thymus histone The 'activity ratio', the ratio of activity without added cyclic AMP to activity with 1 μM cyclic AMP added to the assay reflects the degree of intracellular activation of the enzyme ○, Results from one experiment, performed in duplicate, ●, results from a second experiment, also performed in duplicate

cellular activation of protein kinase We refer to this measure of endogenous activation as the 'activity ratio'

Thyroid slices were incubated with *l*-isoproterenol for various times The activity ratio increased linearly from zero time to 2 min, then remained constant for at least 10 min Subsequent incubations were carried out for 10 min, which was the time previously found for TSH at 50 mU ml^{-1} to produce its maximal effect in this system[2] Figure 1 shows the response of the kinase activity ratio to various concentrations of *l*-isoproterenol Concentrations as low as 10^{-8} M produced a significant increase in the activity ratio, and half maximal stimulation occurred at approximately 7×10^{-8} M

Table 1 shows the relative effects of large doses of *dl*-isoproterenol (5×10^{-5} M) and TSH (50 mU ml^{-1}) on cyclic AMP and kinase activity (Table 1) TSH fully activated the kinase activity ratio (0 99), while isoproterenol, which only raised the cyclic AMP level to 16 pmol mg^{-1}, increased the kinase activity ratio to 0 63 The cyclic AMP level produced when isoproterenol and TSH were combined was not significantly greater than that produced by TSH alone

To characterise the receptors involved, thyroid slices were preincubated with the β-adrenergic receptor blocking agent propranolol for 15 min Control slices contained $6 8 \pm 0 6$ pmol mg^{-1} cyclic AMP and this level was unaltered by preincubation with 10^{-4}M *dl*-propranolol TSH at 16 mU ml^{-1}, a submaximally stimulatory dose, raised the cyclic AMP concentration to 29 ± 5 pmol mg^{-1}, which was also unaffected by propranolol Isoproterenol (5×10^{-5} M) raised

Table 2 Effect of *d*-and *l*-propranolol on the isoproterenol-mediated stimulation of cyclic AMP and protein kinase activity

	Cyclic AMP	Activity ratio

‡$P < 0 005$ compared with isoproterenol alone
Isoproterenol +*l*-propranolol was not significantly different from control

the cyclic AMP concentration to $16 8 \pm 1 4$ pmol mg^{-1}, while propranolol reduced this response to $12 3 \pm 1 0$ ($P < 0 025$) The kinase activity ratio in the control slices in this experiment was $0 42 \pm 0 01$ and was unaltered by propranolol *dl*-Isoproterenol (5×10^{-5} M) raised the activity ratio to $0 64 \pm 0 03$ and this was reduced by propranolol to $0 50 \pm 0 03$ ($P < 0 005$) Preincubation of the slices with 10^{-4} M phentolamine, an α-adrenergic blocking agent, had no effect on the stimulation produced either by TSH at mU ml^{-1} ($0 81 \pm 0 04$) or 5×10^{-5} M isoproterenol

Low concentrations of the purified isomers of propranolol were also compared for inhibitory effects on the stimulation produced by *l*-isoproterenol (Table 2) While 6×10^{-6} M *l*-propranolol significantly lowered the cyclic AMP and kinase activity ratio, preincubation with *d*-propranolol actually enhanced the response to isoproterenol The kinase activity ratio and the intracellular cyclic AMP concentrations correlated closely (Fig 3)

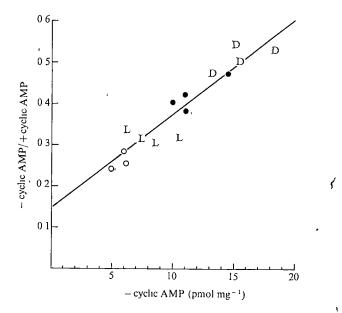
In 1968, Gilman and Rall suggested that β rather than α-adrenergic receptors mediated the effects of adrenaline in bovine thyroid slices[4] Subsequent studies on adrenergic stimulation of the thyroid have, however, been confusing


Fig 2 Correlation of kinase activity and intracellular cyclic AMP Slices were preincubated with *d*- or *l*-propanolol (6×10^{-6} M) for 15 min then incubated with 6×10^{-7} M *l*-isoproterenol for 10 min The two isomers of propranolol had no significant effects in the absence of the isoproterenol Correlation coefficient $r = 0 93$, activity ratio $= 0 023$ (cyclic AMP) $\pm$ 0 146 ○, Control slices, ●, slices incubated with isoproterenol, D indicates preincubation with *d*-propranolol and L indicates *l*-propranolol

and apparently contradictory, but have been generally interpreted as indicating the adrenergic effects on the thyroid were mediated by α receptors[5-8] The adrenergic blocking agents phentolamine and propanolol at concentrations greater than 10^{-4} M have even been reported to inhibit the effects of TSH on adenyl cyclase in thyroid slices[8-11] These findings have been interpreted as a reflection of a direct pharmacological effect on membranes by these blocking agents[11] In this study, however, only *l*-propranolol was inhibitory, while both *d*- and *l*-propranolol exert membrane effects The apparently synergistic effect of *d*-propranolol, while unexpected, is not unprecedented, as stimulatory effects of *d*-propranolol have been observed previously[12]

We have found previously that the activation of cyclic AMP-dependent protein kinase correlates well with increases in the level of intracellular cyclic AMP produced by TSH and prostaglandin E_1 in calf thyroid slices[2,13] Although the magnitude of the response of the activity

ratio to β-adrenergic stimulation is clearly less than that produced by TSH, it is apparently faster, reaching its maximum effect within 2 min, as opposed to about 10 min for TSH[2] Adrenaline was reported to produce a half maximal response in cyclic AMP at a concentration of 3×10^{-7} M in calf thyroid slices[4], although iodide uptake could be stimulated by as little as 5×10^{-7} adrenaline in isolated bovine thyroid cells[5] Our observation of an increase in kinase activity with as little as 10^{-8} M isoproterenol suggests that lower concentrations of this pure β stimulator are required than are needed for an effect of the combined α and β stimulator, adrenaline

Comparison of the action of isoproterenol and TSH reveals that isoproterenol acts more rapidly but does not raise cyclic AMP or stimulate kinase activity to the same degree as TSH These findings, as well as the lack of effect of propranolol on TSH suggest that the two agents act on different receptor sites The inhibition of the kinase response to isoproterenol by *l*- but not *d*-propranolol, as well as the lack of effect of phentolamine, indicates that the isoproterenol effect is mediated by β receptors

We thank Mr J Czarnecki for technical assistance, *dl*- and *l*-isoproterenol bitartrate were obtained from Sigma Chemicals, and *dl*-, *d*-, and *l*-propranolol HCl were the gift of Ayerst Laboratories, Montreal

Influence of the pineal on wound healing

REMOVAL of the pineal gland affects endocrine functions in both birds and mammals, and has been shown to cause increased growth and spread of malignant tumours in the rodent There are several hypotheses as to the mechanism by which the pineal affects these processes[1-4], but no role for the gland or its hormonal product melatonin has been suggested in normal processes We have now found that pinealectomy can slow wound healing and that this effect can be reversed by treatment with melatonin

Twenty 4-week-old inbred C57BL mice were divided into four groups of five The mice in group 1 were pinealectomised, group 2 was sham-operated, group 3 received melatonin (1 mg kg^{-1} body weight) intraperitoneally daily, beginning 24 h after pinealectomy and continuing for 10 d, and group 4 served as untreated controls All animals were kept in transparent plastic cages in a 10×12 foot room at 74–78 °F (23–26 °C) with 40% relative humidity A 60-W bulb provided light during the day, and was turned off at night The animals were fed Rockland hamster diet and water *ad libitum*

Pinealectomy and sham operation were performed as described previously[2], and 10 d later a 2-mm semicircular wound was made in the right ear of each animal, including the controls After 72 h, colchicine (2 mg kg^{-1} body weight) was injected intraperitoneally All animals were killed 48 h later, always at 1030, to control for diurnal variations in pineal hormone

	Control	Sham	Melatonin	Pineal
Observations (*n*)	250 00	250 00	250 00	250 00
Mean	2 09	2 15	2 25	1 58
Median	2 00	2 24	2 27	1 73
Variance	0 60	0 46	0 57	0 53

interaction Daily weighing during the experiment showed no weight loss in any of the animals

For the sake of uniformity, each wound was divided into three areas Samples from the margins of each area were excised, fixed in neutral formalin, dehydrated and embedded in paraffin All samples were treated simultaneously to reduce the chance of artefact to a minimum Serial sections (7 μm) were cut, then stained with haematoxylin and eosin Each ear yielded 200 sections and all were mounted individually We selected 50 slides from each area of each wound randomly, and counted the cells in each high-power field ($\times 40$), the average number in each field was constant from animal to animal Obvious spindles and hyperchromatic nuclei with brush borders were considered to represent nuclei in mitosis and were included in the count

We took as response (*y*) the number of mitoses per high-power field in each slide Hence, the response was a discrete variable $0 \leqslant y \leqslant 20$ with 50 slides from each of five animals We had 250 mitotic values for each group The data showed that the responses did not follow normal distribution and the variances were heterogeneous Therefore, the square root transformation was used in the final analysis Table 1 summarises the transformed data The ANOVA (Table 2) clearly indicates that at

Table 2 ANOVA using square root transformation

Sources of variation	Degrees of freedom	Sum of square	Mean square	*F*
Between groups	3	68 1248	22 7083	42 3
Between animals within groups	16	11 4246	0 7140	1 33
Residual	980	526 0679	0 5368	
Total	999	605 6173		

least two group means are significantly different at the 1% level of significance To distinguish the pinealectomised groups from the others, a multiple comparison test was done The result indicated that control, sham-operated, and melatonin-treated animals form one group, with means not significantly different, whereas the pinealectomised group differed significantly from the others at the 5% level

The small number of mitoses in the healing wounds of pinealectomised mice is possibly the result of a direct hormonal effect on wound healing This observation is in contrast to the previous reports of gonadal hypertrophy and increased growth of malignant tumours after the removal of the pineal[2-4] The gonadal hypertrophy has been postulated to be the result of hyperplasia or of hypertrophy of individual cells of the target organ In the case of transplantable malignant tumours, hormonal influence has been proposed as one of the causes of increased growth and spread

Membrane protein kinase alteration in Duchenne muscular dystrophy

DUCHENNE muscular dystrophy (DuD) is the severe form of heredo-familial muscular dystrophy inherited as a sex linked recessive trait The primary clinical manifestations are progressive muscle weakness usually starting in the pelvic girdle accompanied by hypertrophy in the calf musculature Significant cardiac abnormalities and mental retardation have also been reported The primary inherited metabolic defect is unknown[1] Elevated levels of muscle enzyme activities in the serum and their depletion in the muscle tissue have, however, long pointed to an abnormality in the plasma membrane as the probable site of the genetic defect

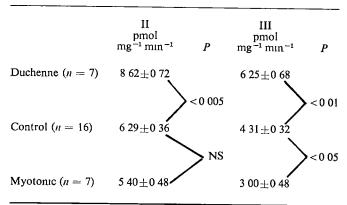
To explore potential membrane alterations in DuD we used a strategy which had been successful in another common form of hereditary familial myopathy, myotonic muscular dystrophy (MyD) Changes of denervation, atrophy, fatty infiltration, or fibrosis may make muscle membrane alterations impossible to interpret unless correlated with similar changes in other tissues So we used red cell membranes to explore the membrane abnormality in studies of MyD MyD red cell ghost phospholipids, polypeptides, and carbohydrates were similar to age and sex matched controls Endogenous protein phosphorylation, however, was decreased in fresh as well as frozen red blood cell membranes derived from patients with MyD[2,3]

Fig 1 *a*, 6% SDS-polyacrylamide gel scan of solubilised erythrocyte membrane protein No differences were demonstrated in scanning patterns from control, MyD, DuD or DuD carriers Molecular weights peak I, 210,000, II, 200,000, III, 90,000–100,000 *b*, Mean phosphorylation of major protein bands (II and III) of erythrocyte membrane measured under assay conditions (see text) Statistical data reported in Table 1

Migration 6% SDS–polyacrylamide gels

Other investigators have similarly demonstrated that clinically inapparent red cell alterations may accompany muscle disorders Layzer and coworkers have noted that the red cell contains a phosphofructokinase (PFK) composed of a muscle M-type subunit as well as a red blood cell or R-type subunit In the inborn error of metabolism affecting this enzyme the muscle M subunit is absent in red cell as well as the muscle and may be used as an index of the genetic defect[4] Morphological studies have similarly suggested red blood cell involvement in muscular dystrophy Using scanning electron microscopy, Matheson and Howland reported specific changes in the shape of RBCs derived from patients with DuD[5] In our own studies, we find no specificity Similar alterations were noted in red blood cells from patients with MyD, myotonic congenita, oculopharyngeal muscular dystrophy, homozygotes for DuD as well as carriers of DuD (S E Miller, A D R, and S H A, submitted for publication) Although our studies do not show that the morphological alterations are specific, they indicate clearly that the red blood cell membrane is involved in many muscular disorders

In this study, our initial intent was to determine whether the alterations in membrane protein kinase noted in MyD were specific for that disorder or were nonspecific alterations as noted in our morphological studies With the subsequent demonstration of a different level and pattern of protein phosphorylation in DuD, we were able to use this sensitive enzymatic reaction to monitor the membrane abnormality

Heparinised blood was obtained from DuD and MyD patients and matched with control heparinised blood Seven DuD patients from five families, three DuD carriers from three families, and seven MyD patients from four families were used Erythrocyte ghosts were prepared as previously described[3,6] All assays were performed on fresh ghosts without freezing or storage Incubations were performed as previously described and all assays were run in duplicate on 6% SDS-polyacrylamide gels Phosphorylation of the major erythrocyte protein peaks (II and III) (Fig 1) was linear for the incubation time of 1 min, and the protein concentration used $[\gamma\text{-}^{32}P]$-ATP was not limiting under these conditions[2,3]


There were no reproducible differences in the protein polyacrylamide gel patterns of erythrocyte ghosts from DuD or DuD carriers from either MyD or controls Similarly phospholipid, fatty acid, and Ca^{2+}-ATPase activities were not significantly different[2]

The phosphorylation of protein bands II and III in DuD membranes was significantly increased compared with controls or MyD patients (Fig 1 and Table 1) No differences were noted between young male controls matched with DuD and the mixed adult control group matched with MyD and DuD carriers These data have been pooled in Table 1 Our previous demonstration of decreased phosphorylation of band III in MyD was confirmed in this series of experiments[3] Also no difference was again demonstrated in the phosphorylation of MyD band II compared with controls

DuD carrier band II phosphorylation was $8\,58\pm1\,03$ pmol per mg ghost protein per min This value is increased significantly compared with controls but is the same value as noted in DuD patients The similarity of the phosphorylation of DuD and DuD carrier band II phosphorylation suggests that one gene dose may be sufficient to reveal alterations in the endogenous protein kinase activity but may not be sufficient to produce clinical dystrophy Mild elevation of serum creatine phosphokinase activity in many carriers have been interpreted as reflecting partial leakage of the muscle membrane[7] Endogenous protein kinase activity may be closely related to the primary defect in DuD and represent a highly sensitive index of membrane alteration But further kinetic studies as well as specific substrate and enzymatic isolations will be necessary before definitive genetic interpretations may be made

These results demonstrate that abnormalities of protein

Table 1 Phosphorylation of erythrocyte protein bands

Myotonic (*n* = 7)	5 40±0 48		3 00±0 48	

Transfer of ^{32}P from [γ-^{32}P] –ATP to erythrocyte membrane protein band under assay conditions *n*, Number of patients or controls *P* is determined by Student's *t* test

phosphorylation are present in red cell membranes from patients with DuD and DuD carriers as well as from patients with MyD, and the specific pattern of alterations is distinctive for each disorder Our studies of MyD demonstrated that muscle membranes possessed a similar decrease in protein kinase activity as had been noted in red blood cell membranes[8] Our present results combined with previous morphological and biochemical data suggest that DuD like MyD is an inherited disorder of membranes with widespread tissue involvement

Inhibitor(s) of prostaglandin synthesis in psoriatic plaque

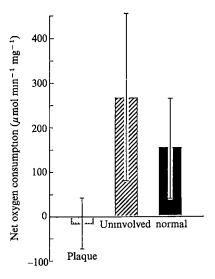
IN 1926, Woronoff[1] described an area of blanched skin surrounding psoriatic lesions The mechanisms of this reaction were unknown but were thought to be a consequence of vasoconstriction In considering the probable explanation of the blanched area, we have noted that the blanched area is approximately the same width (1 cm) around the psoriatic lesion irrespective of the size of the lesion (suggesting that a substance diffuses out of the lesion), and the whitened area does not become red during ultraviolet light therapy Snyder and Eaglstein reported that the redness following exposure to ultraviolet light can be aborted by treatment with indomethacin, which is known to inhibit the synthesis of prostaglandins (PGs[2,3]) We have also found that (1) PGE$_2$ levels in whole skin removed from the blanched area are one-third of those in normal skin, (2) injection of PGE$_2$ into the blanched area produced redness, and (3) an inhibitor(s) of PG synthesis was


Fig. 1 Oxygen consumption of skin homogenates Aliquots of skin homogenate obtained from normal control patients and from plaque and uninvolved skin of psoriatic patients were treated as described in the text Oxygen consumption in the presence of dioxygenase and arachidonic acid alone was subtracted from the oxygen consumption in the presence of added homogenate and the difference is recorded as μmol O$_2$ min^{-1} mg^{-1} The difference in oxygen consumption between psoriatic plaque and uninvolved psoriatic skin is significant ($P < 0 001$) (Student's *t* test for small sample populations) whereas no statistically significant difference was noted between oxygen consumption in psoriatic uninvolved skin and normal control skin ($P > 0 1$)

present in this blanched area (our unpublished results) These observations suggested that a diffusable inhibitor of PG synthesis was present within the psoriatic lesion We now report the detection of an inhibitor(s) of PG synthesis in psoriatic plaque that is not present in extracts of uninvolved skin obtained from either psoriatic patients or normal volunteers

Punch biopsies (4 mm across) were obtained from psoriatic plaques (eleven) and uninvolved skin (nine) of psoriatic patients and from normal volunteers (eight) after injection of 1% xylocaine Skin specimens were homogenised in 100 mM Tris-HCl buffer, *p*H 8 5 Oxidation of arachidonic acid by sheep vesicular gland dioxygenase was carried out as described by Smith and Lands[4,5] Dioxygenase was prepared by homogenising aliquots of acetone powder of sheep vesicular gland (Upjohn) in 100 mM Tris-HCl buffer, *p*H 8 5 Enzyme preparations and skin homogenate were placed in the side of the electrode holder of an oxygen monitor Immediately thereafter, arachidonic acid (Sigma, 20 μM final concentration) was added to the mixture and the reaction rate (μmol O$_2$ min^{-1}) was determined by continuous measurement of oxygen uptake, using an oxygen electrode at 37 °C Protein was determined by the method of Lowry *et al*[6] using bovine serum albumin as the standard

In our assay system, normal human skin homogenates contained substances that increased oxygen consumption (Fig 1) The nature of this stimulation in oxygenation of arachidonic acid is unknown but is under study Oxygen consumption of psoriatic plaque homogenates was markedly depressed compared with that of normal appearing skin obtained from psoriatic patients or normal control patients (Fig 1) Oxygen consumption in the presence of psoriatic plaque extracts was less than that of dioxygenase and substrate alone (control), suggesting a direct interaction between an inhibitor(s) in the psoriatic plaque and dioxygenase, decreased oxygen consumption may also reflect an absence of nonspecific alternate reactions that consume oxygen Clinical observations coupled with other data (our unpublished results) indicate that the area surrounding the psoriatic lesion is deficient in PGE$_2$ during ultraviolet light therapy Our results suggest that the reduction of oxygen consumption in the presence of homogenate from

psoriatic lesions is the result of inhibition of sheep vesicular dioxygenase

The detection of an inhibitor(s) of PG synthesis explains the clinical phenomenon of the blanched area surrounding psoriatic plaques The relationship of this inhibition to the psoriatic process is unknown Studies are under way to define further the nature of the inhibitor(s), and preliminary experiments show that it is dialysable, not susceptible to ribonuclease or deoxyribonuclease, and not destroyed by proteases

Role of macrophages in *in vitro* induction of T-helper cells

MACROPHAGES are of importance in the initiation of immune responses, both *in vitro*[1] and *in vivo*[1,2] Both immune responses involving B cells, such as antibody production[3-6], and those involving T cells, such as the lymphocyte transformation[7], the mixed lymphocyte reaction (MLR) (refs 8 and 9), and the induction of cytotoxic responses[10] require macrophages Various concepts of macrophage function in immune induction have been suggested The simplest concept proposed is that macrophages augment lymphocyte survival *in vitro*[11] Although this is one of their functions *in vitro*, it does not explain fully their role *in vitro* and especially *in vivo* In the induction of antibody responses, two functions were defined, the breakdown of antigens to the appropriate size[5] and the presentation of antigen to B cells in an optimally immunogenic manner[12] Because the T-cell reactions already studied, such as the MLR, involve ill-defined antigens, the surfaces of living cells, even less is known about the mechanisms of macrophage function in the stimulation of T cells than of B cells

Having recently described a system which enables unprimed T cells to be activated by soluble protein antigens and become helper cells[13], we investigated whether macrophages are involved in this reaction and attempt a definition of their role We report that macrophages were necessary, that there are genetic restrictions for effective T–macrophage interaction and that macrophages can be replaced by the supernatants of antigen-incubated macrophages of the same or an F_1 strain The genetic restrictions for effective T–macrophage interaction, however, did not apply if a particulate form of the antigen, keyhole limpet haemocyanin (KLH), conjugated to Sepharose beads (S–KLH), was used, indicating the existence of at least two different cellular pathways resulting in the generation of helper cells

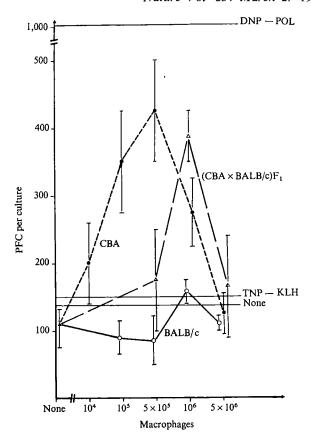
Purified T cells were obtained from cortisone-resistant thymus cells (CRT) of CBA mice by the nylon wool technique[14], which removes adherent cells (macrophages and B cells) To generate helper cells, 15×10^6 adherent cell-depleted CRT were incubated with KLH for 4 d, together with syngeneic (CBA), allogeneic (BALB/c) or semi-allogeneic F_1 (CBA × BALB/c) macrophages obtained from peritoneal exudate In a second stage (cooperation), 10^5 of these cells were incubated together with 15×10^6 normal spleen cells and trinitrophenylated KLH (TNP–KLH) After 4 d, the anti-dinitrophenyl (DNP) or anti-TNP response was measured by counting plaque-forming


Fig 1 Requirement for syngeneic or semi-allogeneic macrophages in the induction of T-helper cells PE from CBA, BALB/c and (CBA × BALB/c)F_1 mice were used as a source of macrophages To stimulate PE, mice had been injected with 1 ml 10% sterile Proteose–Peptone broth (Oxoid Code L46) 3 or 4 d previously Unstimulated PE were just as effective as stimulated PE The PE were washed in saline and treated with a sheep anti-T serum (dilution 1 4) and spleen cell adsorbed guineapig complement (1 8) for 45 min at 37 °C After washing, macrophages were incubated in graded numbers with 15×10^6 nylon wool purified CRT cells from CBA mice and 0 1 μg KLH in 1 ml HEPES-buffered Eagle's MEM containing 10% foetal calf serum in small (1 cm) Marbrook inserts for 4 d at 37 °C in an atmosphere of 10% CO_2 in air The outside compartment contained 25 ml of bicarbonate-buffered MEM with 5% normal calf serum As a control, no macrophages were added to the purified CRT After 4 d incubation the cells were collected, washed and 10^5 viable cells added to 15×10^6 CBA spleen cells containing 0 1 μg ml^{-1} TNP–KLH in Marbrook flasks (as above) and incubated for 4 more d The effect of macrophages on the generation of helper cells was measured by the cooperation between the carrier-activated T cells and the hapten-activated B cells expressed by the IgM plaque-forming ability of B cells against DNP or TNP-coated SRBC In our cultures, unprimed B cells do not make IgG

cells (PFC) against TNP- or DNP-coated sheep red blood cells (DNP-SRBC) thereby giving a measure of the helper activity generated in the first culture

Figure 1 shows that no helper cells were generated in the absence of macrophages, as indicated by the number of PFC which fell in the background range With the addition of increasing numbers of syngeneic macrophages to adherent cell-depleted CRT the helper activity increased as shown by the number of PFC generated Addition of 5×10^5 macrophages gave the highest number of PFC, indicating optimal helper activity A response was not seen when macrophages from BALB/c mice were incubated with CBA T cells, but was seen when they were incubated with BALB/c T cells (P E , and M F , unpublished), indicating that either T cells and macrophages must be histocompatible or that allogeneic macrophages exert an inhibitory effect on the helper cell induction The latter possibility has been excluded, since helper cells are obtained, if a mixture of CBA and BALB/c macrophages are incubated with

Spleen cells were used for the induction of T-helper cells. The adherent and phagocytic cells were removed by incubating 200×10^6 spleen cells (in 10ml of HEPES-buffered MEM containing 10% foetal calf serum) with 0.1 g carbonyl–iron in a 25 ml glass beaker for 1 h at 37 °C, by keeping a strong magnet on the bottom of the beaker while pouring the cells carefully into another beaker. The magnet treatment was repeated once, the cells washed and cultured in small (1 cm) Marbrook vessels with or without antigen (KLH, 0.1 μg ml⁻¹) and macrophage or macrophage supernatant. To obtain pure macrophage supernatant, 5×10^6 CBA, BALB/c or F₁ PE were incubated in the wells of a Linbro culture plate (No. FB–16–24 TC, Biocult, Glasgow) for 2 h at 37 °C, the non-adherent cells removed by extensive washings with HEPES-buffered MEM. Residual T and B cells were removed by treating with undiluted anti-T and anti-B serum and complement for 45 min at 37 °C and washing twice with MEM. The remaining cells (macrophage) were 99.7% phagocytic as judged by uptake of polystyrene beads. The macrophages were then incubated with 25 μg KLH (S/N₄ KLH) or no KLH (S/N₄) in 1 ml of bicarbonate-buffered MEM containing 10% foetal calf serum for 4 d at 37 °C. The supernatant (S/N) was then removed, spun for 15 min at 20,000g and frozen until use (1 ml supernatant was taken as 100%). Before use the supernatant was filtered through 0.45 μm Millipore filter. For the cooperative response, 10^5 viable cells from the first culture were incubated with 15×10^6 normal spleen cells containing 0.1 μg ml⁻¹ TNP–KLH in Marbrook flasks and incubated for 4 d at 37 °C. Dinitrophenylated polymeric flagellin (1.0 μg ml⁻¹) was used as a control. The anti-DNP response was measured by the IgM plaque-forming ability of the B cells against DNP-coated SRBC.

CBA T cells (P. E., and M. F., unpublished). F₁ macrophages were able to generate helper cells, although more semi-allogeneic macrophages were necessary to give a response. But this response was always less than with syngeneic macrophages. The need for syngeneic or semi-allogeneic cells for a successful macrophage–lymphocyte interaction was previously described in guineapigs[15], but was not found in mice[16,17].

In a second set of experiments it was ascertained that macrophages incubated in the presence of antigen, for example, KLH, can release factor(s) able to induce specific helper cells to KLH. Table 1 shows that supernatant taken from purified macrophages, which had been incubated with KLH for 4 d, adequately replaced macrophages and antigen when tested in the helper system. Thus in this system no direct contact between macrophages and T lymphocyte is necessary. Moreover, in accordance with the findings described above, the supernatant raised from allogeneic (BALB/c) macrophages were ineffective,

whereas that derived from F₁ macrophages activated helper cells; and that obtained from syngeneic macrophages incubated in the presence of KLH had no effect, even in high doses.

By contrast, the latter supernatant was effective if used with a particulate antigen, KLH bound to agarose (Table 2), suggesting the existence of different mechanisms of helper cell activation by soluble and particulate antigens. Moreover, the supernatant from allogeneic macrophages had the capacity to induce helper cells, if tested in the presence of KLH bound to agarose (P. E., and M. F., unpublished). The chemical nature and biological significance of a 'specific' factor(s) which replaces antigen and macrophages in helper cell induction, and a nonspecific factor(s) which replaces macrophages, but only in the presence of particulate antigens, remains to be investigated. There are several reports of such nonspecific replacing factors[18-21], but factors derived from macrophages, capable of replacing both macrophages and antigen have not been

described previously. The analysis of the genetic requirements for T lymphocyte–macrophage interaction should also be of interest since other forms of cell interaction have recently been suggested to have genetic (H-2-lined) restrictions, for example, T–B cooperation[22] and the killing of virus-infected cells[23].

Centromeric asymmetry and induction of translocations and sister chromatid exchanges in mouse chromosomes

THE mechanisms involved in chromosome rejoining are not understood. We showed that chromosome rejoining in Robertsonian centric fusion can be studied cytologically[1] with a staining technique based on the quenching by 5-bromodeoxyuridine (BrdU) of the fluorescence of the dye 33258 Hoechst[2]. When mouse cells were grown for one generation in the presence of BrdU and stained with 33258 Hoechst, there was a brightly fluorescent spot appearing over half of the centromeric region in every autosome[3]. (This asymmetry presumably reflects the unequal distribution of thymidine (45% compared with 22%) between the two chains of mouse satellite DNA[4], the fluorescent spot representing the old thymidine-rich chain of satellite DNA.) The arrangement of fluorescent spots in metacentric chromosomes resulting from Robertsonian fusion suggested that the thymidine-rich chain of satellite DNA in the centromeric region is associated with the same DNA chain (in terms of polarity) in every mouse autosome[1]. We have used the centromeric asymmetry in mouse chromosomes as a marker for DNA polarity in studies on radiation and drug-induced chromosomal translocation and sister chromatid exchange (SCE).

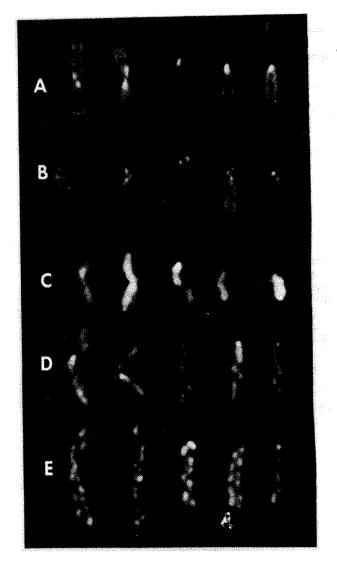
Mouse cells from two permanent lines (RAG and A9) were grown in Eagle's medium with 10% foetal calf serum. For radiation studies, cells growing in Falcon tissue culture flasks were exposed to X rays (350 rad, 190 kV). Thirty minutes before irradiation colcemid ($0.45\ \mu g\ ml^{-1}$) was added to the cultures, and 3 h after irradiation BrdU ($10^{-5}M$)


Fig. 1 Fluorescent staining of X-ray-induced dicentric chromosomes. RAG cells were grown for one cycle of replication in BrdU before fixation and staining with 33258 Hoechst. *a* and *b*, telocentric and metacentric chromosomes from unirradiated cells. *c* and *d*, Telo-dicentric and telo-meta-dicentric chromosomes from irradiated cells, showing the fluorescent spots on the opposite sides of the chromosomes. *e* and *f*, The same as (*c*) and (*d*), but with the fluorescent spots on the same sides of the chromosomes. *g*, Chromosomes from irradiated cells, showing SCE within the centromeric region.

or a mixture of BrdU ($10^{-5}M$), fluorodeoxyuridine ($2 \times 10^{-5}M$) and uridine ($3 \times 10^{-4}M$) was added. The cells were fixed 24–25 h after irradiation. For studies with drugs, cells were grown in medium containing mitomycin C (MC) ($0.5\ \mu g\ ml^{-1}$) and BrdU ($10^{-5}M$) for either 22–24 h or 48 h and then fixed. In one experiment, cells were grown for 18 h in BrdU alone and then for 22–24 h in BrdU and MC together. The techniques for chromosome preparation and analysis have been described previously[2,3].

The relationship between DNA polarity and chromosomal rejoining in X-ray induced translocations was examined cytologically, using the fluorometrically detectable centromeric asymmetry (Fig. 1*a* and *b*) as a cytological marker for the chain of DNA with a given polarity. In non-irradiated RAG cells, end-to-end translocations were not seen. But, one generation after irradiation, (distal) end to (distal) end translocations appeared in more than 25% of metaphases. Both telo-dicentric and telo-meta-dicentric chromosomes (resulting respectively from translocation between two telocentric or between telocentric and metacentric chromosomes) were observed (Fig. 1*c–f*). (Isodicentric chromosomes

resulting from iso-chromatid breakage and proximal union should not be present until the second metaphase after irradiation[5].) In every telocentric unit, a brightly fluorescent spot was associated with half of the centromeric region. In every metacentric unit two bright centromeric spots were arranged contralaterally. In the telo-dicentric chromosomes, the bright spots in the two centromeric regions could be arranged *a priori* either on the same side (relative to the long axis) or on opposite sides of the chromosome. In more than 95% of the telo-dicentric chromosomes, however, the bright spots were located on opposite sides of the chromosomes (Table 1). Similar results were obtained with the telo-meta-dicentric chromosomes. Since the spots presumably were associated with the DNA strand of the same polarity in every autosome, these results suggest that the orientation of the joined chromosomes in end to end translocations is such that DNA polarity is maintained from one centromere through the point of joining to the other centromere. The small proportion of telo-dicentric chromosomes in which the two bright spots were located on the same side of the chromosome (fewer than 5%) could be the result of X-ray-induced SCE at some point between the centromeres.

In the analysis of non-irradiated A9 cells, a stable chromosome aberration (appearing in more than 90% of the cells) was observed. The novel chromosome appears to have arisen from end-to-centromere translocations involving three chromosomes. After one cycle of replication in BrdU, the chromosome had three brightly fluorescent spots, all on the same side (Fig. 2). Assuming that this chromo-

Fig. 2 Fluorescent staining of a spontaneous chromosomal aberration. A9 cells were grown for one cycle of replication in BrdU before fixation and staining with 33258 Hoechst. Each chromosome is from a different cell.

some arose by translocation, these results suggest that the three chromosomes involved in the translocation were oriented such that the polarity of the DNA was maintained through the three regions of satellite DNA. (The stability of this translocation suggests that two of the three centromeres in this chromosome are either non-functional or absent.)

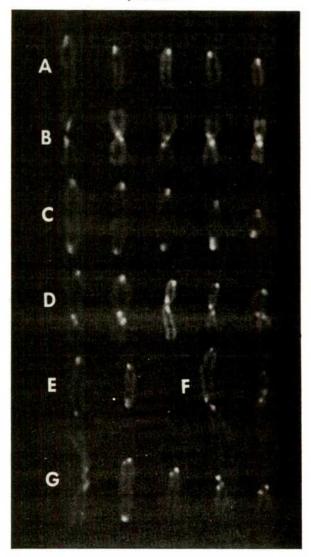
Our results suggest that DNA polarity is involved in determining the orientation of chromosomes during end-to-end and end-to-centromere translocations. This is consistent with the results of previous studies on other types of chromosomal reorganisation[1,5,6].

We have also used centromeric asymmetry to study SCE. The effects of X rays and MC, both previously shown to increase the frequency of SCE[7-9], were investigated. In RAG cells grown for one generation in BrdU, SCE within the centromeric region (appearing as a split in the fluorescent spot) occurred with a very low frequency (0.05 per metaphase). At the first division after X irradiation (Fig. 1g) the frequency of SCE within the centromeric region increased to 0.3 per metaphase. After one cycle of replication in MC plus BrdU (Fig. 3b), the frequency increased to 11.2 per metaphase.

In contrast to the centromeric region, SCE in the non-centromeric region was not observed at all after one cycle of replication in MC plus BrdU (Fig. 3b). After two cycles of replication in MC plus BrdU, however, the effect of MC

Table 1 Arrangement of fluorescent spots in the centromeric region of X-ray-induced dicentric chromosomes

Arrangement of spots	Telo-dicentric	Telo-meta-dicentric*	Total
Opposite side	730	92	822
Same side	32	10	42

RAG cells were irradiated and grown for one generation in BrdU and stained as described in the text. The data were collected from 292 metaphases, all of which contained at least one dicentric chromosome.
* For these chromosomes, the arrangement refers only to the spots associated with the two centromeric regions on either side of the point of joining.


was obvious (Fig. 3e). RAG cells grown for two cycles in BrdU without MC had on the average 12 SCE per metaphase; RAG cells grown for two cycles in BrdU with MC had more than 200 SCE per metaphase.

The difference between the appearance of MC-induced SCE in the centromeric and non-centromeric regions is not caused by a difference in the effect of MC in the two regions. If cells were grown for one generation in BrdU and then for a second generation in MC plus BrdU, there was a marked increase in the frequency of SCE (to 92 per

Fig. 3 Fluorescent staining of MC induced SCE. RAG cells were grown for different times in MC plus BrdU before fixation and staining with 33258 Hoechst. *a*, Cells grown for one generation in BrdU without MC. *b*, Cells grown for one generation in MC plus BrdU, showing SCE only in the centromeric region. *c*, Cells grown for two generations in BrdU without MC. *d*, Cells grown for two generations in BrdU, with MC present only during the second generation. *e*, Cells grown for two generations in MC plus BrdU.

metaphase) in the non-centromeric as well as the centro-meric region (Fig. 3d). Thus MC-induced SCE in the non-centromeric region can be observed in the first division following MC treatment, but only if BrdU is added one generation before MC. The failure to observe MC-induced SCE in the non-centromeric region until the second meta-phase when MC and BrdU are added together is in agree-ment with autoradiographic results that suggested that SCE involves exchanges of double stranded DNA molecules rather than exchanges of single polynucleotide strands[10]. The ability to detect SCE in the centromeric region at the first metaphase when MC and BrdU are added together is due presumably to the asymmetric distribution of thymi-dine in the two strands of mouse satellite DNA. This natural asymmetry thus provides a system in which SCE can be detected within the first generation after labelling, which could facilitate certain types of studies on chromosome breakage and rejoining.

Fig. 1 *a*, Time course of hybridisation reactions using RNA from nuclei ($\triangle$) and polysomes ($\bullet$) of PY AL/N cells. Data are corrected for DNA self-reassociation as determined from controls which contained DNA alone[1]. *b*, Double-reciprocal plots of the data in (*a*). The procedures for isolating and characterising non-repetitive DNA labelled with thymidine-2-^{14}C have been published[1]. To obtain RNA, cells were removed from the bottles with 0.05% trypsin+0.02% EDTA, washed twice in serum-free medium and resuspended at 8×10^6 cells ml^{-1} at 0 °C in 10 mM Tris, pH 8.4, containing 0.14 M NaCl and 1.5 mM $MgCl_2$. Nuclear and cytoplasmic fractions were prepared using 0.05% Triton X-100[2]. Nuclear RNA was obtained by hot phenol extraction[1]. Polysomes were purified from the supernatant by centrifugation through discontinuous sucrose gradients[7]. Polysomal RNA was isolated by phenol–chloroform extraction[8]. Nuclear and polysomal RNA preparation were treated with DNase and passed over columns of Sephadex G-100 (ref. 1). Hybridisation reactions containing the appropriate RNA (12 mg ml^{-1}) and labelled non-repetitive DNA (12 µg ml^{-1}) were carried out as previously described[1].

Non-repetitive DNA transcripts in nuclei and polysomes of polyoma-transformed and non-transformed mouse cells

WE have determined the extent to which non-repetitive DNA is represented in nuclear and polysomal RNA of polyoma-transformed and non-transformed mouse cells in culture. Our RNA–DNA saturation-hybridisation experiments have shown that in transformed cells, polysomes contain only 10–20% of the informational complexity present in nuclear RNA. Similar results were obtained with RNA from confluent cultures of non-transformed cells. In subconfluent cultures of non-trans-formed cells, however, polysomes contained about 40% of the sequence diversity present in nuclear RNA. Further experiments, with appropriate RNA mixtures, suggest that there are also qualitative differences in polysomal RNA between transformed and non-transformed cells, as well as between confluent and subconfluent cultures of non-transformed cells.

The results of experiments using RNA from the nuclei of PY AL/N cells and from polysomes prepared by centrifugation through discontinuous sucrose gradients are shown in Fig. 1. On the assumption that only one strand of DNA is transcribed the saturation values were taken as twice the intercept values of the double-reciprocal plots. The value obtained for nuclear RNA (30%) is the same as that reported earlier using total RNA from these cells[1]. The average saturation value for polysomal RNA was 6.4% (four experiments, range 5.2–8.0%).

Two experiments were carried out to determine the degree to which the polysomal RNA might be contaminated with RNA released from nuclei that were lysed or damaged during cell fractionation. First, DNA was labelled with thymidine-2-^{14}C, and nuclei and polysomes were isolated as usual. Approximately 99.5% of the acid-insoluble counts remained in the nuclei; only 0.5% was found in the polysomes. The second experiment was based on reports[2,3], that when cells are labelled with uridine, no counts appear for 10–15 min in either polysomal messenger RNA or cytoplasmic ribosomal RNA. In cells labelled with uridine-2-^{14}C for 10 min and fractionated as usual, the distribution of radioactivity between nuclei and polysomes was identical to that observed when DNA was labelled. When these nuclei were treated with DNase, lysed with SLS and centrifuged as in the preparation of polysomes, 14% of the acid-insoluble counts was recovered in the pellet. If this is a reasonable estimate of the maximum amount of nuclear RNA that could contaminate the polysomes, the 0.5% found above suggests an upper limit of contamination of about 3–4%.

A second set of experiments was carried out using more stringent criteria to define polysomal RNA[4,5]. Polysomes were centrifuged through linear sucrose gradients and the material sedimenting at > 100S was collected. After treatment with EDTA, this fraction was again centrifuged through a sucrose gradient and the portion sedimenting at < 80S was collected and the RNA was extracted. The results of hybridisation experiments using such RNA are presented in Fig. 2. The saturation values for two experiments (3 and 4%) are in fairly good agreement with those obtained by Bishop *et al.*[6] using the poly(A)-containing RNA from the cytoplasm of HeLa cells.

In the case of non-transformed cells it was necessary to collect from many bottles to obtain adequate quantities of RNA. Therefore, polysomes were prepared only by the procedure involving centrifugation through discontinuous sucrose gradients. In the experiments with transformed cells, polysomal RNA isolated by this method gave the highest

Table 1 Saturation values of RNA–non-repetitive DNA hybridisation experiments with RNA from non-transformed AL/N cells

	Nuclear RNA Average	(Range)	No of experiments	Polysomal RNA Average	(Range)	No of experiments
Growth state						
Confluent	20	—	1	5 7	(5 0–6 4)	3
Subconfluent	19	—	1	8 6	(8 4–8 8)	3

Each experiment used the appropriate RNA (12 mg ml^{-1}) and non-repetitive DNA (12 µg ml^{-1}) Hybridisation reactions were carried out as described in Fig 1 Assuming that only one strand of DNA is transcribed, the intercepts of double-reciprocal plots were doubled to obtain the tabulated values

saturation values, consequently the measurements with non-transformed cell RNA are likely to be maximum estimates of the RNA sequence diversity in polysomes

The saturation values obtained with nuclear and polysomal RNA of nontransformed cells are summarised in Table 1 As with transformed cells, the saturation values obtained with nuclear RNA from confluent and subconfluent cells agree with those previously obtained using total RNA from these growth states[1] The values for polysomal RNA from confluent (5 7%) and subconfluent (8 6%) cells suggest that more non-repetitive DNA is represented in the latter Experiments using a mixture of RNA from the two growth states gave saturation values of 10 4% and 11 2%, implying qualitative as well as quantitative differences with respect to the sequence diversity of polysomal RNA in confluent and subconfluent cells

Qualitative differences between the polysomal RNA species in transformed cells and subconfluent non-transformed cells are also suggested, since experiments with RNA mixtures yielded saturation values of 9 2% and 11 6%

To determine whether the hybrids contained only non-repetitive DNA, the DNA was isolated from the hybrids and its reassociation behaviour was examined in the presence of an excess of unlabelled, unfractionated mouse DNA As Figure 3 shows, except for 5% which bound to hydroxylapatite immediately after denaturation, the DNA from the hybrids reassociated as expected for nonrepetitive sequences The labelled DNA used in these experiments contained some sequences resulting from DNA self-reassociation, as well as sequences from RNA–DNA hybrids Even assuming that only 50% of the hybridised DNA originated from RNA–DNA duplexes

Fig 3 Reassociation of DNA isolated from hybrids in two experiments Hybridised DNA was isolated from hydroxylapatite and the RNA was removed by alkaline hydrolysis The DNA was dialysed into distilled water Sheared, unlabelled and unfractionated mouse embryo DNA was added to the sample to a concentration of 1 0 mg ml^{-1} and the ionic strength was adjusted to 0 12 M phosphate buffer The sample was denatured and incubated at 60 °C Samples were removed periodically and assayed on hydroxylapatite The reassociation of the unlabelled DNA was determined by the A_{260} (O), and that of the labelled DNA on the basis of its radioactivity (● and △)

Fig. 2 *a*, Time course of hybridisation experiments using the >100S PY AL/N RNA that sediments at <80S after EDTA treatment *b*, Double-reciprocal plot of the data in (*a*) Hybridisation conditions were similar to those in Fig 1 Cells were lysed, nuclei removed, and polysomes isolated as described in Fig 1 Polysomes suspended in buffer (10 mM Tris, pH 7 4, containing 10 mM NaCl and 8 mM MgCl$_2$) supplemented with polyvinyl sulphate (50 µg ml^{-1}), hereafter referred to as B+PVS, were layered over 30 ml, linear 15–30% (w/v) sucrose gradients (sucrose in B+PVS) built over a 2 0 ml cushion of 60% sucrose After centrifugation in a SW27 rotor at 25,000 r p m and 4 °C for 3 h, the material sedimenting at >100S was pooled and diluted 1 2 with B+PVS, and the polysomes were pelleted by centrifugation overnight in a type 60 Ti rotor at 55,000 r p m and 4 °C Polysomes were resuspended in B+PVS and the solution was made 25 mM EDTA The treated polysomes were layered over 15–30% linear gradients and centrifuged as before The material sedimenting at <80S was collected, MgCl$_2$ was added to 5 mM, and the polysomes were precipitated by adding ethanol to 50% and storing overnight at −10 °C The polysomes were collected by centrifugation at 25,000*g* for 15 min and resuspended in 10 mM Tris, pH 7 4, containing 0 1 M NaCl, 1 mM EDTA and 0 5% SLS RNA was isolated by phenol–chloroform extraction[8]

and that all the material which initially bound to hydroxylapatite occurred in this fraction, the results still indicate that at least 90% of the DNA which hybridised with RNA was comprised of non-repetitive sequences

To assess the precision of base pairing in the hybrids formed, their thermal stability was determined Samples were bound to columns of hydroxylapatite and eluted as a function of temperature at 5 °C intervals The thermal dissociation patterns resembled those obtained for total RNA–DNA hybrids[1], the midpoints of the transitions were 79–80 °C We concluded that no extensive mismatching of base pairs occurred in these hybrids

The results of these experiments can be summarised as follows First, although the saturation values obtained in RNA–DNA hybridisation reactions show a dependence on the method used for polysome isolation, only a fraction of the non-repetitive DNA transcripts found in the nucleus of either transformed or non-transformed cells are also found in the polysomes Second, confluent and subconfluent cultures of non-transformed cells are identical in the amount of non-repetitive DNA represented in nuclear RNA On the other hand, both quantitative and qualitative differences exist in the non-repetitive transcripts in the polysomes of cells in these growth states Third, the nuclear RNA of the virus-transformed cells contains a more diverse population of non-repetitive DNA transcripts than does the nucleus of the non-transformed cells In contrast, non-repetitive DNA is represented equally in the polysomes of transformed and

non-transformed cells Qualitative differences exist, however, in the polysomal sequences of these two types of cell

Different susceptibility of DNA and RNA to cleavage by metal ions

METAL ions are required in virtually every phase of genetic information transfer, and they are generally essential components of biochemical processes involving DNA and RNA Under certain conditions, however, metal ions can have deleterious effects, and one of these, the degradation of polyribonucleotides, is not frequently considered by those who deal with nucleic acids in the presence of metals No such degradation has been demonstrated with DNA, although it is known[1] that DNA, like RNA, is subject to thermal degradation, and therefore can be expected to undergo some degradation also in the presence of metal ions It is important to understand the relative susceptibility of polydeoxynucleotides and polyribonucleotides to degradation by metal ions to answer the following questions To what extent is DNA, compared with RNA, vulnerable to metal ion degradation during biochemical experiments? What are the implications for metal ion toxicology? Is the difference in susceptibility to metal hydrolysis sufficient to make possible a quantitative separation of degraded RNA from undegraded DNA in a DNA–RNA mixture? Finally, does this difference in susceptibility reflect differences in the intrinsic stabilities of DNA and RNA, and perhaps throw light on the reason for the evolutionary selection of DNA, rather than RNA, as the favoured bearer of the primary genetic information? These questions can be answered by a comparison of DNA and polyribonucleotide degradation by metal ions using a method of detection sensitive enough to respond to the first break in the macromolecule

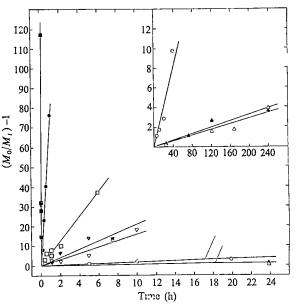
Polyribonucleotides are readily degraded by heating in the presence of various metal ions[2][3] Zinc(II) ion[3] is a very effective degrading agent, and the characteristics and mechanism of the zinc reaction have been thoroughly investigated[3-5] The zinc degradation of poly(rA) is typical of that of polyribonucleotides[2] For these reasons we have chosen to compare the degradation, in the presence and absence of zinc(II) ion, of poly(rA) with that of calf thymus DNA The non-degradability of DNA by metal ions has been suspected[2][6,7] on the basis of assays which could, however, detect only very extensive cleavage By following the zinc cleavage reaction by sedimentation velocity measurements, in conditions of strand separation, we can detect even one break per strand The reactions were carried out at pH 7 0, low ionic strength, with and without 2 Zn per nucleotide residue, and, for comparison of single and double stranded DNA, at each of two temperatures 50 °C, which is below the melting range of the DNA under these conditions, and 80 °C, which is above it[7] (Poly(rA) is single stranded at both temperatures[8,9])


Fig 1 Time course of cleavage of calf thymus DNA and poly(rA) at 50 °C and 80 °C, pH 7, with and without 2 Zn per nucleotide residue, as measured by reduction of the weight average, single-strand molecular weight during times t from the initial value M_0 to values M_t DNA 50 °C, (▲) with Zn, (△) without, 80 °C, (▼) with Zn, (▽) without Poly(rA) 50 °C, (●) with Zn, (○) without, 80 °C, (■) with Zn, (□) without Calf thymus DNA $(M_0 = 1\ 2 \times 10^6)$ was from Worthington Biochemicals, the stock solution was prepared as before[11] Poly(rA) $(M_0 = 0\ 41 \times 10^6)$ was from Miles Laboratories Reaction mixtures contained 0 10 mM nucleotide residue and 5 mM $NaNO_3$, and zinc ion was introduced as $Zn(NO_3)_2$, pH was initially adjusted to 7 0 by addition of NaOH For sedimentation measurements, zinc was removed from DNA solutions by batch exchange on Dowex-50(Na), and then to separate the strands[12] NaOH was added to 0 1 M and NaCl to 1 M, poly(rA) solutions were made 0 01 M in sodium EDTA buffer, pH 7 0 and 0 1 M in NaCl[3] (poly(rA) remains single stranded under such conditions[8,9]) Weight average sedimentation coefficients were determined at 20 °C (Beckman Model E ultracentrifuge, ultraviolet absorption optics) from the movement of the half-maximal position of the integral boundary pattern Weight average molecular weights were calculated for DNA, using the correlation of Studier[12] for the alkaline medium, $S_{20,w} = 0\ 0528\ (M^{0\ 40})$, for poly(rA), from the correlation of Fresco and Doty[13] for neutral 0 15 M NaCl, $S_{20,w} = 0\ 024\ (M^{0\ 45})$ (S in Svedbergs)

The sedimentation results, in terms of the calculated weight average, single-strand molecular weights, are presented in Fig 1 It is immediately obvious from Fig 1 that a large difference in susceptibility to zinc cleavage exists between single or double stranded DNA, and poly(rA), so that very extensive zinc depolymerisation of poly(rA) occurs during a time in which DNA sustains negligible damage Some cleavage of the DNA—both with and without zinc—was eventually detected, even at the lower temperature (inset of Fig 1), but the effect of zinc on DNA cleavage was insignificant, both at 50 and 80 °C, compared with its effect on the cleavage of poly(rA)

All the plots of Fig 1 fit straight lines reasonably well Table 1 provides quantitative comparisons of the slopes of these plots, which represent rates of depolymerisation on a single strand basis The Table also lists times required for reduction of the molecular weight to given fractions of the initial value Table 1 shows that there was no significant added effect of zinc on the cleavage of DNA, either above or below the melting temperature, while there was a 200–300-fold increase in the rate of depolymerisation in the case of poly(rA) The rate for poly(rA) was 4,000 times greater than the rate for DNA, in the presence of zinc, when the DNA was double stranded (at 50 °C) When the DNA was single stranded (at 80 °C), poly(rA) was still degraded 1,000 times more rapidly than DNA In the absence of zinc the degradation of poly(rA) was only 14 times faster at 50 °C and four times faster at 80 °C

These results indicate that cleavage induced directly by metal

Table 1 Rate of reduction of the weight average, single-strand molecular weight of calf thymus DNA, and of poly(rA), at 50 °C and 80 °C, pH 7 0, with and without 2 Zn per nucleotide residue

ions is generally unlikely during *in vitro* manipulations of DNA, although it must be taken into account with polyribonucleotides Figure 1 and Table 1 can serve as a guide to the amount of damage to be expected under various conditions

The great difference in the susceptibility of polyribonucleotides, compared with polydeoxynucleotides, to zinc cleavage makes possible the quantitative removal of RNA from a DNA–RNA mixture This becomes evident when one calculates from the data of Table 1 that, at 50° C with zinc, about 5,000 breaks occur in a poly(rA) strand for one break in a DNA strand Selective zinc degradation of RNA has already been utilised[10] in connection with chromatin reconstitution studies, our results indicate that the DNA components remain intact during such degradation

Our results suggest also that DNA should be much less susceptible than RNA to deleterious action by metal ions *in vivo* Thus the question arises whether these effects may be part of the reason for the predominant evolutionary selection of DNA, instead of RNA, as the bearer of the primary genetic information

Obviously, any attempt to answer this question, as any question involving evolutionary hypotheses, must be speculative It has been suggested[1] that the relatively small difference in thermal stability of DNA and RNA can account for the choice of the DNA duplex as the repository of genetic information But this difference in thermal stability is only about one three-hundredth the difference in stability to metal ions Moreover, metal ion degradation of polyribonucleotides proceeds[5] through a mechanism that involves the 2′ OH group, the presence of which in RNA and absence in DNA constitutes the only primary structural difference between the two types of nucleic acid For both of these reasons, if stability of the primary genetic material is a criterion of its evolutionary selection, susceptibility towards metal ions seems much more important than susceptibility towards heat It is of course possible that evolutionary selection of the structure was in response to pressures other than stability and coincidentally resulted in DNA with high stability to metal ion degradation

Amounts of isoaccepting lysine tRNAs change with the proliferative state of cells

VARIATIONS in isoaccepting tRNA populations occur in mammalian cells during development, neoplasia, and virus infection, and such changes may reflect the involvement of tRNA in regulatory processes[1,2], although firm evidence to that effect is not available Ortwerth and Liu[3] have shown that in normal or neoplastic cells an isoaccepting species of lysine tRNA, $tRNA_4{}^{Lys}$, is present in dividing cells but absent from non-dividing cells Ortwerth *et al*[4] determined some of the functional properties of $tRNA_4{}^{Lys}$ from various tissues and obtained evidence that the species is a real isoacceptor of $tRNA^{Lys}$ rather than an artefact Normal, proliferating cells that were examined had only relatively small amounts of $tRNA_4{}^{Lys}$, however, a larger proportion of the isoacceptor was found in neoplastic cells such as mouse leukaemia and Morris hepatoma cells It is desirable, therefore, to establish whether the large amount of $tRNA_4{}^{Lys}$ is peculiar to the neoplastic state or whether normal cells may also have large amounts of that isoacceptor under some growth conditions Therefore, we studied isoaccepting lysyl-tRNA profiles from mouse cells in different states of proliferation adult liver, embryo and growing and quiescent primary cultures of embryonic cells We found that normal growing cells also have an appreciable amount of $tRNA_4{}^{Lys}$

Ten-day-old mouse embryos, with heads and extremities removed, were prepared for monolayer tissue culture by dispersing cells with trypsin and seeding in roller bottles in Eagle's MEM[5] containing penicillin G (100 U ml⁻¹), streptomycin (100 µg ml⁻¹) and 10% foetal calf serum tRNA and aminoacyl-tRNA ligases were isolated from primary cells, embryo and liver as previously described[6] and tRNA was purified further by DEAE–cellulose chromatography[7] tRNA was aminoacylated with lysine as before[8]

In mouse leukaemia cells in suspension culture, $tRNA_4{}^{Lys}$ is 47% of the total $tRNA^{Lys}$, and this amount decreases to 16% as cell density increases and proliferation stops[3] Comparable data on the amount of $tRNA_4{}^{Lys}$ in a uniform population of rapidly dividing normal cells and the effect of increasing cell density were not available We have compared the Lys-tRNA^{Lys} profiles of growing and density-inhibited quiescent primary cultures of embryonic cells The results (Fig 1a) indicate a much larger amount of $tRNA_4{}^{Lys}$ in growing cells than in resting cells Consistent with these results is the finding of an appreciable amount of $tRNA_4{}^{Lys}$ in embryonic cells which were not in tissue culture (Fig 1b) These results also indicate that placing the cells in tissue culture does not in itself lead to an altered tRNA^{Lys} profile In contrast to results with proliferating cells, $tRNA_4{}^{Lys}$ is present only in a very small amount in adult mouse liver (Fig 1c)

The results are summarised in a quantitative manner in Table 1 $tRNA_4{}^{Lys}$ varies from 3% in adult mouse liver to 24% in proliferating monolayer culture Similar results with cultured murine sarcoma virus-transformed cells (H J , D J , and C H , unpublished) and SV40-transformed cells (J Katze, personal communication) have been obtained In both cases, $tRNA_{5a}{}^{Lys}$ (ref 8) seems to be present in addition to $tRNA_4{}^{Lys}$ in rapidly proliferating cells and decreases as the cell population becomes

Table 1 Effect of state of growth of cells on chromatographic distribution of isoacceptors of lysine tRNA

Cells	Growth state	Distribution of lysine tRNA isoacceptors			
		1	2	4	5
Adult mouse liver	Quiescent	−	58	3	38
Primary mouse embryo	Quiescent	2	50	9	40
Mouse embryo	Growing	4	37	15	44
Primary mouse embryo	Growing	2	35	24	38

Fig. 1 Comparison of lysyl-tRNA from primary embryo cells in growing and quiescent states, from adult liver and from whole embryo Growing primary cells were collected at $5\ 5 \times 10^4$ cells cm^{-2}, and quiescent primary cells were collected 48 h later at $9\ 4 \times 10^4$ cells cm^{-2} The generation time for primary cultures of mouse embryo cells is about 18 h Lysyl-tRNA was chromatographed in the RPC-5 system[9] on a $0\ 9 \times 100$ cm column with a linear gradient (500 ml) from 0 5 to 0 65 M NaCl in 10 mM sodium acetate buffer, pH 5, containing 10 mM MgCl$_2$ Fractions of 4 ml were collected at a flow rate of 1 3 ml min^{-1} Radioactivity in each fraction was determined in 15 ml of a 2 1 mixture of toluene-base scintillation fluid and Triton X-100 tRNA$_3^{Lys}$ is a minor species and is not resolved in our system a, Growing primary cells (- - - -, ^{3}H) and quiescent primary cells (———, ^{14}C), b, growing primary cells (- - - -, ^{3}H) and embryo (———, ^{14}C), c, growing primary cells (- - - -, ^{3}H) and liver (———, ^{14}C)

dense (The presence of tRNA$_{5a}^{Lys}$ is not always detected by RPC-5 chromatography, but benzoylated DEAE–cellulose chromatography provides resolution[8]) The effect of cell density on profiles of other isoaccepting tRNAs has been noted[10]

It is now clear that the distribution of isoaccepting species of tRNA^{Lys} in both normal and neoplastic cells varies with the proliferative state of cells The constancy of the sum of percentages of tRNA$_2^{Lys}$ and tRNA$_4^{Lys}$ suggests that species 2 and 4 are structurally related with differences attributed to the degree of modification[4] Confirmation of that possibility and investigations into functional differences are the subjects of continuing investigations

In the article "An ancient lunar magnetic dipole field" by S K Runcorn (*Nature*, **253**, 701, 1975) the legends to Fig 2a and b were transposed

In the article "A gene cluster in *Aspergillus nidulans* with an internally located *cis*-acting regulatory region" by H N Arst and D W MacDonald (*Nature*, **254**, 26, 1975) there was an error in Fig 1 The two arrows linking L-proline and L-Δ^1-pyrroline-5-carboxylate should be reversed—so that the top arrow points to the right and the bottom to the left

matters arising

Cooling velocity and cell recovery

FARRANT et al[1] have suggested that two separate processes determine the survival of cultured cells thawed from −196 °C storage, namely a holding temperature of about −26 °C preceding the subsequent storage temperature We report that optimal recovery of cultured cells after freezing depends on an optimal cooling velocity[2,3] rather than temporary attainment of a particular subzero protective temperature zone[1] before storage in liquid nitrogen at −196 °C

Normal human diploid fibroblasts were cultured in Dulbecco's modified Eagle's (DME) medium with 16 6% foetal calf serum, 20 mM HEPES buffer, penicillin, streptomycin and neomycin Cells were suspended and dispensed into glass ampoules (cryules, Wheaton Glass Company) each containing 10⁶ cells ml⁻¹ of medium and either 5% or 10% DMSO as described previously[3]

In pilot experiments, using an electric thermometer whose tip reached into an ampoule filled with 1 ml of the cryoprotective medium, we measured the time required to cool an ampoule from +25 °C to −25 °C This was done either by immersion of the ampoule in liquid nitrogen followed by rapid transfer at −25 °C to a methanol bath set at −26 °C or immersion in the methanol bath directly The time required was 30 s or 2 5 min, respectively

We designed the freezing experiments as follows (1) rapid cooling from +25 °C to −25 °C within 30 s followed by maintenance at −26 °C for 1 h, (2) slow cooling from +25 °C to −25 °C within 2 5 min followed by maintenance at −26 °C for 1 h, (3) slow cooling from +25 °C to −25 °C within 2 5 min followed by immediate immersion in liquid nitrogen After 1 h, the ampoules of series (1) and (2) were also rapidly immersed in liquid nitrogen All experiments were performed with two different concentrations of DMSO (5% and 10%)

Table 1 shows survival of only 0 75% of the cells cooled rapidly to −26 °C (cooling velocity about 100 °C min⁻¹) and maintained there for 1 h before immersion in liquid nitrogen, 52 7% survival when cooled more slowly to −26 °C (cooling velocity of about 20 °C min⁻¹) and then immediately immersed in liquid nitrogen, 61 2% survival after cooling slowly to −26 °C and maintained at this temperature for 1 h before transfer to liquid nitrogen

We have previously shown that optimal recovery of frozen human diploid fibroblasts from storage at −196 °C is achieved if the cooling velocity at subzero temperatures down to −30 °C is about 1 5 to 4 5 °C min⁻¹ (ref 3) Furthermore, cells do not cool at a constant rate in the range of +10 °C and −30 °C (Fig 1)

The assumption that the freezing velocity is the most important parameter for recovery agrees with Farrant et al[1], except for one experimental detail They state that (starting at room temperature) −26 °C had been reached in less than 1 min, while optimal recovery of frozen

cells required at least 5 min immersion in a bath at −26 °C This is inconsistent with our results (experiment 1) and does not demonstrate conclusively the existence of a protective temperature zone As our results show, on the one hand, nearly optimal recovery can be reached without keeping cells at a protective temperature zone (experiment 3) and on the other almost no viable cells remain even though they were kept at a recommended protective temperature for 1 h if the initial freezing rate was too high

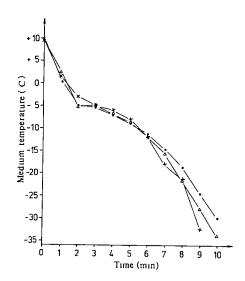
Farrant et al[1] happened to apply the optimal cooling rate for their cells when they immersed their glass test tubes for some time at −25 6 °C, whereas −22 °C,


Fig 1 Cooling rates of three independent experiments using ampoules containing 1 ml of tissue culture medium

−30 °C, and −40 °C provided less optimal cooling rates Larger sample volumes cooled in polypropylene tubes rather than glass recovered less well at −25 6 °C, because Farrant et al[1] were working outside the optimal cooling velocity for their particular cells We have described elsewhere that the cooling velocity can be controlled well by different types of insulation of the vial used for freezing[3]

As shown previously[2,3], the optimal cooling velocity differs between lymphocytes, red blood cells, Chinese hamster

Table 1 Survival rate of human diploid fibroblasts following different freezing procedures

DMSO in medium (%)	Time for cooling +25 °C to −26 °C	Time held at −26 °C	Number of cells recovered		Recovery rate (%)
			Viable	Non-viable	
5	30 s	1 h	5,084± 1,987	752,230± 78,352	0 67
10	30 s	1 h	5,698± 2,358	676,523±106,958	0 83
5	2 5 min	1 h	448,818±26,010	296,360± 38,823	60 22
10	2 5 min	1 h	524,235±73,263	318,570± 52,770	62 20
5	2 5 min	0	369,737±82,016	340,845± 42,823	52 03
10	2 5 min	0	463,636±55,812	398,483± 9,061	53 34

All vials were immersed rapidly in liquid nitrogen after they had reached −26 °C according to the schedule given above Cells were thawed rapidly to +37 °C after about 1 h, medium containing DMSO was removed by centrifugation and each ampoule seeded into one 25 cm² culture flask (Falcon Plastics) containing 5 ml DME culture medium Cell survival was measured as percentage attached (viable) cells compared with floating (non-viable) cells after incubation for 15 h at +37 °C (ref 2) Each figure represents the mean of four independent determinations

DR FARRANT *et al* REPLY—We believe that the protection of living cells against freezing damage given by cooling rate techniques or by a period at a constant subzero temperature are both due to the effects on the cells of the time of exposure to the subzero conditions

We have evidence that a continuous reduction in temperature (cooling rate) is not essential for protection The conclusive point is the onset of protection against subsequent rapid cooling damage with time at a subzero holding temperature once that temperature has been reached This can be seen (1) in our data[1], where the recovery of lymphocytes and tissue culture cells thawed from −196 °C increased with time (between 1 and 10 min) after −26 °C had been reached, (2) in other work on increases in protection with time at a constant subzero temperature in spermatozoa[2,3], red blood cells[4], platelets[5], tissue culture cells[6], nematodes[7], and mulberry twigs[8], (3) from unpublished work with Chinese hamster cells cooled in capillary tubing to −26 °C within 17 s, in which protection against rapid cooling to −196 °C is absent for the first 1 min and yet increases to a maximum at 2 5 min, and also (4) from the data of Rudiger *et al*[9], where there is an improvement in survival of diploid cells with time at −26 °C

The argument put forward by Rudiger *et al*[9], that cooling rate is essential for protection depends solely on their data showing very low survival of the cells cooled to −26 °C within 30 s It is possible that cooling a 1-ml sample with liquid nitrogen and relying on an 'electric thermometer' of unspecified thermal mass to determine when the sample has reached −26 °C (ref 9), in fact cools regions of the cell suspension to a much lower temperature, thus producing intracellular ice before the period at the holding temperature This should be checked in

control samples thawed immediately from the holding temperature, which in our experiments gave high survival Also, with a different cell type, amount of cryoprotective additive (including serum) and the slower thawing rate unavoidable with a larger sample, the optimal conditions of time and holding temperature are different (our unpublished work) The conditions we described originally[1] therefore do not constitute a universal recipe

In short, cooling rate is important but survival using cooling rate techniques can be explained in terms of the cells being exposed for different times to different subzero temperatures however, protection acquired with time at a constant subzero temperature cannot be dependent on cooling rate

Long-term periodicities in the sunspot cycle

COHEN and LINTZ[1] claim that their work shows the presence of a 179-yr periodicity in sunspot cycles, and that this is a beat phenomenon Another method of analysis can be used to demonstrate more clearly that a period of approximately this length exists in the data, and is indeed the result of beating between two more rapid oscillations Cohen and Lintz used the term "beat frequency" in the sense of half

the difference frequency, but here the beat frequency will be taken to be the difference frequency Whatever definition is adopted, successive maxima in the beats resulting from frequencies with periods 10 9 and 9 7 yr (ref 1, Fig 2) occur at 83-yr intervals, taking the frequency separation to be 0 012 cycle yr⁻¹ as they do The 167-yr interval mentioned by Cohen and Lintz is approximately a waveform repetition period

To study beat phenomena it is advantageous to consider the transformed sunspot numbers obtained by changing the sign of the numbers for alternate cycles in the way proposed by Bracewell[2] and others Cole[3] has carried out a spectral analysis on such data by standard methods and the results in his Fig 1 shows that the resulting power spectrum is much simpler than that obtained by using the ordinary, positive, sunspot numbers It should therefore be much easier to make deductions about the behaviour of sunspot numbers from this type of spectrum For instance, as Cole's spectrum (in his Fig 1*d*) shows three main peaks, the largest with a period of 22 2 yr and two smaller ones with periods of 19 7 and 18 3 yr, one would expect to find beat frequencies with periods of 175 and 104 yr in the data

If one uses the ordinary sunspot numbers, any period appearing in the envelope of the maxima will also appear as that of a genuine spectral component because the envelope of the sunspot minima is almost constant (nearly zero) This need not happen if the transformed sunspot numbers are used, and indeed does not happen in Cole's spectrum Therefore the 175-yr period in the maxima is certainly a beat phenomenon

Matters arising

DRS COHEN AND LINTZ REPLY—We had hoped that use of the term "beat" would help the casual reader to better understand the phenomena observed Given the confusion that has arisen, however, we probably should have discussed the sunspot cycle only in terms of the waveform repetition period (or frequency) In doing so, the data indicate that the waveform should repeat about every 179 yr

Specifically, through correlation analysis, and guided by the periods of significant signatures in the maximum entropy (MESA) spectrum for the data interval 1750–1963, we find that the spectrum of the 12-month smoothe

sunspot numbers shows components at 89 6, 57 1, 11 2, 9 9 and 8 1 yr We estimate, therefore, that to a first approximation, the repetitition period for a waveform produced by the superposition of sinusoids having these periods is about 179 yr $(2 \times 89\ 6 = 179\ 2, \quad 3 \times 57\ 1 = 171\ 3, \quad 16 \times 11\ 2 = 179\ 2, \quad 18 \times 9\ 9 = 178\ 2, 22 \times 8\ 1 = 178\ 2)$

That an 89 6-yr component is found in the spectrum suggests that the Sun may be behaving as a nonlinear (square law) device, passing not only the two major driving frequencies (11 2 and 9 9-yr periods), but also generating components corresponding to twice the driving frequencies, and to the sum and difference frequencies Thus, we might expect to find spectral components at the following frequencies

$$
\begin{aligned}
f_2 - f_1 &\quad 89\ 6\ \text{yr} \\
f_1 + f_2 &\quad 5\ 3\ \text{yr} \\
2f_1 &\quad 5\ 6\ \text{yr} \\
2f_2 &\quad 5\ 0\ \text{yr}
\end{aligned}
$$

Weak, but significant, components are found in the 214-yr MESA spectrum at periods of 4 8, 5 5 and 5 8 yr (correlation analysis yields period estimates of 4 8, 5 3 and 5 8 yr) and these may represent the expected heterodyne components

Population stratification as an explanation of IQ and ABO association

A RECENT study[1] of English villages claims to have shown significant differences in mean IQ between some of the ABO blood group phenotypes The population can be divided into two groups, namely those who were born locally and those who were born elsewhere, henceforth referred to as locals and non-locals respectively There is a significant difference in ABO frequencies between the two groups The frequency of ABO phenotypes varies significantly[2] throughout England, so that differences in frequencies between the local and non-local populations are not surprising Also, the non-locals have significantly higher mean IQs than the locals, regardless of the blood group phenotype The authors[1] claim that "There is thus genetic evidence for at least two population groups in the area, but this alone cannot be responsible for the association between ABO blood group and IQ which the analysis reveals "

We should like to suggest that the observed association could in fact be the result of this stratification of the population The combination of the difference in ABO frequencies and the difference in

mean IQ between the local and non-local groups causes an association This is explained below in a very simple model

The population is divided into two groups, local and non-local Each group is subdivided into, for example, blood groups, which will be labelled 1, 2, and 3 The population frequencies of blood group i are p_i and q_i for locals and non-locals respectively

$$
(i = 1,2,3, \sum_{i=1}^{3} p_i = 1 = \sum_{i=1}^{3} q_i)
$$

The total sample size of locals is N_1 and non-locals N_2 (Table 1) Define $M = N_1 / (N_1 + N_2)$

Denote the mean IQ of locals by x_1 and that of the non-locals by x_2 (independent of blood group) Then the mean IQ of blood group 1, denoted a_1 is given by

$$
a_1 = \frac{N_1 p_1 x_1 + N_2 q_1 x_2}{N_1 p_1 + N_2 q_1}
$$

$$
= \frac{M p_1 x_1 + (1-M) q_1 x_2}{M p_1 + (1-M) q_1}
$$

Similarly the mean IQ of blood group 2 is

$$
a_2 = \frac{M p_2 x_1 + (1-M) q_2 x_2}{M p_2 + (1-M) q_2}
$$

So

$$
a_1 - a_2 = \frac{M(1-M)\,(x_1 - x_2)\,(p_1 q_2 - q_1 p_2)}{(M p_1 + (1-M) q_1)(M p_2 + (1-M) q_2)}
$$

Thus $a_1 \neq a_2$ if $x_1 \neq x_2$ and $p_1 q_2 \neq q_1 p_2$ So if the mean IQ of the locals and non-locals is different and their blood group frequencies are also different, then in the total population the mean IQ of each blood group will be different

Is this sufficient to explain the difference observed in the Otmoor study? The appropriate parameter values are obtained from Tables 4 and 5 of that paper[1] They are $p_1 = 0\ 5238$, $q_1 = 0\ 3869$, $p_2 = 0\ 3691$, $q_2 = 0\ 4696$, $p_3 = 0\ 1071$, $q_3 = 0\ 1435$, $x_1 = 100\ 671$, $x_2 = 110\ 965$ (Blood group 1 refers to the A_1 phenotype and 2 to O) The values of N_1 and N_2 in those Tables 4 and 5 are different But the same general result holds for both sets of numbers The values in Table 4 will be used as they are closest

Table 1 Numbers observed in each subgroup

Blood group	Local	Non-local
1	$N_1 p_1$	$N_2 q_1$
2	$N_1 p_2$	$N_2 q_2$
3	$N_1 p_3$	$N_2 q_3$

to the total used in Table 1 Thus $N_1 = 168$, $N_2 = 460$ so $M = 0\ 2675$

Using this model we estimate that the mean IQ of A_1 phenotypes in the total

population sampled would be 107 56 and the mean IQ of O phenotypes 108 67 Thus the expected difference in mean IQ between these two blood groups, for this particular population, is 1 11 (The standard error of this estimate is 0 15 so that the difference predicted is significantly different from zero) The observed values of 106 95 and 109 75 for A_1 and O respectively are not significantly different from these expected values Although the observed difference of 2 8 IQ points is significantly different from zero it is not significantly different from the estimated expected value of 1 11 Thus the stratification of the population would be an adequate explanation of the observed differences in IQ between the blood groups

The model described above does not take account of the observed sex differences in IQ and ABO frequencies, but can be simply extended to do so In this case the expected difference in IQ between the A_1 and O phenotypes is 1 2 and the same general result applies

1 Gibson, J B, Harrison, G A, Clarke, V A, and Hiorns, R W, *Nature*, 246, 498 (1973)
2 Kopec, A C, *The Distribution of the Blood Groups in the United Kingdom* (Oxford University Press, London, 1970)

GIBSON, HARRISON and HIORNS REPLY—We appreciate the model proposed by Thomson and Bodmer and accept that its application to the Otmoor data makes the hypothesis that the association we reported between ABO blood group status and IQ is caused by the presence of two population groups in the area (locally born and non-locally born), more likely than we originally thought We still however consider that this explanation as we originally stated, is unlikely to be the sole cause for the association on the following grounds

On the basis of the model, the ability of a test to detect IQ differences between people of blood groups A_1 and O ought to be greatest in those villages where the proportions of locals and non-locals are most equal There is no relationship between this proportion and the level of association in the various villages Indeed, in Beckley and Horton, where the sample contained the second highest proportion of locally-born subjects, the

phenomenon was not detectable and the actual differences between A_1 and O were in fact the other way round from those found in the other villages

Although regional differences in the frequency of ABO genes certainly occur, there is no evidence in the data of Kopec[1] for micro-differentiation between neighbouring Oxfordshire groups from which most of the non-local individuals came Further the migration matrix analysis of movement into the Otmoor populations[2] not only predicted that there would be no between-village heterogeneity but that the genetic composition of the villages should be the same as those in the surrounding neighbourhood It therefore seems unlikely that the differences in ABO frequencies between locals and non-locals arise from their being two primary populations (We should perhaps add here that further analysis of other polymorphic systems indicates genetic heterogeneity between the Otmoor villages, but this is not shown by the ABO system)

An overall analysis of the IQ variance according to the ABO status reveals significant heterogeneity In the four groups, local males, local females, non-local males and non-local females the IQ variance is always smaller for O subjects than for A_1 ones Although these differences do not reach individual significance, an analysis of variance of logarithms of variances according to blood group status, sex and origin, indicate significant differences by AO status and sex ($t = 2\,23$ and $2\,03$ respectively with 629 d f) (This variance analysis includes additional information to that previously reported, but the same trends are present in the original data) The two-population model cannot account for variance differences but selective migration can If, for example, high IQ individuals tend to out-migrate from Otmoor, which seems likely, and if these outmigrants tend to have a relatively high frequency of blood group O, then one would find a comparatively low variance of IQ in those O individuals who remained and were tested Selective migration of this form could also explain the differences in the ABO frequency of the locally and non-locally born groups and particularly, the unusually low frequency of the O gene in the locally born males

It is perhaps also worth mentioning that in some of the village groups a significant difference in the IQ of A and O people also exists among the non-locals

Dantrolene sodium and 'skinned' muscle fibres

HAINAUT and Desmedt[1] have reported the results of their work with Dantrolene sodium (1- {[5-(P-nitrophenyl) furfurylidine] amino} hydantoin sodium hydrate salt) and skeletal muscle In single fibres of frog semitendinosus muscle they showed a greatly reduced twitch force and a shift in the dose–response curve for potassium contractures These results in general agree with those already obtained with whole muscle[2] Other workers[3] have shown that Dantrolene sodium has no effect on sarcolemma resistance or capacitance, and all evidence[2-4] points to the intracellular Ca^{2+} control mechanisms as the level at which Dantrolene sodium produces its effect

If the contractile proteins themselves are not involved, the twitch tension following a single release of Ca^{2+} from the sarcoplasmic reticulum may be reduced in two ways less Ca^{2+} may be released, and also the rate of uptake of Ca^{2+} may be raised Hainaut and Desmedt[1] show a reduction of 30% in the aequorin luminescence of barnacle fibres, following treatment with high concentrations of Dantrolene sodium, thus demonstrating that Ca^{2+} release is certainly reduced in this muscle In the frog, however, the twitch may be reduced by 75% with 15 μM Dantrolene sodium and it is possible that several mechanisms may be involved A good method for detecting changes in Ca^{2+} uptake into the sarcoplasmic reticulum is the Ca^{2+}–gel pipette technique of Gillis[5], which can be used for frog muscle Here, controlled local contractions are produced by a short contact with the Ca^{2+}-containing gel on an area of the muscle fibre from which the sarcolemma has been mechanically removed Thus Ca^{2+} is introduced from an external source, and relaxation follows with the uptake of these ions into the sarcoplasmic reticulum Drops of Dantrolene sodium in aqueous solution were added to the fibre under paraffin oil The concentration of Dantrolene sodium was about 15 μM, a saturated solution in 120 mM KCl In this 'skinned' preparation with no membrane it may be expected that the concentration of the negatively charged Dantrolene ions within the sarcoplasm is much higher than that inside an intact fibre The volume of Dantrolene sodium solution given was roughly twice the volume of the 'skinned' region of the fibre, so it would be expected that the concentration at the point of the test contractions remained high for some time

Contraction–relaxation cycles before and after Dantrolene sodium treatment were recorded on cine film and compared for speed and distance of contraction, spread of activation and rate of relaxation

There was absolutely no change in any of these parameters, either a few seconds after Dantrolene sodium or several minutes later In view of the undoubted effects of Dantrolene sodium on the intact muscle it would seem that it acts uniquely on Ca^{2+} release—the event bypassed using the Ca^{2+}–gel pipette It is clear that sliding filament reactions and Ca^{2+} uptake are not altered in the 'skinned' fibre Also, as the spread of activation was not reduced it seems likely that the regenerative release of Ca^{2+} from the reticulum is not inhibited This aspect of the possible actions of Dantrolene sodium has been discussed previously[4] in relation to other results

This work was financed by the Fonds National de la Recherche Scientifique of Belgium under the Royal Society European Exchange scheme

[5] Gillis, J –M, thesis, Louvain, Vander (1972)

DRS HAINAUT AND DESMEDT REPLY— Studies on single muscle fibres have demonstrated that Dantrolene sodium reduces the Ca^{2+} release from the sarcoplasmic reticulum during a twitch[1] The finding that Dantrolene sodium does not accelerate the myoplasmic Ca^{2+} uptake studied in skinned muscle fibres[2] is in line with our observations on intact barnacle muscle fibres injected with aequorin Figure 2d–e from our paper[1] indeed showed that the calcium transient, though markedly reduced in size, was not significantly changed in its time course by Dantrolene sodium The half time of the exponential falling phase of the luminescence transient studied for different depolarisations in six different fibres was 38 9 ms (s d = 1 8 ms) before and 38 4 ms (s d = 2 9 ms) in presence of Dantrolene sodium These and other data (K H, and J E D, unpublished) confirm that Dantrolene sodium depresses the Ca^{2+} release but does not affect the rate of reuptake of Ca^{2+} in intact muscle fibres

reviews

Sides of Bacon

A MEASURE of Francis Bacon's influence and importance to the history of ideas lies in the number of ways in which his works can be studied, and the number of books written about him. Not so long ago it was the fashion to emphasise his modernity and see in his writings the nascent scientific revolution of the 17th century. Now there is a useful corrective in a tendency to regard him as a Renaissance man (he was three years older than Shakespeare and Galileo) and to examine his thought in terms of 16th century concepts.

Out of this latter tendency comes Dr Jardine's extremely learned and lively study, based upon a scholarly examination of the dialectical tradition to which Bacon was exposed at Cambridge and which, as Dr Jardine shows, he never entirely shook off. There were in the later 16th century many new treatises on the art of discourse, intended to teach the young student both the art of logical argument and its application in rhetoric. Here we see how Bacon duly followed their precepts in all his works to some extent, most especially in his literary writings and in his logic; it is useful to be reminded what is easy to overlook, that the *Novum Organum* is first and foremost a logical or dialectical work, and only secondarily scientific.

This said, it must be added that this is not the whole of Bacon; this Bacon is studious, scholarly, derivative, pedantic, and eminently forgettable. There is another Bacon, who transcended his

Francis Bacon : Discovery and the Art of Discourse. By Lisa Jardine. Pp. viii+267. (Cambridge University Press: London, 1974.) £4.90; $15.50.

sources and his dialectical methods of thought to fire the imagination of budding natural philosophers born after (sometimes long after) he wrote. It is revealing to consider Bacon's elaboration of forms in terms of his dialectical education, but it provides neither the whole meaning nor any of the relevance of his work to the advancement of science. Dr Jardine is eminently successful in showing the traditional content; her approach cannot and does not help us to understand why it was important to later natural philosophers that Bacon said of heat that it was "a motion, expansive, restrained, and acting in its strife on the smaller parts of bodies". Nor does it allow us to appreciate that it was relevant to the development of the mechanical philo-

sophy that Bacon connected the "form of whiteness" with the reflectivity of the small particles of bodies. The scientist and historian of science looks favourably upon Bacon's remark : "A leaden ball of a pound weight dropped from a tower reaches the ground in (say) ten seconds : will a ball of two pounds in weight (in which the force of natural motion, as they call it, ought to be doubled) reach the ground in five seconds? No, but it will take almost the same time in falling, and will not be accelerated in proportion to the increase of quantity". Surely this is close to the heart of advancing science in 1623.

It may be true, as Dr Jardine says, that "in treating systematic experimenting as subsidiary to a formal logic which manipulates essential definitions . . . Bacon dismissed as secondary and provisional much of what we now regard as science"; but did he dismiss so much of what was then called natural philosophy? Rather, may it not be the case that his casting of new ideas in an old framework and his use of the language and methods of thought in which his readers in the next two generations were as thoroughly trained as he had been, made these ideas easier to understand, and certainly no less effective?

But modern readers, not so educated, are less able to appreciate the 16th century context of Bacon's thought and, above all, expression. Dr Jardine's book is valuable in providing understanding. **Marie Boas Hall**

THIS volume is the first of a projected series to be based on courses of lectures given at the Harwell Education Centre, by lecturers both from Harwell itself, and from outside. These Harwell lectures have been generally at an introductory level, and the present volume is in line with that trend. This description is in no way to be construed as an implicit criticism, for there has been a clear need for just such a volume. According to the preface, "the principal aim of the book is to provide a balanced and integrated account of instrumental methods (used for the characterisation of materials) for those who carry responsibility for research programmes and who must be able to judge the potential contribution from alternative techniques, and for specialists in any one technique who require an overview in adjacent fields of work".

The book achieves these aims effectively, especially the first; the second category of readers may find some (not all) of the chapters somewhat elementary for their requirements. The book

The stuff tis made of

Modern Physical Techniques in Materials Technology. (UKAEA Research Group—Harwell Series.) Edited by Mulvey, T., and Webster, R. K. Pp. xiv+321. (Oxford University Press: London, November 1974.) £9.50.

is also well pitched for an introductory course in a materials science course at university; I am already using it for that purpose.

Of the 20 chapters (8 by Harwell staff), 4 deal with various forms of

diffraction, 7 with micrographic methods (with a heavy emphasis on electron instruments), 7 on diverse methods of chemical analysis by physical means (optical emission and absorption spectrometry; electron-probe microanalysis; Auger, X-ray and mass spectrometry; activation analysis) and 2 with Mössbauer and magnetic resonance spectroscopy, regarded primarily as means of chemical identification.

Loosely, the book offers advice on how to find out what it looks like and what it's made of. The advances of the last 15 years have changed these twin arts out of all recognition, and this book offers a useful outline of what is now feasible. Some of the techniques are still difficult enough to oblige the wise casual user to contract the work out: Harwell is ready and waiting. **R. W. Cahn**

Span Quaternary fields

Pedology, Weathering, and Geomorphological Research. By Peter W. Birkeland. Pp. xiii+285. (Oxford University Press: London and New York, October 1974.) £6.25.

FEW books set out to bridge the considerable gaps between the various disciplines in Quaternary studies. This may be a reflection of the range and diversity of material, and consequently of the specialisms demanded of the author. It must, therefore, have required a commendable boldness to embark on a work as complicated as that suggested by the title of Professor Birkeland's new book.

The text spans the interesting and fruitful field between pedology and other Quaternary studies, but each reader will probably have a different view of the likely contents, and may therefore be frustrated by what is actually covered. The title does not represent the emphasis accurately. The major stress lies on the factors of soil formation (chapters 6–11), but there are introductory chapters on soil profiles, properties and classification (chapters 1 and 2), a section on weathering and soil forming processes (chapters 3–5), and a final single chapter on the use of soils in Quaternary studies. Pedologists will be familiar with most of these topics, and anyone interested in weathering and soil processes will find the material rather brief but succinct.

Geomorphologists may be thwarted in their search for appropriate material as there is no chapter specifically upon geomorphological work. Topics of recent geomorphic interest, such as quantitative research into processes, slope analysis and chronology are barely mentioned. The level is more appropriate to senior undergraduate and first year postgraduate students in British universities.

The text is geared to the American market. Nearly all the examples are taken deliberately from North America, and it is a matter of some regret that there are relatively few publications discussed, even in English, from outside that area. The depth of recommended reading varies from 73 references for one chapter down to 11 for another.

The lack of a review of biological factors leads to some imbalance; neither the chapter on vegetation and soil relationships (which fails to consider either fauna or microorganisms), nor the final chapter give adequate consideration to the biotic influences on soil development.

Despite these general criticisms and a number of minor quibbles, this book makes worthwhile reading on several counts. It does present a summary of recent (particularly American) research and it does bring together the research of diverse but related fields. Amplification of the topics presented, and a more extensive review of allied geomorphological research would add to the value of any future editions.

Peter A. Furley

Bubble devices

Magnetic Bubbles. By T. H. O'Dell. Pp. x+159. (Macmillan: London and Basingstoke, January 1975.) £8.50.

MAGNETIC BUBBLES will prove invaluable in a variety of roles; it will, for example, provide an excellent introduction and foundation course for device engineers and materials scientists entering the new field of magnetic bubble devices. In spite of the rapidly growing bibliography on magnetic bubbles the extensive references provided by the author will considerably aid established workers in this field to recover previously published information. The author has concentrated on the underlying physics of both the operation of devices and the materials used. The treatment has emphasised, where appropriate, the mathematical aspects of the subject, and in most cases it has been done in such a way as to inspire confidence, maintaining a balance between the basic philosophy of bubble devices and a rigorous mathematical treatment.

Consider a thin layer of magnetic material which, because of its structure, can easily be magnetised to saturation only in directions normal to itself. A magnetic bubble is a small and mobile cylindrical region, extending through the layer, which is magnetised in a sense opposing the remainder of the layer. Bubbles are used for data processing and storage, each one representing a '1' digit. A bubble device consists simply of an assembly of a number of integrated circuits each of which carries magnetically activated tracks, that is, shift registers, along which are driven patterns of bubbles and gaps representing binary data.

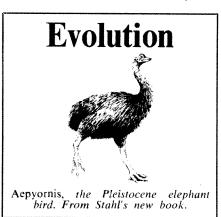
Chapters on magnetostatics and bubble dynamics are particularly well presented, bringing together a well balanced explanation incorporating a number of basic concepts which previously have been scattered among a handful of technical articles. These chapters would be valuable in aiding a first degree course in magnetics.

Two chapters deal with areas close to device design and technology. One provides a review of the range of magnetic materials which have been studied as candidates for bubble devices and explains the important characteristics which ensure adequate bubble stability. Although sufficient detail is given on garnet layers—which are prepared by liquid phase epitaxy—to indicate that they represent a viable device basis the author has omitted details on the epitaxy process itself. That is a pity because were such detail included it would be clear that the models used to represent the layers are idealised in that available layers actually possess nonuniformities in composition throughout their thickness. The other sections dealing with devices provide an excellent treatment of bubble motion in the potential wells produced by the shift register elements. The author's approach is, I believe, unique and is certainly likely to inspire the device engineer.

This review would be incomplete were I not to report the one error I found. Although nothing which follows it is invalidated, the approximation used by the author in Chapter 3 for the exchange constant may mislead readers to assume that the exchange constant is virtually independent of temperature. Actually, it decreases monotonically with increasing temperature, reaching zero at the Curie temperature.

Anthony Marsh

Vertebrate History: Problems in Evolution. (McGraw-Hill Series in Population Biology.) By Barbara J. Stahl. Pp. ix + 594. (McGraw-Hill: New York and Maidenhead, 1974.) £8.75.

THIS is the most interesting book on this subject that I have read, because it deals with the problems involved in understanding the course of vertebrate evolution. Most textbooks on vertebrate history are primarily accumulations of information on the structure and diversity of each group of fossil vertebrates, and are really textbooks of palaeo-osteology. Yet, for any reader, the interest of a subject lies in the problems it contains, in the lines of evidence available for solving those problems, and in the methods that can be used for obtaining and analysing that evidence. For example, the problem of the origin of the amphibians is not merely one of osteological modification; the papers that have discussed this subject also include opinions based on studies of the embryology, life history and behaviour of present-day amphibians, the anatomy and physiology of respiration, the ecology, climatology and geography of the Devonian, and the nature and distribution of Devonian sediments. Consideration of such wider topics in turn forces the reader to ponder to what extent they may or may not be relevant to the central question. It provides, therefore, a far better methodological training than the normal textbook description of the trees to the exclusion of the wood they make up.


The book is divided into nine main chapters: fossils (their nature, discovery and investigation); the origin of the vertebrates; bone and cartilage in early vertebrates; the first fishes with jaws; the rise of the modern fishes; the amphibians and their origin; the rise and fall of the reptiles; birds; and finally, mammals. The mammals are thus cut down to their proper status—in most books on vertebrate palaeontology, which give a description of all the diverse orders of mammal, they occupy one third to one half of the text.

The chapters themselves are written in a style that is concise and enjoyable to read, and the concepts and questions that arise are clearly defined. The format is attractive, with topic headings to the side of the text. In considering the main problems raised in these chapters, Dr Stahl has had to read and evaluate a large number of papers. The most important of these are listed in a well-selected bibliography of about 280 titles (some as late as 1972), and there are 216 excellent figures.

Dr Stahl's book cannot replace such textbooks as those of Romer or Colbert as a source of information on vertebrate palaeontology. It does, however, provide an opportunity for the interested student to find out more without becoming surfeited by facts, and thus to come to appreciate the proper significance of the information those other textbooks provide.

Barry Cox

Evolution

Aepyornis, *the Pleistocene elephant bird. From Stahl's new book.*

The Genetic Basis of Evolutionary Change. By R. C. Lewontin. Pp. xiii + 348. (Columbia University Press: London and New York, 1974.) £2.15.

FOR Darwin, evolution was the conversion of variation among individuals within an interbreeding population into variation between species and genera. The central ideas of molecular biology did not have an immediate impact on evolutionary thought. They did change our concept of mutation from a process of shuttling back and forth between wild-type and mutant states to that of an infinite series of changes which almost never back-tracks. But the full impact waited on the development of two experimental techniques: the determination of amino acid sequences in peptides, and gel electrophoresis. These techniques provided for the first time quantitative answers in genetic terms to two important questions—how fast has evolution proceeded, and how much genetic variation is there in natural populations? The classical evolutionist may object that the level of description has been changed from the important to the trivial—from morphological to biochemical differences.

Dr Lewontin has not only played a large part in the development of theory but was among the first to answer the second question experimentally, in 1966, by showing that in wild populations of *Drosophila* there is probably genetic variation at the majority of loci specifying peptide chains; a finding subsequently confirmed in many species by other workers. This book derives from a series of lectures he gave in Columbia in 1969 and, consequently, perhaps suffers in structure. It is not as wide in scope as the title would suggest and concentrates too much on the evidence from gel-electrophoresis. The approach is historical and the first 100 pages are almost a grand build-up to the presentation of the answer to my second question. The theoretical framework is presented as an antithesis between two views. In the first of these —the 'classical' view—most of the genetic variation in populations is thought to be selectively neutral or harmful. Much evolutionary change may not have been adaptive but has resulted from the chance fixation of neutral alternatives. In the other view—the 'balance' view—it is held that variation is actively maintained in population by selective forces, although there would be disagreement about their exact nature, and that evolution proceeds by the active fixation of available alternatives at loci, with a gradual change of selection pressures over time. The necessary synthesis has not been achieved (though the author clearly leans scientifically and politically on the 'balance' side); Lewontin suggests that the profusion of facts which are now available for the 'theory machine' have merely led to "a great clashing of gears".

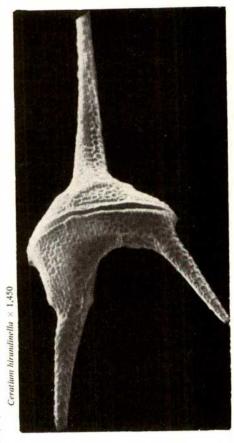
There are perhaps two main reasons for the present confusion. The first is that all wild populations have to cope with the wide diversity of environments, both in space and time, and we have neither an adequate description of these, from the point of view of the organism, nor an adequate theoretical treatment of their implications. The second is that differences in fitness between genetic alternatives may be so small (say of the order of 1% or less) that there is great difficulty in measuring them adequately. This is particularly true for the measurement of fertility. With *Drosophila* far too much work has been concentrated on the measurement of viability differences, which is relatively easy to do, even though recent evidence shows that fertility differences are much more important. In my view, the great merit of the book lies in its critical discussion of the present confusion and of the validity, both biological and statistical, of some of the evidence that other workers have put before us.

But we must remember that the loci that we observe with these techniques only refer to a small part of the DNA, the 'single-copy' set coding for proteins. The evolutionists have hardly faced up to the evidence now accumulating from the multiple-copy sequences, such as the satellite DNA or those sequences which code for ribosomal RNA. I suspect that the mechanisms that we shall have to invoke for the evolution of this part of the DNA will lie quite outside our present philosophy and outside the scope of this book. **Alan Robertson**

In honour of Lanczos

Studies in Numerical Analysis. (Papers in Honour of Cornelius Lanczos.) Edited by B. K. P. Scaife. Pp. xxii + 333. (Academic: London and New York, September 1974. Published for Royal Irish Academy.) £5.00; $13.00.

THIS Festschrift volume is published under the auspices of the Royal Irish Academy as a tribute to Cornelius Lanczos on the occasion of his 80th birthday (February 2, 1974). It is devoted almost exclusively to numerical analysis, since, although Lanczos made significant contributions to areas of theoretical physics, he is most widely known for his work in this particular field. Professor Lanczos died in Budapest on June 24, 1974 but, happily, he had lived to see this personal and affectionate tribute to him from many distinguished scholars.

Lanczos was educated in Hungary and worked first in Germany (1922–31), then in the United States (1931–54), and lastly in Eire (1954–74), and he was completely imbued and enthused with the traditional viewpoint of the complementary interaction between mathematics and physics, as exemplified by the Göttingen school of mathematics founded by David Hilbert. His work may be divided into two main areas: relativity theory and quantum theory (1922–38) and numerical analysis (1938–74), and in both of these he made important and lasting contributions to knowledge; his abiding interest lay with geometry and the nature of space and time. Lanczos was a prolific author of papers and books, which show clearly his viewpoint of the essential unity of mathematics and physics (the viewpoint, for example, of John von Neumann) and their cultural appeal and importance (as, for example, discussed by Morris Kline).


The Festschrift opens with a biographical note on Lanczos, supplemented by a list of publications by him (94 articles and eight books), and it continues with 19 contributed articles. Professor B. K. P. Scaife, who has charmingly dated his editor's foreword for Lanczos' birthday, has obviously sought, by the particular choice of contributers, to associate as far as possible current developments in numerical analysis with Lanczos's original ideas in that field. These include the application of Chebyshev polynomials in approximation theory and the development of the economisation (or telescoping) method and the tau method (1938); the fast-Fourier transform (1942); the first exact method for obtaining all the eigenvectors and eigenvalues of an arbitrary matrix (1951); a fundamental theorem on the decomposition of an arbitrary matrix (1958); a precision approximation to the Gamma function (1964); and Sigma factors for smoothing Gibbs's oscillations in Fourier series (1966).

In summary, in addition to articles of a specialist nature on topics in numerical analysis, there are three articles of a biographical nature and also a review article on conservation laws in Einstein's general theory of relativity. The book will appeal especially to those with interests in numerical analysis and also to those interested in the life and achievements of Cornelius Lanczos.

H. G. Hopkins

Red tide

Ceratium hirundinella × 1,450

Fossil and Living Dinoflagellates. By W. A. S. Sarjeant. Pp. vii + 182. (Academic: London and New York, December 1974.) £5.00; $13.00.

THE gulf called *Sinus arabicus* by the Romans was known to the Arabs themselves as the Red Sea, and it was under that name that it became known to the rest of the civilised world at least as long ago as the ninth century. The visually spectacular effects of the 'red tide' blooms of dinoflagellates have been recognised, therefore, for over 1,000 years, but not until the publication of this work has a book been devoted solely to these extraordinary organisms. Even if there were no other reason, that aspect alone must recommend Dr Sarjeant's volume, but the whole has the additional merits of clarity, readability and profuse, well chosen illustrations. The publishers maintain their high standards with good quality paper, clear printing and format, and strong and attractive binding.

Dr Sarjeant is a palynologist and micropalaeontologist; originally, he intended to deal only with the fossil dinoflagellates and their resting cysts ('hystrichospheres'), and it is with these that his strength lies. Appropriate techniques of sample preparation are outlined clearly and fully, thecate dinoflagellates and cysts are described morphologically, and a separate short chapter is devoted to the taxonomic problems which have resulted from nomenclature based separately upon thecae and cysts. A concise but thorough suprageneric classification of fossil dinoflagellates is appended, and the stratigraphic history of the group is summarised. The acritarchs are mentioned but not described in detail, and there are no illustrations or descriptions of the great majority of the genera and species listed in the stratigraphic section; the reader must turn to the references given by the author for that information. Recent attempts to achieve an objective terminology for the description of cyst walls are not discussed at all. Otherwise, the account is very comprehensive, and it is invaluable to have it (and such a valuable collection of reference lists) now so conveniently to hand.

The chapters dealing with biology, ecology (12 pp.) and palaeoecology (6 pp.) are much less thorough. The faculty possessed by some species to generate extraordinary levels of bioluminescence, with marked periodicity, still deserves further treatment—not only for its own sake, but also for the field work it has stimulated which is contributing greatly to our knowledge of the ecology of these organisms. Much detailed ecological work has been done in recent years, not least in the Red Sea itself, where dinoflagellates dominate primary production for most of the year. The important role played by dinoflagellates in food webs deserves more attention: symbiotic dinoflagellates (zooxanthellae) form a significant primary role in the productivity of coral reefs, and the motile swarms of the 'red tide' itself make their contribution to nutrition as well as to spectacular mass mortalities.

Dr Sarjeant's book will surely deserve a second edition on the merit of its micropalaeontology alone; if neontology and ecology could then be equally well covered, it would undoubtedly be a major contribution to synoptic studies in the natural sciences.

F. T. Banner

Landscape a l'americaine

The Origin of Landscapes: A Synthesis of Geomorphology. By H. F. Garner. Pp. xx + 734. (Oxford University Press: London and New York, October 1974.) £10.75.

THIS long and well-produced text is designed for use at US college level and presumably, therefore, for undergraduates in European universities. In it the author attempts to combine geology, geomorphology, climatology, botany and other branches of natural science in a synthesis of landscape study. The resultant theme seems to be halfway between physical geography in the European sense and physical geology in the American sense.

The presentation of the geomorphic subject matter is said by the author to be "at once new and not new" insofar as it emphasises the relationships of processes and treats any particular process in its several environments: for example, the effect of running water at the surface is discussed in humid, arid, and glacial contexts, and again with respect to alternating environmental conditions. The general theme reflects the genesis of landforms by associations with environmental systems and through the substitution of one system for another in time and space. Thus, the essential theoretical thread that binds together the otherwise detached concepts is the fact that most landscapes are the products of environmental sequence.

The main body of the text opens with a chapter on the concepts of geomorphic theory and the development of geomorphic ideas. The discussion is lively and stimulating but needs some revision. For example, the author thinks the peneplain was the ultimate landform in the Davisian cycle whereas it was penultimate; he considers that downstream increase in the velocity of rivers augments their erosive power whereas, presumably, the velocity is increased because of relative decrease in bed friction or erosional contact.

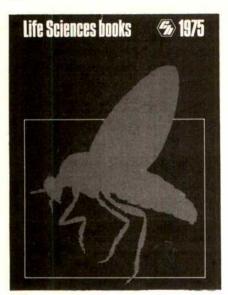
This introductory matter is strengthened by the succeeding chapter on geomorphic techniques which summarises modern advances. That is followed by a long account, forming nearly one-seventh of the book, on recent tectonic theories and findings, including plate tectonics, mid-oceanic ridges and sea floor spreading. The excellence and detail of this well-illustrated synopsis are not maintained in the next chapter which deals with "surficial geomorphic patterns" and contains *inter alia* a rather elementary account of the atmosphere and of the circulation of the oceans.

The chief superficial landscape systems are discussed. Humid, vegetated environments—the Davisian norm—are given far less textual space than are glaciation and glacial landforms, arid non-vegetated systems or alternating arid–humid environments. Coasts and mountains are treated separately as polygenetic landscapes, the former being the zone of contact between two distinct environments and the latter the areas within which internal uplift conflicts markedly with external erosion.

The closing chapters consider the application of geomorphological techniques to the theoretical reconstruction of ancient buried landscapes, and the nature of the various physical problems associated with alterations of the present day environment. The volume ends with a glossary of basal geomorphological terms which will be useful for beginners, and a comprehensive index that includes reference to the many striking illustrations, about 600 in all.

An attractive and lavish production, with many progressive ideas, this volume is a welcome and worthwhile addition to educational geomorphological literature. It is not easy, however, for a European to assess it with equanimity. The author thinks that Great Britain is "an island near the Gulf Stream" and in his index Europe receives 17 entries against 33 for Ecuador, 31 for Venezuela and 25 for Peru. Such a locational bias can be understood as the text is intended for American colleges; but less understandable are the frequent misuse—for depicting spatial distributions—of Mercator's cylindrical world projection (with each pole exaggerated in length 24,000 times to equal the equator), and the occasional textual error, such as Gibralter, duracrust, mollasse, and cannons (for canons of landscape evolution). Occasionally, too, the language probably becomes rather too-American or too askew to appeal to European taste. Is there arising an Old World–New World linguistic divide? We read that "coastal geomorphic systems . . . exist where the sea embraces the land, lingeringly, and often with what might well pass for passion"; that "the tectonics of plates is a fascinating jigsaw puzzle with many of the nobler attributes of a floating crap game". Whereas the pundits of the Oxford Press seem ignorant of the evils of Mercator, they are obviously experts at crap. **Robert P. Beckinsale**

Borers, foulers, sprats, and mangroves

The Biology of Estuaries and Coastal Waters. By E. J. Perkins. Pp. ix + 678. (Academic: London and New York, 1974.) £14.60; $37.35.


PERKINS' attempt to review comprehensively the biology of estuaries and coastal waters has resulted in a large book. The first fifth is introductory and covers the basic physico-chemical and dynamic characteristics of inshore waters; but the treatment is terse and fragmentary. No reader is likely to benefit from such short sections on tides and waves; and the hydrography of estuaries—so fundamental to what follows—surely merits thorough treatment.

The biota of the various habitats are described in the middle portion of the book, and environmental factors which limit distributions and/or vital activities are discussed. Microorganisms, plants and animals are covered, so most readers will find new information here. There are inconsistencies in approach: discussion is limited largely to estuarine plankton although rocky shores are mainly non-estuarine. And it seems a pity that the ecologically significant differences in the timing of primary production cycles in oceanic and neritic water masses could not have been mentioned. Rocky shore zonation is introduced principally by reference to one British locality but, as coverage (here and throughout the book) is by no means confined to the British Isles, a generalised Stephensonian scheme would have been more appropriate: the pages on Australian zone-formers may then have integrated better. The superficial approach can be appreciated when it is considered that, although sedimentary beach biota include salt marshes and mangroves the description of this group is restricted to 15 pages.

Even so, the author's interest in the interactions between man and the coastal environment is apparent, and that theme at least is expanded. The detrimental activities of borers and foulers are covered, as is the production of those organisms which man uses for food. Shellfish, except for tropical prawns, are treated fairly fully; but fish, as elsewhere in the book, receive scant attention. Thus the sprat, with an annual catch of up to 100,000 tons in the estuaries and embayments of the North Sea, gets only an incidental mention, and the importance of estuaries as herring and sprat nursery areas is omitted.

The chapter on pollution is somewhat philosophical, but waste disposal and management are both discussed. Prominence is given to the high standards laid down by the United States Federal Water Quality Administration, which contrast with the low standards (except for radioactive waste disposal) acceptable in the UK.

By opting for breadth the author opens himself to criticism for the brevity with which many topics are treated, especially in those fields in

which he seems not entirely at home. But the compilation is impressive and uses a vast literature. Unfortunately, though, the bibliography is presented chapter by chapter in the sequence in which they are mentioned, so the location of references is an exasperating business. Mistakes and typographical errors are few and the book is well produced; but the price is far beyond the means of many of those who would wish to buy it.   **J. S. Ryland**

Life

Life—The Unfinished Experiment. By S. E. Luria. Pp. 167. (Scribner's Sons: New York, June 1973.) $7.95.

SALVADOR LURIA is well known for his work in virology and molecular genetics. In 1969 he shared the Nobel Prize in Physiology with Delbrück and Hershey. His aim in the present book is to explain modern biology and its social relevance to the general reader.

The scope of Luria's book is superficially the same as Monod's *Chance and Necessity* but there are significant differences. The scientific parts of *Chance and Necessity* were too advanced for the general reader. Luria has attempted a more elementary account. He also deals less with metaphysical issues than Monod, and his social and ethical views are differently slanted. I believe that Luria has succeeded in producing a valuable and readable book, and that it could be usefully incorporated into science courses in schools and generalist courses in universities; and that it would be of interest to laymen and to some professional biosciences.

Luria emphasises molecular aspects of biology, but not to the exclusion of organismic aspects. He builds up a masterly picture of biology, bringing out key concepts in lively, non-technical ways. Starting with an introduction to evolution theory, he goes on to genes, cells, bioenergetics, form and function in higher organisms, and biogenesis. He concludes by discussing social and philosophical issues connected with biology. All this he compresses into only 150 pages, without losing readability, by pruning out unnecessary detail and dealing only briefly with many of his points. Those with little previous biological knowledge will need supervision or complementary reading to appreciate the more subtle points. An apposite reading list is appended to the text.

Luria's underlying theme is "the dualism of the material nature of life's programme on the one hand and the historical nature of biological evolution on the other hand". In his chapter on evolution theory he first discusses the impact the theory has had on man's image of himself and of nature, and

then goes on to consider the scope and limitations of the theory. He emphasises the mutual interaction of individual and environment, and accepts the 'genetic assimilation' view that selection acts on phenotypes rather than on genotypes. In his chapters on heredity, he introduces the subject in a striking way by comparing modern genetics to the great generalisations of physics. At the same time, he points out the uniquely high degree of order in biological phenomena and its historically-derived nature. In each of the succeeding chapters, he also presents the subjects in stimulating and illuminating ways. He does not try to gloss over difficulties and uncertainties.

In the penultimate chapter, Luria discusses issues of medicine, population and genetic engineering. He considers the humane regulation of population growth to be of overriding importance, but recognises the great social and political problems involved. He discusses possible biological consequences of population control and maintains that eugenics programmes (apart from those meant to reduce serious genetic disorders) should be avoided for both social and biological reasons. Though recognising the great technical obstacles to direct genetic intervention in man (such as genetic engineering and cloning), he considers that "in science, once a task has been clearly defined, its accomplishment is generally only a matter of time", and that some genetic intervention may be in medical use within 30 years. And he explores the social and ethical problems that this would raise in our "competitive, caste-ridden, power-dominated society"

In the final chapter, Luria gives a stimulating glimpse into some philosophical issues relating to biology, such as language and brain structure, nativism and learning, biological and cultural evolution, determinism and free will, values, and existential dilemmas. He emphasises the uniqueness of every human individual. He locates the central dilemma of life science as the relations of human purpose, values and will to the fortuitous nature of the evolutionary process. He considers the human brain to have arisen through a process in which "evolution has dialectically surpassed and denied its own past history". Inevitably, various controversial points arise. Among these, I believe that Luria's treatment of existential problems in terms of natural selection is weak; and I would like to see the physicalist position—which he presupposed throughout—explicated and examined in relation to possible counter-evidence (from, for example, parapsychology). In spite of such criticism, my impression is of a well balanced, humanly sensitive, and penetrating world-view.   **Robin Monro**

obituary

Roderick O Redman, FRS, a leading British optical astronomer, has died at the age of 69

Professor Redman studied mathematics at St John's, Cambridge, gaining his Ph D in 1929 At Cambridge, he was greatly influenced by Sir Arthur Eddington, Plumian Professor of Astronomy, and took up his first appointment with the Dominion Astrophysical Observatory at Victoria, British Columbia He returned to the Cambridge Observatory in 1931 to become its Assistant Director and was elected a fellow of St John's in 1932 In 1937, he became Chief Assistant at the Radcliffe Observatory in Pretoria, South Africa, where he started his researches on astronomical photometry While in South Africa, he made an expedition to the total solar eclipse of 1940, from which he obtained high dispersion chromospheric spectra superior to those obtained previously Returning to Cambridge in 1947 as Professor of Astrophysics, he fully integrated the Solar Physics Observatory into a new unit, called the Cambridge Observatories Under his direction, they rapidly recovered from the difficulties of the war years His enthusiasm and warmth were his major assets in re-equipping the observatory with good modern instruments Redman led an equally successful expedition to Khartum in 1952 and served as President of the Royal Astronomical Society from 1959–61 Much of his time before and after his retirement was devoted to the planning and construction of the 150 inch Anglo-Australian Telescope and the success of this instrument owes much to his enthusiasm After his retirement, he also took part in the planning of the Northern Hemisphere Observatory

Anatolii Arkad'evich Blagonravov, academician and one of the leading figures in the Soviet space programme, died on February 4 at the age of 90

Blagonravov, a Lieutenant-General of Artillery, and a full Member of the Academy of Sciences of the USSR since 1953, became attached to the Soviet space programme during the 1950s as a rocket designer In 1959, he addressed the press conference held in connection with the launching of Sputnik 1 From 1960 onwards, he published a number of works on space research, including *Physics of Cosmic Space* (1962) He was an early member of the Pugwash movement, Deputy Representative of the Soviet Union at the UN Committee for the Peaceful Use of Space, and Chairman of the Commission of the Academy of Sciences of the USSR on Space Research and Utilisation He was a full member of the Czechoslovak Academy of Sciences, and a Member of the International Academy of Astronautics, and held a number of Soviet medals and awards, including the Order of Lenin (five times), the Order of the Red Banner of Labour (three times) and Hero of Socialist Labour

Clarence Ray Carpenter, the psychologist and anthropologist, died in Athens, Georgia, on March 1 at the age of 69

Dr Carpenter studied monkeys and apes for the clues they gave to human behaviour and began his studies on the social life of monkeys in Central America in the 1930s In 1937, he was a leader of the Asiatic Primate Expedition to Thailand and Sumatra, and studied gibbons in Siam from the point of view of the evolutionary background of human society In 1939, he travelled from India with 500 macaques that he resettled on Santiago Island, off the east coast of Puerto Rico, observing them set up home In 1960, Dr Carpenter took a census of the howler monkeys of Barro Colorado Island, Canal Zone, hoping that a study of their ways would serve as a conceptual bridge between the realms of lower animals and man From 1940–69, he was on the staff of Pennsylvania State University and became emeritus professor of psychology and anthropology, directing the use of closed-circuit television for educational purposes there As a leader in promoting educational film and television techniques, he served on the Commission on Instructional Technology and on the Advisory Committee of the US Office of Education, and was a past-president of the Joint Council of Educational Communications and the Association for Higher Education Dr Carpenter was a former editor of *Behaviour* and of the *Journal of Evolution*

announcements

Awards

Her Majesty the Queen has approved the grant of a **Royal Charter** to the **Institution of Metallurgists** at a meeting of the Privy Council **Dr W. E. Duckworth** will be succeeded in May as president by **Sir Montague Finniston, FRS.**

The Zoological Society of London has made the following awards **Scientific Medal** to **P F. Baker** (ionic transport across cell membranes) and **H. Kruuk** (behaviour and ecology of gulls and carnivores), **Stamford Raffles Award** to **A. E. Ellis** (study of molluscs), **T. H Huxley Award** to **I G. Priede** (circulation during swimming in trout), **Silver Medal** to **E. Hosking** (animal photography and educational zoology), **Frink Medal** to **J. Z. Young, FRS** (original contributions to wider implications of Zoology)

A. R Ubbelohde, CBE, FRS, has been awarded the **George Skakol Memorial Award** by the American Carbon Society for contributions to the understanding of the intercalation of graphite by elements and compounds, and of the electrical and thermal properties of graphite

The Society for Analytical Chemistry has awarded its **Gold Medal** to **R. L. Mitchell** for contributions to emission spectroscopy for trace elements

International meetings

nature

Concentrate on fundamentals

"WE are here today", said Mr Ian Lloyd as he opened the Science Sub-Committee hearings on the needs of scientific research in British Universities, "to look into the funding of scientific research from all sources, public and private The University Grants Committee, the Research Councils, charities and foundations—we shall investigate the distribution of funding amongst them We shall also look at the relation of research to teaching, and the implication of changes in funding on research " To hear the six witnesses, there were three MPs, four pressmen and one member of the general public Hardly an auspicious beginning to a penetrating survey

On display were representatives from two of the newer and more technologically-oriented universities—City and Brunel It was difficult to discern any very clear threads from their presentations There was a certain amount of special pleading for things like tenured technicians, more travel money and less accounting duties, but the array of professors lost a major opportunity to put sharply in focus the plight of universities Instead they indulged in a rambling dialogue in which important points were left unmentioned or given inadequate emphasis Out of it all emerged a picture of two universities whose professors have slight chips on their shoulders about status and have a general desire to do something about the Science Research Council, but no very clear idea what they would do

The most worrying impression left was that whilst the educational system faced crisis and some departments are denuded of students, there is no serious thought given to a strategy for universities or any well marked-out policy options which are being discussed in common-rooms If universities themselves cannot present compelling evidence that they are thinking carefully about policy, they must expect that policy will be decided for them

The primary need of scientific research is a continuous flow of highly intelligent manpower, and it is to this problem that the committee should pay greatest attention, for if the numbers coming into science at the undergraduate level continue to decline, then the *raison d'être* for many university staff disappears and any call for new facilities and equipment or even for the long-term financial commitments that every Vice-Chancellor dreams of landing is bound to be muted Unfortunately, few in the university environment have yet come up with much original thinking either on how to reverse the decline or what to do if the decline proves irreversible There are, of course, various crumbs of comfort, up to the present the loss in recruitment has been mainly of the less qualified, and up to the present it has been possible to fill classes up with overseas students But both of these situations could change within a year or two for the worse

Although a City representative did touch on the "disastrous shortfall" in native-born applicants for graduate studentships, he did not pursue any line of thought on reasons why or remedies considered—nor, one suspects, will many of those who come to give evidence It is unthinkable that a business which saw a steady decline in demand for its services would not go to great lengths to learn about the trend and try to respond to it, the committee would do well to ask some plain questions of future witnesses on their understanding of the decline in recruitment to science—maybe to the extent of asking whether the trend towards producing 44 equal universities (and even moving the polytechnics up to a level footing) is an intelligent response to a situation in which the science departments of half these universities are gasping for students

Future witnesses might also be at some pains to spell out their views on the purpose of a university Not unnaturally, in times like these the committee is pursuing rather doggedly the question of science in the national interest and the need for better industry/university links Science for the country is a particularly tricky issue and needs some careful prior thought If the laboratories really are full of overseas students, and if the international corporation, capable of exporting technology at will, increasingly dominates science-based industry, then talk of national interest is bound to become of diminishing relevance

Certainly the international context of science—even the European dimension—is a difficult idea to get through to politicians who obviously want to see returns for taxpayers' money And yet to fail to make the broader scene clear would be to run the risk that university science departments be forced to pay too much attention to presumed national needs—and too little to the advancement of learning □

international news

CONTINUING its investigation of the way in which energy is being conserved in the UK, and at the same time reinforcing its disbelief at what it sees as a "surfeit of inconclusive thinking" on the part of the government, the Energy Resources Subcommittee of the Select Committee on Science and Technology last week turned to the chemical industry, represented by three members of the Chemical Industries Association (CIA) Limited

The subcommittee was clearly anxious to hear firm advice from the CIA about what sort of measures the government should be taking to see that energy is not wasted In the event, what it got were some general comments about price restraint and taxation, but few specific recommendations

The CIA did say, however, that the chemical industry in the UK expects to reduce its energy requirements per unit of output by about 10% by 1980, principally by good energy 'housekeeping'—maintaining a watchful eye on the amount of lighting used, unnecessary leakages of steam, the quality of insulation and lagging, and so on Capital investment also helps, but usually only in situations where the increased cost of energy has made it economically sensible to replace equipment before it is worn out As the association pointed out, although energy costs to the chemical industry have gone up by about 80% between 1973 and 1975, capital costs are not far behind with an increase of some 55%

The CIA emphasised, however, that improvements in chemical manufacturing techniques could make for extensive energy savings Some 4 million MW h of the 19 million MW h of electricity

British energy users' views

by Roger Woodham and Eleanor Lawrence

used by the chemical industry in a year —equivalent to about 460 MW out of 2,200 MW on a continuous basis—goes in the manufacture of chlorine alone, the CIA stated by way of an example, and the efficiency of that process has been increased in recent years by some 5% as metal anodes have come to replace carbon ones Quite a respectable saving of energy

Mr G G Harrison, of ICI, also confirmed the need for courses in energy awareness for people entering and working in the chemical industry

● Following the CIA, the Energy Subcommittee took evidence this week from another massive energy user, the British Steel Corporation (BSC) With an annual total fuel bill of £600 million and a 10% share of Britain's total energy requirements, the steel industry is obviously in a position to affect the government's energy-saving plans considerably

The main burden of BSC's argument was that modernisation of its plant and processes is essential if any further saving in energy consumption is to be made If modernisation could go ahead quickly, the BSC reckoned on reducing the energy costs per tonne of steel produced by 10% by 1978

Unlike many industries where energy costs have previously been only a few percent of total basic costs, British Steel has always been aware of the

possibilities of a more efficient use energy Since 1967 it has made a red tion of 13% in its energy requiremei but the 10% reduction envisaged to 1978 would represent a mi stepped-up effort Asked about possible shortage of qualified fuel eng eers, BSC's Director of Research i Development admitted ruefully that energy crisis and the growing need fuel engineers had meant a mass turnover in BSC's own engineeri force as it was one of the few sourc of trained, experienced fuel engine in the country He envisaged that much more extensive in-house traini scheme would be necessary in t future

A long term possibility for minim ing energy costs for the steel industry to harness the heat-requiring reactio (basically the reduction of iron or directly to the process heat fro nuclear reactors without the inte mediate generation of electricity U fortunately for the steel industry Britain, the only reactor capable reaching the required temperatures around 1,000 °C is the high temper ture reactor, which is not exactly high priority in Britain's nuclear r search programme The Select Commi tee appeared slightly pained to lear that we should have to import this typ of reactor technology from the USA Japan or Germany in about 15–20 yeai when the link-up has been sufficientl developed But as BSC gently pointe out, it was hardly fair to expect commercial reactor to be develope without a market for electricity genera tion This market has now bee cornered by the SGHWR, the Seleç Committee's own choice

IN a further step forward in the British government's efforts to cut defence expenditure from 5 8% of GNP in 1974 to 4 5% in the late 1970s, the Statement on the Defence Estimates, 1975 (Cmnd 5976, HMSO, £1 22) announces more explicitly the targets to be aimed at Previous plans were for expenditure (at 1974 prices) to rise from about £4,000 million for 1975–76 to £4,300 million in 1978–79 and £4,450 million in the 1980s Now the aim is to cut £300 million a year off the budget in the next few years and eventually, in the 1980s, to be paying only £3,790 million for defence

Research and development expendi-

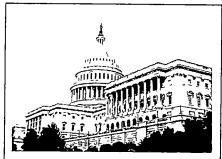
ture is also to be cut fairly heavily Throughout the 1960s the proportion of the defence budget devoted to it declined steadily from 15 5% (1961) to 9% (1970) Since then there has been a steady rise back to 12% and the plans were for it to stay at that figure until 1978–79 and then decline to 10% by the mid-1980s Revised plans call for no substantial change in these percentages, but in absolute terms £440 million (1974 prices) less will be spent in the coming decade on research and development Research accounts for about one-sixth of the expenditure, and of that sixth about one-fifth is called 'general or basic' research One-

third of expenditure on research and development goes to aircraft, another third to guided weapons and electronics 38,000 civilians and 1,500 military personnel work in the research and development field

Part of the cut in expenditure that will be called for should come from the rationalisation process now going ahead in research and development establishments The plans are for four 'systems' establishments for the four environments sea, land, air and underwater, and a number of 'technology' establishments dealing with service-wide requirements such as communications or propulsion

THE final chapter is yet to be written in that 50-year squabble between the Administration and Congress over whether or not the United States should ratify the Geneva Protocol, which prohibits first use in war of chemical weapons Although the Senate voted to ratify the Protocol in December last year and President Ford signed it on January 22, legal doubts about the Administration's interpretation of its terms have delayed the final stage in ratification—the articles have not yet been deposited with the government of France, which means that the United States is still not a formal party to the treaty

The problem, according to sources in the Administration, involves the question of whether or not herbicides and tear gases are covered by the Protocol When President Nixon resubmitted the treaty to the Senate for its approval in 1970, he did so with the understanding that a formal reservation would be written into the ratification, stating that the United States government believes that herbicides and tear gases are not included within the terms of the protocol The Senate Foreign Relations Committee refused to accept that understanding, however, and an impasse developed until late last year, when a compromise was worked out between the Ford Administration and Senator William Fulbright, the chairman of the Foreign Relations Committee It enabled the treaty to be approved unanimously by the Senate

The compromise, in short, allowed the Administration to retain its belief that herbicides and tear gases are not covered by the Protocol, but no formal reservation to that effect would be written into the ratification Instead, President Ford announced that he would issue an executive order setting out a 'national policy' that the United States would never be the first to use those agents in war, except in four minor instances (such as clearing undergrowth around military bases and controlling rioting prisoners of war)


The executive order has, however, never been issued because it is under legal review in the Justice Department, and until that review is completed, the articles will not be deposited with the French government The review was initiated by President Ford's legal counsel, Philip Areeda, because of doubts about the legal status of such a 'national policy' Since the Justice Department has little experience in such international matters, the review is taking considerable time

One Administration official last week described the affair as simply a "bureaucratic snafu" which would soon be resolved He pointed out that the

Japanese government has adopted a similar interpretation of the Protocol, and its ratification of the treaty has not been challenged on legal grounds

Nevertheless, it should be noted that the United Nations adopted a resolution in 1969 stating that the protocol covers use in war of all chemical agents

● Meanwhile, the Department of Defense has, as expected, renewed its

Washington seen
by Colin Norman

request for Congress to provide funds to allow production of binary nerve gas weapons to begin Last year, Congress refused to provide $5 8 million for production of binaries, chiefly on the grounds that if the United States develops a new generation of nerve gas weapons, chemical disarmament talks now taking place in Geneva would be torpedoed Undaunted, however, the Department of Defence is now asking for $8 8 million for binary production

It is considered unlikely that Congress will approve the request, because the arguments raised against binaries last year will be just as strong this year Already, Mr Richard Ottinger, a liberal Democrat from New York, has introduced a resolution barring production of binaries and the campaign against the weapons is likely to be stepped up in the next few weeks

● There are indications that the Food and Drug Administration (FDA) may partially lift its controversial ban on cyclamates in the next year or so If so, the agency will bring down almost as much criticism as it encountered when it abruptly removed the sweetener from the market in 1969, following reports that it causes bladder cancer when fed in high doses to rats

The latest development in the cyclamate saga occurred last month, when the FDA informed Abbott Laboratories, the manufacturer of cyclamates, that it would ask the National Cancer Institute to determine whether or not the sweetener is a carcinogen The move represents a considerable retreat from the FDA's contention, announced in September last year, that insufficient

new data are available to justify reconsidering the ban

According to a letter sent to Abbott by Richard J Ronk, Director of the FDA's Division of Food and Color Additives, the question of whether or not cyclamates are carcinogenic "remains a difficult one to resolve"

Although he noted that some FDA scientists believe that there is sufficient evidence to conclude that cyclamates do cause cancer in rats, Ronk suggested that "it is the apparent opinion of the oncological community of the world that cyclamates when tested in accordance with appropriate protocols are not carcinogenic"

On the day that the letter was sent to Abbott, FDA Administrator Alexander Schmidt asked the National Cancer Institute to set up a panel of cancer specialists "with impeccable credentials" to review the evidence on the carcinogenicity of cyclamates as soon as possible The outcome of the cancer institute's review is crucial because a provision in the food and drug laws, known as the Delaney Amendment, forbids use of any food additive which is found to raise cancer in test animals Unless the review comes up with the conclusion that cyclamates are not carcinogenic, there is therefore no chance that the sweetener will be brought back on the market

But even if the National Cancer Institute gives cyclamates a clean bill of health as far as carcinogenicity is concerned, there are other doubts about the safety of the sweetener The FDA's letter to Abbott notes, for example, that tests have shown that cyclohexylamine—a metabolic product of cyclamates—causes softening of the testes when fed to rats Because of that, the letter hints that if the sweetener is allowed back on the market, the FDA would probably propose regulations to regulate intake to about 0 5 g per day

Although the tone of the FDA's letter seems to indicate that the agency believes that cyclamates are not carcinogenic, a final decision is not likely to be made for at least a year If the agency does lift its ban on cyclamates, a flood of complaints can be anticipated from Congress and from consumer groups, and the FDA is therefore trying to tread cautiously

● Congress has, as expected, rejected President Ford's suggestion that $351 million be cut from this year's budget for the National Institutes of Health Both the House and the Senate have passed bills directing Ford to spend all the money appropriated for this fiscal year—which now has only three months left to run—and so, barring last ditch delaying tactics by the Administration, the money will now be made available

Little progress for Indian education

from Narender K Sehgal, Jullundur

EDUCATION is a subject that has nearly always been topical in independent India—probably because, in spite of all the discussion and debate over it, so very little has been done during the past quarter of a century At present two-thirds of all Indians are illiterate Yet large numbers of the educated, and the highly educated are unemployed, not to mention the multitudes of the uneducated unemployed and those who are underemployed Such anomalies abound there is an acute shortage of doctors in rural India but at the same time not only are thousands of Indian doctors working abroad, there is also widespread unemployment among medical graduates in the country, India badly needs middle-level skilled professionals and other types of trained worker suitable for rural areas—the kind our system is just not turning out It appears that the Indian nation spends countless crores in educating and training individuals who only seem of value in foreign lands

These facts speak volumes about education in India, among other things The system of education—a legacy from the bygone colonial era—has been a constant target for criticism And understandably so, because the present system differs little in content and character from the one the English rulers had devised with a set of aims and objectives of their own—quite different, one would think, from those which might have most suited a free nation

In view of the general situation at the time of independence, the leadership thought it fit to maintain the *status quo* in education, as in many other areas, and to let the drastic changes wait till normality had returned But this turned out to be a blunder, because as time went by those who took charge of education, perhaps incapacitated by their own background and training, did little or nothing to devise a new system or to modify and improve the existing one As the Prime Minister, Shrimati Indira Gandhi, admitted as late as last year "One of the biggest mistakes we made when we gained independence was not to have overhauled thoroughly our educational system and structure We are paying for it now"

All that the government has been able to do in this direction till now is to appoint committees and commissions to go into various aspects of the system and structure of education These bodies have produced tonnes and tonnes of words in the form of voluminous reports which are gathering

dust on shelves in the offices of bureaucrats in the Ministry of Education and elsewhere One would like to believe that, armed with all these investigative and in-depth reports from eminent and learned men, the government would by now be quite clear about what needs to be done and how This, however, is not the case Confusion and uncertainty mark statements made from time to time by those in authority The education policy of the government of India seems to be unclear and lacking in definite direction

The Prime Minister herself has not helped matters by sounding inconsistent in her numerous speeches on the subject, and sometimes at variance with the approach educational planners in her own government would like to adopt On more than one occasion she has explicitly agreed with the widely held view that the present system of education must be drastically changed, or even discarded altogether, as in her own words 'it has little contact with life in the country   It belongs not only to another civilisation, it belongs to another century And we need a minor or even perhaps a major revolution   " On another occasion, not too long ago, she chose to caution educational planners against policies and drastic measures which would cause major 'dislocations' in the existing educational process As recently as February 1, while speaking at the Silver Jubilee celebrations of the National Chemical Laboratory in Poona, the Prime Minister said   "With all the known shortcomings of our educational system and of our organisation of science, the fact remains that India pro-

---

SHEIK Zayed Bin Sultan Nahayam, ruler of Abu Dhabi, has a good line in greenhouses They are soon to cover a 15-acre site in the desert in an attempt to start the first commercial market garden in the Gulf States The greenhouses will be the plastic-dome type and the irrigation supply will be from water reservoirs that have been discovered under the desert by scientists from the French national oil company, CSP

The great problem with desert irrigation is, of course, evaporation This will be overcome by a recently discovered system in which hose pipes, punctured with small holes of calculated size and spacing, are laid out along the rows of plants Water is thereby delivered at the optimum site and rate to minimise waste

And who discovered the irrigation system? According to Israeli scientists it was devised at the Weizmann Institute (where it can be seen on the campus flower beds) Will Sheik Zayed give credit where it's due?

---

duces exceptionally gifted scientists and an impressive number of highly competent scholars "

To cope with mounting unemployment among the educated youth, planners in the Central Advisory Board of Education (CABE) would like to adopt a strategy which stresses the vocational aspects of the educational process This, besides enhancing chances of employment and self-employment through inducements like financial and technical assistance from various governmental and other agencies, will also help ease pressure on enrolment in institutions of higher learning—in line with another CABE proposal which seeks to place drastic restrictions on expansion in higher education Again, Shrimati Gandhi in her Poona speech last month observed "Many student groups come to see me and often argue that our educational system should be given a vocational orientation   But training a person for a job is not the sole or the highest purpose of education, nor is it adequate for the longer run That purpose is to train better human beings who can give more to life and be capable of deriving more from life "

In regard to curbs on expansion in college and university enrolments (which have increased by 800% in the past 20 years), the Prime Minister cautions that it must not in any way result in limiting heightened expectations of those in the backward classes, and that such curbs on expansion of higher education must also be accompanied by concrete steps to bring about a change in the composition of the student population in such a way that weaker sections of society can get their fair share of opportunities

Views expressed by the Prime Minister on a subject are generally looked upon as being indicative of the official line of thinking, if not as statements of official policy So if Shrimati Gandhi's views are looked at in that light, we can look forward only to more of what has been going on for so long—more debate, more committees, more reports and substantive action, if any, so snail-paced that the passage of time will more than nullify its effects

The Prime Minister's warning on 'dislocations' in the existing process of education was unfortunate and really unnecessary For what use was it asking those who hardly move at all to go slow? And again, her linking of the present 'system' to the fact that India produces "exceptionally gifted" individuals was amusing because many Indians are able to achieve what they do in spite of the 'system' and not because of it It may be more relevant and instructive to investigate the number of talented Indians this system helps send into oblivion or nip in the bud each year   □

VERY recently, the first cigarettes at least partly made of substances other than tobacco were launched onto the market—in Germany and Switzerland One brand contains an American substitute, the other a German-made one Imperial Tobacco, which has 65% of the cigarette market in Britain and the largest volume turnover of cigarettes of any company in the EEC, now "hopes that its cigarette, containing its New Smoking Material (NSM) will be on sale to the public within 12 months Imperial (in conjunction with ICI) has spent £6 million on developing this tobacco substitute and a £13-million factory to produce 30 million pounds of it a year is nearly ready at Ardeer, Scotland The project is held up by the deliberations of the Hunter Committee —a body set up in 1973 under Dr R B Hunter to advise the Secretary of State for Health on guidelines for assessing and testing the risk/benefit ratio of the tobacco substitute, it has yet to report, though it gave Imperial the go-ahead for consumer acceptability trials of its product last August

Presumably on the basis of these trials the expected "new-smoke" (to use an Orwellian term for an Orwellian concept) is not likely to contain more than 20% of NSM—the rest will be standard cigarette tobacco I have smoked a cigarette made entirely from NSM and quite see the point It is supremely non-addictive In fact it resembles nothing so much as lighting the wrong end of a filter-tipped cigarette—which is perhaps not too hard to understand since filters are made of cellulose and so is NSM with the difference that NSM is toasted to reduce the

---

Nosmoke without fire

from Angela Croome

---

water content and give it a nice dark tobacco colour The brands launched elsewhere in Europe are much the same —it seems there is no substitute for wood—and one of the German lines has the appealing name "Nosmoke"

But with 80% tobacco, "no-smoke" it isn't Nor, one hazards, would a cigarette without nicotine satisfy the complex needs that a cigarette smoker seeks Curiously the massive research that Imperial has put into improving the smoking (including medical) characteristics of their cigarettes does not at present include measuring the nicotine level Tar and nicotine delivery are lumped together, and come out at 28 30 micrograms per cigarette as against only 7 micrograms for a cigarette consisting solely of NSM But Imperial's philosophy is explicitly that it is the tar that counts, and refers to the classical mouse-skin painting tests The company claims that not only is there less tar from NSM but that it is a different tar It is something that toxicology tests on NSM are being run by the independent laboratory with the greatest experience in toxicological testing, the Huntingdon Research Centre, and that screening there includes possible teratogenic effects It would be even more comforting to know that the Hunter Committee was going to recommend measures and standards of carbon monoxide delivery, implicated in heart disease which smoking is considered to accelerate—and that the committee was going to publish its report which it has no obligation to do

We are assured that NSM or "No-smoke" or any other semi-substitute cigarette will not be cheaper—"the Government cannot afford it", nor of course can the cigarette companies So the new-smokes must be sold on the "better for you" argument which on the evidence so far is specious Also one understands that cellulose from wood pulp (the nearest to a specific description of the new smoking material one can get) is cheaper than tobacco There is no prize for guessing who is going to be better off if the cigarette-smoking public can be persuaded to switch

---

IT'S very exceptional indeed in the Netherlands that an essentially scientific dispute ends with people dragging each other into the courts Yet this is what happened when two Groningen archaeologists, Drs H Tj Waterbolk and D Stapert, accused a highly esteemed amateur, Tjerk Vermaning, of showing and selling fake Stone Age artefacts

Vermaning, a 46-year-old mowing machine repairer who has been living on an archaeology grant for several years, replied that one does not readily imitate (for example) a few hundred stone axes, that his accusers are of no scientific standing anyway, that he wants some "real archaeologists" to look into the question, and that he will sue Stapert and Waterbolk for libel

After being under arrest for two days, Vermaning was released

The whole affair seems to be the dead-end of a continuing story of trouble-laden cooperation of amateur and scientist Some ten years ago Vermaning gained national renown and became a local hero by digging up the remains of a Neanderthal camp site with several hundred artefacts in it, among which were various types of fist axes and a number of splinters The Groningen archaeologists could even restore some of the original firestone cnolls, from which Neanderthal man

---

Neanderthal axes to grind

from Arie de Kool, Rotterdam

---

had chipped his tools

Vermaning was very proud of his finds and expected rewards—not just the few hundred pounds that were paid for the stones, but an honorary doctorate and a staff appointment at the institute The university did not grant this to the astonishingly little educated man (three winters of elementary school, in summertime he had to help his parents), but they thought his talents sufficiently important to give him financial support Altogether this amounted to some £20,000 over several years

Vermaning decided, however, that this was not the recognition he was entitled to and he he refused to co-operate further—after he had found a new site, again containing several hundred pieces

Suspicions began to to grow, said Dr Stapert, when on a site where Vermaning had found more than 400 pieces, the archaeologists were not able to uncover one single chip more Vermaning uses this as an argument that the professional people are just not as com-

petent as he, but Stapert began to think that the 400-odd pieces that Vermaning found were just those he might have buried a short while before

His suspicion was greatly enhanced when he found what he thought to be traces of machining on two of the artefacts, and he became certain when he discovered that the typical shiny surfaces, supposed to be caused by weathering, were what he described as an easily removable recent kind of lacquering

He called in the police, accusing Vermaning of fraud—not just scientific but also financial, since he had sold recent imitations as genuine, old artefacts Vermaning was arrested and scientists, police and provincial government called a press conference

But Vermaning asked the police what proof there was in the statements of people who had refused to recognise him for his discoveries, which amounted to many times what they themselves had been able to dig up At the same time he accused the scientists of libel and demanded impartial evidence

In the Netherlands people are wondering who did make the axes, if not Neanderthal man, and also whether it was wise to cause a public rumpus before the matter had been dealt with in court □

UNDETERRED by the Arab boycott, an American firm with a stake in local science-based industry this week announced that it will be increasing its activities in Israel The firm, Miles Laboratories of Elkhart, Indiana, plans to invest an additional £8 million in its Israeli subsidiaries, which produce everything from the company's famous Alka-Seltzer to a broad range of sophisticated c h e m i c a l s for research laboratories

Two of the Miles' ventures in Israel are closely linked with local institutions of higher learning Miles-Yeda, located next to the Weizmann Institute in Rehovot, makes research chemicals based on Institute know-how These include lectins, spingolipids, affinity chromotography material, peptides, O^{17} and O^{18} stable isotopic compounds and a considerable number of immunochemicals At Ames-Yissum in Jerusalem, where Hebrew University research is utilised, diagnostic kits for testing the thyroid level in blood are the main product Export sales of these science-based firms last year hit £1 2 million

Miles, a "non-Jewish" company, was not attracted to the country by sentiment but by the chance of making a profit The Israeli Government realises this and does its part to encourage science-based industries by giving them loans and grants, as well as by fostering the establishment of special science-based industrial parks near universities and research centres

The conditions offered are apparently so attractive that many enterprises which could hardly be called science-based try to push their way into these parks In order to ensure that the parks serve the purpose for which they were established, the Ministry of Commerce and Industry announced this week that only enterprises which have ties with nearby academic centres would be allowed into them Those firms already in the parks will only be allowed to expand if they carry on a substantial R & D programme of their own

As elsewhere, orders from the military have played a key role in the development of science-based industry, notably in the electronics field Some achievements in electronics have been publicised, others are still under wraps

Publicity often comes when the firms concerned seek to enter the export market This is probably the reason why Israel Aircraft Industries, which already has multimillion pound overseas sales of rockets and planes to its credit, last week unveiled the Autocommander, a supersonic automatic pilot

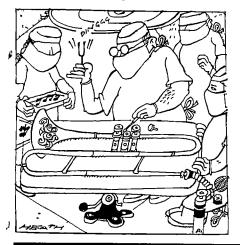
Fully automated, the Autocommander relieves pilots of mechanical flight routine and enables them to concentrate on target pinpointing and other tasks while flying at more than twice the speed of sound It incorporates a reliable and fast-working detection system, including dual circuits, which ensure smooth functioning even if part of the device should fail Now being produced for the Israel Air Force, the Autocommander may become a major export item

● The military situation has also given impetus to research on war-related medical problems, such as that conducted by Professor Arye Weinrab of the Hebrew University and Mr Ezra Loewinger of the Hadassah-Hebrew University Medical Centre on the detection and identification of metal

Letter from Israel
from Nechemia Meyers

splinters which enter deep into the eyeball as a result of accidents or battle injuries Exact information about such splinters is important for surgeons, who must decide whether a delicate and difficult operation on the vitreous body of the eye must be performed

If the metal in the eye is steel, it may be removed by an electromagnet Chips of many other metals, though a source of irritation, can be left in the eye as they do not cause biochemical damage Copper splinters, however, present a special problem Sometimes the fragment of copper becomes encapsulated in the vitreous body of the eye and is rendered at least temporarily harmless On other occasions, the fragment of copper dissolves, releasing copper ions which, if they reach a certain level, can cause metal poisoning and an eventual loss of sight The doctors therefore require some means of keeping a constant watch on the copper level

Weinrab and Loewinger developed a system to detect the presence of metal ions in the eye by means of X-ray fluorescence The radiation is measured by a solid state detector which translates the X-ray energy into electric pulses of varying intensity according to the metal present Before the Yom Kippur War they were doing experiments on rabbits, when the war broke out and soldiers with eye injuries began pouring into Israeli hospitals, the metal detecting test was tried out on them


In many of the cases involving tank crew members, copper was found It came not from the tank itself (which is made of steel), but from the copper sheath near the head of the Russian anti-tank missiles hurled at the tanks The copper melted at the high temperature of detonation, so almost every steel splinter in a tankman's eye was either encased in copper or had copper adhering to it

● The severity of eye injuries during the war has led some of the country's leading ophthamological experts to recommend that all members of armoured and motorised units wear a special plastic shield Such a shield, already used by Israel Air Force pilots, is made of a plastic compound ten times more resistant than glass to high velocity particles It is also light, translucent and does not cloud with water vapour

● This shield will, of course, be of no benefit to men who have already lost their sight in combat, but attention is also being paid to their problems Chemist Avraham Schwartz of the Defence Ministry's Weapons Development Authority, using spinoff from research on plastic materials, has developed a process for printing books for the blind cheaply, quickly and in multiple copies In the new process, typewriters punch tapes similar to those of teleprinters, instead of pressing out the usual Braille reliefs These tapes are mounted on paper, and plastic is poured over them, penetrating the holes The raised dots that result can be printed on both sides of the sheet of paper, which itself serves as a relief plate for reproduction of the "printed" material

● The recently suspended talks between Israel and Egypt prompted several dozen scientists to recall an off-the-record discussion they had had some ten years ago with Henry Kissinger, then visiting Israel as a private citizen It was a discussion with special relevance to the question of how much trust can be placed in US guarantees of an eventual settlement, should one be reached

The conversation occurred at a time when Kissinger was campaigning against the proliferation of nuclear weapons, and so he naturally urged the scientists present to oppose the development of such weapons by Israel When Kissinger's presentation was completed, one of the Israelis put forward a question present in everyone's mind "If," the scientist said, "we were to accept your advice and forego the development of atomic arms in return for an American promise to assist us should we be under threat of attack by a nuclear power, could we be sure that such a promise would be kept?"

After pondering the query for a few moments, the Harvard scholar answered "No, you couldn't be sure American policy is made on an empirical, day-to-day basis It would depend on the circumstances of the situation when the crisis developed " One wonders what kind of an answer Kissinger would give today

Note paper follows?

A member of the physics department at the University of Surrey, Dr John Bowsher, must be working on one of the most unusual projects to be sponsored by the Science Research Council He is to bring the scientific method to bear on the burning problem of why really good trombones sound the way they do All trombones, it would seem, do not sound the same even though they may look indistinguishable, and it is generally the skill of a craftsman who knows just where to change the shape of a given instrument slightly that saves many new instruments from the ignominy of being $\beta+$ rather than α

With the music company Boosey and Hawkes, who produce 300 trombones a week, relying on the skill of just one craftsman in his 50s to suggest a little judicious adjustment in such and such a place, Dr Bowsher seems almost to be working against the clock in his analysis of the 'transient qualities' of trombone notes—namely what goes on in the first and last few milliseconds Fortunately Dr Bowsher and one of his research students are actually trombone players themselves □

correspondence

Czech conditions

SIR,—The discussion in *Nature* on the plight of the Czechoslovak scientists and my participation in it has had very unexpected and grave consequence for me personally

A few days ago I learnt of a decision of the Czech Ministry of Inner Affairs, according to which I have been stripped of my Czech citizenship The motivations for such an extraordinary decision are given as follows

(1) The lecture about human rights I gave at the annual meeting of the German section of Amnesty International in June 1974 in Duisburg (2) My letter to *Nature* (September 20, 1974), which, I have now learnt, had been broadcast in Czech by Rado Free Europe

Needless to say, I protest strongly against this decision, which I consider unlawful and contradicting the Universal Declaration of Human Rights as well as other generally valid and accepted declaration and principles

After being unemployed for more than three years because of my public activity and statements I was allowed to leave Czechoslovakia temporarily in December 1973 When leaving my country I submitted letters to the President of the Czechoslovak Academy of Sciences and to the Ministry of Education, informing them that I was leaving only because I could not find a proper job there, that I would be working abroad as a Czechoslovak scientist and citizen, and that I wished to return home as soon as a job was offered to me

The decision of the Prague authorities provides another strong argument against the opinion that things are being normalized in Czechoslovakia, it shows what is the real situation and the con-ditions Czechoslovak intellectuals have to live in

Yours faithfully,
FRANTISEK JANOUCH
Stockholm

Citation analysis

SIR,—Concluding their recent letter (March 13), Pragier and Ronayne, citing Langrish, state " our results raise serious doubts as to the validity of citation analysis in the determination of the relationship between science and technology "

I suggest that these conclusions have been reached because of a misconception about the scope of citation analysis, and do not, in fact, cast doubts on validity

Langrish examined citations from articles by British industrial chemists, finding that they were largely of non-university origin, whereas Pragier and Ronayne studied citations from biologically oriented articles in *Reports on the progress of applied chemistry*, finding them to be mainly of university origin

From this it may be concluded, as Pragier and Ronayne state, that information was drawn from different sources by these two communities, but this does not mean that such studies are not of value for studying the background of university and industrial science and technology

What it does mean is that such studies are likely to be most useful when applied to a community whose members are characterised by having an interest in a specific aspect of science

If the same pairs, triples, quads , of references are observed in a number of articles, there is an implied consensus of opinion—the authors are perceiving a relationship between the earlier cited articles The heavily co-cited articles form the putative 'core' literature of the subject This technique, originated by H Small, was used to study the literature generated by the scientific community engaged in amorphous (chalcogenide glass) semi-conductor research from 1968 to 1973 Until 1972 the core articles, with one exception, came from universities

In 1972 the core was augmented by articles from non-university sources The cause of this was heavy co-citing of 1972 articles by 1973 authors These authors often used title words indicating that device applications were described in their articles It may be concluded that during this period materials, hitherto of research interest, started to

A hundred years ago

Dingler's Polytech Journal contains an account of researches made by Dr Otto Krause, of Annaberg, on tobacco smoke, which he finds contains constantly a considerable quantity of carbonic oxide The after effects of smoking are said to be principally caused by this poisonous gas, as the smoker never can prevent a part of the smoke from descending to the lungs, and thus the poisoning is unavoidable The author is of opinion that the after effects are all the more energetic, the more inexperienced the smoker is, and he thus explains the unpleasant results of the first attempts at smoking, which are generally ascribed to nicotine alone

from *Nature*, **11**, 456, April 8, 1875

be used in devices having practical applications

Articles identified in this way may be depicted as interconnected elements on a citation map Replotting of the maps periodically enables the growth, decay and changing interrelationships of specialities to be studied It seems likely that this will provide an overview of the ramifications of science for the benefit of science policy makers and others

Great Plains weather

Sir,—A number of authors have pointed out the periodicity or quasi-periodicity of 20 to 22 years in the recurrence of droughts in the Great Plains of North America, the region between the Rocky Mountains and the Mississippi River Perhaps most notable of these droughts was the "Dust Bowl" era in the 1930s which retarded the Great Plains agriculture and economy for a full decade Most authors have also pointed out that the mid-years of the droughts coincide fairly well with every other sunspot minimum, specifically the minimum in which the polarity of the leading spots in the Sun's northern hemisphere is changing from north-seeking to south-seeking

Since we are now approaching another solar minimum of the type mentioned, the question of the reality of the sunspot drought relationship is of great interest The dates of the four most recent solar minima of this kind, and the central year of the four most widespread droughts in the Great Plains, were as follows

Sunspot minima	Mid-years of droughts
1889	1892
1912	1912
1933	1934
1954	1953

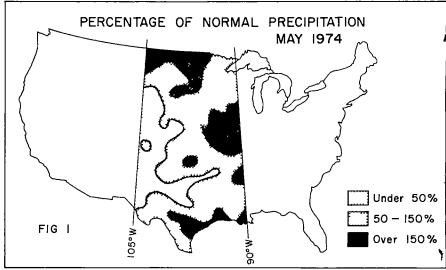
The causes of these droughts are not well understood J R Borchert has pointed out that some of these in the table were associated with greater than normal zonal circulation of the atmosphere, and some with increased meridional flow, evaluated on a hemispheric basis The common element in drought situations seems to be stability in the type of weather pattern, that is, drought tends to be associated with a highly persistent pattern, either meridional or zonal

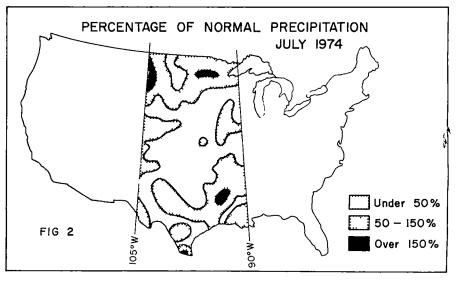
I R Tannehill points out that drought in the Great Plains is associated with higher than normal pressure in the eastern Pacific area, whereas others find that droughts in western Kansas tend to occur simultaneously with positive height anomalies at 700 millibars over the eastern Pacific between latitudes 30° and 40° N and with negative surface temperature anomalies

over the eastern tropical Pacific

In the spring and summer of 1974 there was evidence for the beginning of another drought in the Great Plains If the situation is the same in most of the next several years, we may well conclude that the periodicity of 20 to 22 years is recurring A sunspot minimum of the type mentioned, is expected in, perhaps, 1976

In the spring the drought was confined to the western and southern parts of the Great Plains (Fig 1) Most of the Great Plains region was actually suffering from too much rainfall, with serious delays to the starting of the spring planting in large areas Meteorologically, the region was affected by greater than normal westerly wind flow Thus the drought in the area just east of the Rockies may perhaps best be described as primarily a rain-shadow effect

By mid-June and extending through July (Fig 2), the situation had changed to a more meridional flow, with a stable high pressure cell over the Mississippi Valley in the upper atmosphere This created an extended period of low precipitation and abnormally high surface temperatures just at the time when


certain crops, such as corn and soy beans, were reaching the maturing stage For instance, Grand Island, in central Nebraska, reported no precipitation from June 15 until July 22, the longest rain-free period ever recorded at that station The resulting damage to crops in such states as Iowa, Kansas, Nebraska, Oklahoma and adjoining states approached $10,000 million dollars This loss was caused mainly to the extreme but short summer drought, but also in part by the spring drought in western Oklahoma and northern Texas


A mere coincidence in timing between the droughts and the double sunspot cycle will not, of course, constitute proof of a physical relationship If, however, the drought of the 1970s does materialise, over the next several years, we will have a very strong incentive to search for physical mechanisms to explain the linkage or to provide other reasons for the recurrence

Wider implications of catastrophe theory

from Henry Chilver

THE interesting article you publish today by Thompson on 'experiments in catastrophe' (page 392) prompts me to make a plea for wider study, by both physical and social scientists, of a very important area of 'systems analysis' in which the concepts of catastrophe theory may well have an important part to play It will be evident to anyone who has attempted to 'design' a system—and particularly a complex system—whether this is in the field of engineering, organisation, planning, or in other fields, that modern design has encouraged designers to converge, in their ideas, on optimal systems

The forces at work to encourage designers to converge on optimal solutions are very strong All systems are based on ideas of increasing efficiency in one form or another for example, in his article Thompson demonstrates how the search for the lightest (and therefore most efficient) structural forms leads to potentially catastrophic engineering structures There are other examples in the fields of solids and fluids the breaking of bonds between solid particles leading to the catastrophic failure of materials, the breakdown of smooth flow around bodies, leading to turbulent flow

But there are many other types of systems—of widely different sorts—where catastrophe becomes more critical as design becomes more 'optimal' Many transport systems are highly sophisticated and optimised—and therefore highly sensitive to small perturbations which may lead to collapse or catastrophe One of the most sophisticated transport vehicles—the aeroplane—is itself a highly optimised system its structure is highly efficient and its power in flight is highly sensitive to the reliability of its engines, more optimisation comes into the picture during the operations of the aircraft, and the history of the aeroplane is very sensitive to any perturbations which lead to loss of control and thus to catastrophe, again, this particular mode of transport is highly sensitive to weather conditions, and fog at the airport may mean diversion to other airports, and, thus, to disruption of the system

But social systems themselves are 'planned' and 'designed' for equally critical states one of our present social problems is that we are optimising so strongly the complex interlocking and interdependence of institutions of many sorts that small perturbations of these systems can be catastrophic and lead to complete disruption States of employment (and unemployment) of vital minority groups are clearly very sensitive to small changes of economic parameters, and this suggests we have built highly critical systems of social institutions

Again, in manufacturing industry, the economy of production processes is highly sensitive to the volume of production, to the supply of crucial materials and components, and to the attitudes of small groups of staff For this reason, the present world decline in trade is giving some industrial manufacturing companies serious problems, because their continuing good health is so sensitive to the scale of production In such situations, sensitivity to small changes of the important parameters is wholly undesirable, but how can this be avoided if we are constantly forcing production processes to the extremes of low-cost and efficiency?

As pointed out by Thompson, Zeeman has shown some interesting catastrophe phenomena in natural systems Alternative animal states may be compared with the bifurcating paths of classical stability theory, although in such cases it may be very difficult to give numerate values to the many 'axes' or 'vectors' involved The state of good health of an individual is obviously an optimised condition—the 'design' in this case being reached through evolution and natural selection In the course of evolution, many inadequate optimal states have been weeded out, a possible reason for their being weeded out is that they showed high sensitivity to small perturbations of their systems In spite of this evolutionary process, the state of good health, in some respects, is still highly sensitive to a limited number of parameters, as, for example, to blood temperature and the working of a limited number of vital organs

Some aspects of ecology may well present problems of potential catastrophe The ecological balance in some systems is a delicate one perhaps between tropical forest and desert, or between alternative forms of animal life

In extending the concepts of Thom, Zeeman and Thompson to a wider range of systems one is tempted to look for a common thread between all these problems Following classical stability theory, we may search for 'potential functions' for all such problems, but this is not possible, since many of the common problems do not possess a simple potential function, nor, indeed, can be expected to possess them Another approach would be to construct simple models of these systems and apply general concepts of perturbation in studying their behaviour, this would bring catastrophe theory very close to general control theory

But one feature common to all these problems, and very correctly Thompson emphasises this, is that they are generally optimal systems Many are indeed highly optimal If we try to formulate a general problem it is something on the following lines as we pursue increasing optimisation in the design and planning of systems, how can we determine in simple terms those parameters to which the stability of the whole system is most sensitive? We might then follow this question with another is the degree of instability, or sensitivity to the critical parameters, an acceptable one?

Answers to these questions would be invaluable to designers of systems in many areas The teaching of such concepts as part of the philosophy of design would add a new dimension to our design methodology The ultimate goal in such studies is to determine common patterns between the many different systems we design and build, and in which catastrophe can occur What can be envisaged long-term is not only concepts of how to build optimal systems—indeed our knowledge of this is already very extensive—but how to study their sensitivity to disturbances and perturbations, and thus be able—as designers—to distinguish between highly critical and less critical systems

At the end of the day, of course, catastrophe cannot be avoided, but at least we should have a feel for the sensitivity of any optimal system to catastrophe Thompson's paper is a helpful pointer in this direction how can we encourage others in the same general direction?

Strontium isotopes and crustal evolution

from J Sutton

ONE of the most intriguing problems in geology at the present time is the investigation of the first 2,000 million years of the Earth's history We have now a detailed knowledge of small areas of crust dating from the latter part of the first 1,000 million years of geological time But the remnants of crust formed more than 3,500 million years ago are no more than a few tens of kilometres across at the most and are widely separated from one another

What we badly need is information on large scale activities within the primitive Earth, for this might link our fragmentary scraps of knowledge obtained from the ancient rocks exposed in Minnesota, west Greenland, southern Africa and Antarctica

Moorbath's paper in this issue of *Nature* (page 395) provides just such information, for the strontium isotope studies he reports here and those which Moorbath, Powell and Taylor have reported elsewhere (*J geol Soc Lond*, **131**, 213, 1975) bear directly on the question of the movement of material between crust and mantle in Precambrian times Moorbath reports very low $^{87}Sr/^{86}Sr$ ratios in the crustal rocks he and his colleagues have investigated and deduces that the rocks in question had formed from material which had been transferred to the crust from the mantle shortly before the times when they last crystallised He is in effect employing ^{87}Sr as a natural radioactive tracer to follow the circulation of silicates in Precambrian times This is now a well established technique but Moorbath's application of the method to the very old (roughly 3,700–3,600 Myr) rocks of Greenland and Rhodesia has produced results of

great importance for our understanding of the early Precambrian

The use of strontium isotopes in this way is in itself a fascinating concept Since the time the Solar System formed, ^{87}Sr has increased in abundance as ^{87}Rb breaks down, the rate of increase in any rock being governed by the amount of rubidium present The distribution of strontium isotopes through the Earth is therefore influenced by the manner in which rubidium and strontium are associated in rocks Since rubidium can be admitted to K^+ sites in the main rock-forming potassium-bearing minerals it is widely distributed as a trace element in the potassium-rich granitic rocks abundant in the upper crust but is much less abundant in the potassium-poor basic and ultrabasic rocks of the lower crust and mantle Study of the ratio $^{87}Sr/^{86}Sr$ can provide critical information as to the origin of an igneous rock A melt derived from the mantle will be marked by relatively low initial ratios of $^{87}Sr/^{86}Sr$ (0 699 from 4,600 million years ago to about 0 704 at the present day) In contrast in continental crust rubidium-rich granite can accumulate ^{87}Sr much more rapidly as the figures illustrating Moorbath's article indicate Accordingly a melt derived from granites which have resided for long periods of geological time in the crust may inherit this high ratio as an initial feature and so be distinguished from rock derived directly from the mantle Moorbath has been able to show that the initial $^{87}Sr/^{86}Sr$ ratios of the 3,700–3,600 million years old Greenland and Rhodesian rocks are so low as to suggest derivation directly from the mantle of those times He has also

found, as have earlier investigators of rocks formed rather later in the Precambrian, that rocks developed between 2,800 and 2,500 million years ago are marked by low $^{87}Sr/^{86}Sr$ ratios These are close to, or at most a little above, values expected of the mantle at that stage in the Earth's history

Moorbath concludes that these younger Precambrian rocks, some of which come from Scotland and Greenland, could not have been derived, as has been suggested, by the reworking of very much older granitic crustal rock such as the 3,700 million year old examples of west Greenland Moorbath follows Hurley in concluding that these facts indicate a progressive addition of mantle material to the crust He points out in the concluding paragraphs of his article that such transfers of material from mantle to crust seem to have been especially active at certain periods of time during geological history Some of these periods, it may be noted, coincide with the abrupt changes in continental movement indicated by the hairpins in the apparent polar wander paths established by palaeomagnetic investigations

One question raised by Moorbath's work with its additional evidence for a near identity of crustal and probable mantle $^{87}Sr/^{86}Sr$ ratios through early Precambrian time is of particular interest Do these results indicate, as Armstrong has proposed, that matter was exchanged more effectively between mantle and crust during the first 2,000 million years? Perhaps at that time no extensive portions of the crust remained isolated for sufficiently long to establish $^{87}Sr/^{86}Sr$ ratios significantly higher than those of the mantle

What came out of Kohoutek's comet?

from J F James

A YEAR and a quarter have now passed since Kohoutek's comet passed perihelion with awful anticlimax and if we have learned nothing else, we are now warned once again of the danger of letting empiricism masquerade as science With the nine months' warning of its approach there was ample time for elaborate international co-operation to be arranged and in spite of the disappointment of the amateurs and the disillusionment of the public the professional astronomers received it with a great broadside of astronomical equipment and studied it more comprehensively than any previous comet

Many of the more important obser-

vations have been reported in the December 1974 issue of *Icarus* (**23**, No 4), which was especially dedicated to the comet, and the editors have promised more later on

The discovery was made by Dr Lubos Kohoutek on March 21, 1973 and from three positions, one from a pre-discovery plate, Dr Brian Marsden published a preliminary orbit on March 26 (IAU Bulletin no 2514) From its position and magnitude at the time of discovery and from an empirical formula used to predict the future brightness of comets, it was concluded by some astronomers that it would be very bright indeed at perihelion and would become even brighter later on

as the tail developed In fact it did get to magnitude −2 3 at perihelion and was observed at the time by the crew of Skylab IV, 200 miles above ground It was of course invisible at ground level because of the glare of sunlight

Curiously there was no elaborate series of observations from Skylab IV and the observers there used the archaic method of making drawings of the appearance of the comet These drawings were sent down to Earth by television link Skylab's crew were the first to observe the tail of the comet and also found the 'anti-tail', a sunward-pointing spike like that of the Arend–Roland comet of 1956 As the

comet drew away from the sun after perihelion passage this spike became less intense, and was only very faintly visible to photographers in mid-January, the time when the comet was most favourably placed for ground-based observations By then the spike was much attenuated and more like a fan The spike is thought to be part of the dust-tail of the comet, comprising particles travelling in a different direction from, but in the same line of sight as the head The dynamics of these spikes are well understood following the theoretical analysis of Finson and Probstein some years ago, in *The Astrophysical Journal*

More remarkably, the Skylab observers noted that the tail near perihelion was bright yellow It is hard to see how this could be anything other than resonance scattering of sunlight by sodium vapour and the fact that it was bright enough to be seen by the colour-sensitive cells in the retina bears witness to the comet's magnitude at perihelion

The comet failed to develop a marked dust tail after perihelion passage and this was the cause of all the disappointment Observers below 40° latitude who knew where to look and what to look for could just see the comet with the naked eye It was an easy object in 7×50 night glasses, but never spectacular This did not stop a NASA team (Hyder, Brandt and Roosen) from taking some very fine detailed photographs showing structure in the tail and showing the separation of the dust and gas components

The chief investigation seems to have been, by common consent, the search for molecules and the analysis of dust in the tail The central problem—the nature of the head—was not attacked directly, chiefly because the comet was never close enough for any object smaller than about 500 Km across to be resolved In any case, this is not a problem likely to be solved by anything less than a comet interception probe—a spacecraft designed to 'fly by' at a close distance from the head or even to collide with whatever is at the centre of the head (This is something that will be well worth doing when a comet comes close enough and enough warning is given to make it feasible) Thus the contest between the two theories of the nature of the head, the 'dusty snowball' and the 'dense cloud of dust' is no nearer a decision, but the dusty snowball model, the current favourite, received a knock when Traub and Carleton of the Smithsonian Institution searched for and failed to find either water vapour or methane, the chief materials likely to form the 'snow' of the snowball

Various people found and measured the familiar cometary molecules, such as C_2, CHOH and CN and new tech-

niques were used for some of these observations For example, Blamont and Festou of CNRS observed OH by resonance scattering, in the infrared, of the lowest electronic transition band of this molecule and HCN was detected by its radio emission in the 3 mm band by a group from Los Alamos, Boulder and Green Bank More complicated molecules were also observed For instance, Ulrich and Conklin reported radio emission from methyl cyanide (*Nature,* **248,** 121), and other groups made searches at radio wavelengths Atoms too were identified by their spectra, sodium and hydrogen being measured by a group from Bell Laboratories and Earlham College, who simultaneously searched for and did not find any trace of helium Hydrogen emission at Lyman-α (1215 6 Å) was used to photograph the head, both from Skylab and from a rocket-borne camera This is the brightest of all resonance lines, and showed an enormous halo of about 4° diameter, strongly condensed towards the head of the comet It was possible to measure the outward velocity of this hydrogen by searching for the moment when its velocity relative to Earth was zero and the light, not shifted by Doppler effect for the moment, was absorbed by the hydrogen in Earth's geocorona This outward velocity was lower than expected, sufficiently to indicate that the hydrogen was the product of OH dissociation rather than H_2O dissociation

The dust emitted by the comet received its share of attention but produced nothing startlingly new E P Ney of the University of Minnesota saw once again the 'silicate bump' in the infrared emission spectrum of the dust In the 8–13 μm 'window' in the Earth's atmosphere the radiation received from the dust is predominantly its own thermal emission rather than scattered sunlight The black-body curve is followed except near 10 μm where there is an excess of intensity This has been found in the laboratory to be characteristic of metallic silicates, and has been observed in interstellar dust grains as well as in comet tails Curiously the bump is missing in the spectrum of the anti-tail of Kohoutek's comet

To sum up although the public was disappointed the astronomers were not, and if the comet was unremarkable, this was in great contrast to the number of novel and powerful techniques that were used to study it As in all good investigations, more questions have been raised than answered, and what we all pray for now is a modest comet passing close to earth with plenty of advance warning Then we might really know what comets are made of and what comes out of them

Trying to smooth background radiation

from A C Fabian

THE two main handles that we have on background radiations are provided by measurements of spectrum and isotropy Data on these have been well marshalled by students of the microwave background to show that the Universe has passed through some hot, early phase The other major background radiation occurs at X-ray frequencies, and its origin is still unknown, although it is reasonable to suppose that most of it is extragalactic and originates at cosmological distances One problem in interpreting observations of small angular scale (about 5°) fluctuations in the X-ray background stems from the point that these fluctuations arise from those sources just not resolved A glance at the *Uhuru* catalogue of X-ray sources and recent literature shows that a growing number (~30) of extragalactic objects such as clusters of galaxies, radio galaxies and QSOs are detectable by their X-ray emission This means that the more distant and weaker members will contribute to the fluctuations, and indeed most of the fluctuations will be due to those sources having intensities such that there is about one per detector beam in the sky They need not necessarily be at cosmological distances, and so the fluctuations may not directly assist in the quest for the source of the X-ray background

It has been suggested that the fluctuations observed with *Uhuru* are less than would be expected from the counts of sources already detected This can then be used to suggest that some of the as yet unidentified X-ray sources are really at cosmological distances and that perhaps we are seeing to the edge of the Universe Other possible interpretations include consideration of the distribution of the sources in the sky, for they may form some crude lattice or at least anti-clump This means that the formation of one source may inhibit the formation of any other sources nearby

D A Schwartz of the Center for Astrophysics, Cambridge, Massachusetts has posed the question "Can the constraint of finite mass smooth fluctuations in the background radiation?" (*Astrophysical Journal,* **194,** L139, 1974) The idea here is that the Universe may be considered composed of volume elements each containing an exactly equal finite amount of mass This mass is then divided between all known objects including X-ray sources At the extreme, if all the mass goes into X-ray sources the sky must take on a roughly lattice structure and even

if non-X-ray matter is allowed some constraint is still placed upon the X-ray source distribution Schwartz notes an analogy with the Fano effect, which applies to the number of ion pairs produced by a fast particle in a detector chamber The distribution of the number of ion pairs is tighter than the Poisson distribution often applied to such problems He has taken the formulae for this effect over to his work and attempts to show that smoothing is possible and believes that it is not unreasonable that a factor of two smoothing should emerge No assumptions are made about the distances to sources and it appears that the principle is to be taken quite generally

What Schwartz has not done is demonstrate that his approach is consistent and that he is justified in using a method from a different branch of physics Consider a Universe consisting of constant mass elements of some fixed scale size, within which any dispersion of the number of X-ray sources is restricted in some way Each volume element contains one or more sources but an X-ray detector will observe fluctuations which will be dominated by the distance from the observer where there is about one source per beam The beam will therefore only observe a small portion of a volume element at one given time, so it matters whereabouts in that element the sources are situated If they are all in one corner, very large fluctuations will result! The Fano effect does not translate directly to this problem, since the positions of the ion pairs in a detector chamber is irrelevant

We can conclude therefore that the finite mass constraint does not smooth background radiations to the extent suggested by Schwartz If the real situation is compared with the artificial one just discussed, it is hard to see that any significant reduction will result at all

Predators' good housekeeping

from our Animal Ecology Correspondent

PREDATORS, in their concern to maintain a supply of food, rarely eat more than a small proportion of the population of their principal prey Kruuk and Turner (*Mammalia, 31*, 1, 1967), for example, calculated that lions consumed annually no more than 3% of the wildebeest stocks—their main prey —in the Serengeti If this did not supply enough food, alternative sources were tapped Similarly Pearson was able to show that feral domestic cats exerted a powerful pressure on declining rodent populations but switched to alternative

prey when these became too scarce (*J Anim Ecol*, 35, 217, 1966)

For large predators, such as lions and cats, a switch to alternative prey may be far easier than for small predators which are specifically adapted for feeding on a restricted size range of prey Brown and Lasiewski have drawn attention to the problems facing weasels in northern tundra regions (*Ecology*, 53, 939, 1972) Males and females, being of markedly different sizes, exploit different feeding niches and thus function much like two separate species of small predators Perhaps this size dimorphism makes existence possible in these conditions, or at least permits higher populations Iverson has pointed out that weasels have a metabolic rate between two and three times higher than that of other mustelids, and a food requirement to match (*J cell comp Physiol*, 81, 341, 1972) The ecological implications of an inability to switch to alternative prey coupled with an unusually high food demand are twofold First, weasels might be expected to be highly territorial with each territory containing sufficient amounts of the correct prey species, and second, they might be expected rapidly to decrease breeding when food becomes too scarce in order to conserve stocks

Erlinge of Lund has recently published some interesting data on territoriality and population size of the weasel in relation to prey abundance (*Oikos*, 25, 308, 1974) His study area was 80 ha of spruce plantation, both young and old, deciduous woodland and replanted clearings Various stone walls and dense cover throughout rendered the whole area a most favourable weasel habitat Weasels were trapped and marked by ear-clipping during two autumns and one summer The very high number of recaptures revealed that in the autumn of 1972 the habitat was divided up between three resident territorial males, two females showing evidence of having suckled young, and six young weasels Three other males visited the area as transients During the winter of 1972–3 the territorial system was much as it had been the autumn before but a rapid turnover in territory ownership was evidenced by only one of the autumn residents being a territory holder the following summer

In the autumn of 1972, most weasels had been caught in the spruce plantation The population of short-tailed voles was then between 30 and 40 per ha By the following summer the vole density dropped to less than 10 per ha with the result that most of the residents left the plantation and settled in the replanted clearing where the rodent population was some 60% higher The emigration of all the females from the

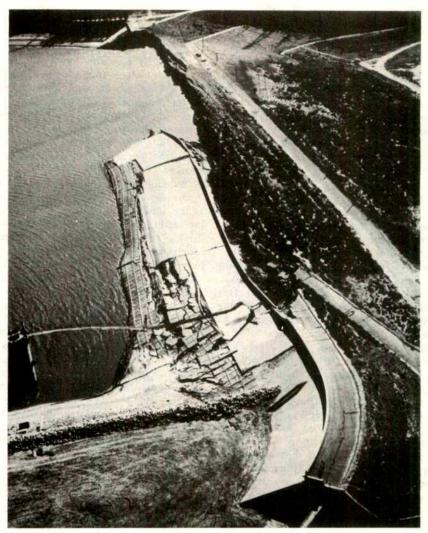
study area later in the summer of 1973 meant that there was no breeding

East and Lockie have made some observations on the food requirements of captive breeding weasels (*Proc zool Soc Lond*, 143, 395, 1964) A pregnant female weasel needs 20–30 g of mouse each day for about 35 days, and during the 21 days of lactation she requires about 60 g each day Once the litter of, say, six young weasels starts eating meat the requirement of food increases over the next 40 days from 69 g to 192 g daily Translation of these figures into rodent densities requires the acceptance of certain assumptions, namely, that each vole weighs 25 g, that breeding female voles produce 0 125 young each day per adult in the population, that a generation time is 45 days and that the sex ratio is equal These assumptions accord well with the many published observations on vole productivity Given them, more than ten reproducing voles are necessary to produce sufficient food for one breeding weasel

It seems that when the prey density in Erlinge's study sank to less than 10 per ha, breeding was inhibited by the emigration of lone females Given that the average territory size of females is about 1 5 ha and of males considerably larger, it is hard to see that the reported rodent densities could not support both sexes especially if there is any differentiation in feeding niches One must conclude that such differentiation is perhaps less clearly defined in rich woodland areas than in the more rigorous northern latitudes Erlinge's data highlight some of the problems faced by highly specialised, small predators, and some of the difficulties encountered by ecologists in interpreting them

Noisy meteors

from David W Hughes

THE sounds associated with bright meteors and fireballs can be divided into two fundamental types—a single or repeated sharp cracking noise and a distinct rumbling, these occurring a few minutes after the passage of the meteoroid—and a second much rarer noise, a hissing sound reported to be heard almost simultaneously with the visual phenomenon


Theories about the origin, and problems associated with measuring the first type of meteor noise are discussed by ReVelle in the February edition of *Sky and Telescope* (49, 87, 1975) He concludes that only fireballs brighter than visual magnitude −8, with kinetic energies of the order of 10^{15} erg can produce sounds These penetrate to the lower levels of the atmosphere where

the air is dense enough to act as a fluid and therefore to sustain organised sound waves. One example quoted is the large fireball seen and heard by Wilson at College, Alaska. The meteor at a range of 300 km produced an airwave signal of maximum amplitude 4.6 dyne cm^{-2} which lasted for 12 s. The radius of the strong shock region surrounding the train was estimated to be about 450 m, the incident meteoroid having an energy of 6×10^{20} erg. Assuming a density of 0.3 g cm^{-3} and a geocentric velocity of 11.2 km s^{-1} the meteoroid had a mass of 9×10^{8} g and a diameter of 13 m.

During atmospheric entry the meteoroid can be travelling at 40 to 250 times the speed of sound. The hypersonic flow of air around the meteoroid produces an effect analogous to the explosion wave produced by a cylindrical line source. As the disturbance propagates outward from the meteor it eventually becomes weak enough to be described as a sound wave. The frequency is, however, usually below the audible limit of the human ear and all that can be detected of this infrasonic wave is a sharp 'crack' as it passes due to the rapid pressure change.

The transmission of the sound wave to ground level depends on the temperature, density and wind profiles of the atmosphere. In general the steeper the angle of entry of the meteoroid the less likely it is for a ground observer to hear the sound. Winds in the 40–60 km region can produce channelling effects enabling the sound to propagate over unusually long distances. Atmospheric damping of the wave energy increases with frequency, which accounts for the low frequency rumbling sound analogous to thunder, heard after the passage of the meteoroid. Meteor sounds have characteristic frequencies from about 0.05 to 5 Hz. In general the more energetic the meteoroid the lower the frequency of the sound wave produced.

ReVelle describes how microbarographs are to be used to detect and measure infrasonic sounds from meteors. These are designed to detect pressure amplitude changes in the range 0.1 to 100 dyne cm^{-2} with frequencies between 10^{-3} and 10 Hz and will be installed in the areas of the North America prairies covered by the meteor cameras of the Smithsonian Astrophysical Observatory and the National Research Council of Canada. From known incident fireball fluxes ReVelle expects to record about 10 meteor sounds per microbarograph station during 6 months of night-time observing. Wind noise is one of the major problems but filtering techniques can reduce this to a tolerable level provided the wind speed is less than

THE upper and lower Van Norman dams, which lie in the northern San Fernando Valley about 32 km north-west of Los Angeles, were built between 1912 and 1921 with hydraulic fill placed on young valley alluvium. During the 1971 San Fernando earthquake (magnitude 6.5) both were badly damaged by slope failures on the reservoir embankments. This US Geological Survey picture shows the lower dam just after the earthquake. The 1971 shock was accompanied by the most intense ground motions ever recorded instrumentally for a natural earthquake. But on the basis of geological and historical studies, R. F. Yerkes of the US Geological Survey estimates that earthquakes with magnitudes of at least 7.7 may be expected in this highly populated area. A magnitude 8+ event on the San Andreas fault about 40 km away could also cause extensive damage in the Van Norman area.

10 m.p.h. The recordings will yield energy-against-frequency characteristics of the sound waves and should provide new clues about the meteoroid ablation processes in the lower atmosphere and the complicated interactions which take place at the meteor train–atmosphere boundary.

The second type of noise, the hissing, swishing, buzzing sound heard at the same time or just before the fireball is seen is much more difficult to explain. Such noises have been termed 'anomalous' because they seem to be transmitted at the speed of light. Romig and Lamar in a detailed study of the phenomenon (*Rand Corporation Memorandum* RM-3724-ARPA) have

ruled out the possibilities that the noises are just imagined by the observer (unconsciously associating the fireball with a skyrocket for example) or just chance coincidences. Many trained observers have heard these anomalous sounds and the report contains many examples of people who heard a whizzing noise, looked up and then saw the fireball.

How can this sound be produced? Two other natural phenomena might provide clues. Lightning leader strokes produce brontophonic sounds heard just before the thunderclap from the return stroke. Also aurorae have been reported to produce hissing sounds. Brontophonic noises are produced by

small coronal discharges from surrounding vegetation but it seems very unlikely that enough free charges could be deposited by the fireball passage to explain the noise. The origin of auroral noise is still a mystery.

Considerable radiation must be produced by the fireball in regions of the electromagnetic spectrum other than the visual and this could provide a possible explanation. Electrophonic sounds for example have been heard by people exposed to beams of low powered radar sets. These have been described as buzzing, clicking, hissing or knocking sounds and seem to depend on the transmitter characteristics. An electromagnetic power density as low as 400 μW cm^{-2} can be heard, but only by people whose audible hearing by air or bone conduction was good above 5,000 Hz. Perhaps radio frequency electromagnetic waves are acting directly on the brain or inner ear. There are distinct similarities between electrophonic noises and anomalous sounds from fireballs but the production mechanisms of both are still unknown.

With luck the bariophonic recorders will pick up examples of anomalous noise as well as the more normal meteor sounds and help solve this problem also. One snag is that anomalous noise seems to be associated with brighter fireballs (average magnitude −13) which are rare objects indeed.

Plate tectonics and general relativity

from Peter J. Smith

THE mechanism responsible for the movement of lithospheric plates over the Earth's surface is a subject of continuing debate. The majority view is that plate tectonic processes are related to convection in the mantle, although there is less agreement about whether convection is the prime mover or a secondary consequence. If the prime mover, convection would be directly responsible for the motion of the overlying plates, and that of ocean floors in particular; but it is also possible to envisage that plates drift for other reasons (for example, by sliding under gravity) and that 'convection' arises from the need to complete the flow patterns at depth. The latter hypothesis bears some resemblance to the minority view of Van Bemmelen (*Tectonophysics*, **1**, 385; 1965) and others, whose 'undation theory' proposes that selective high radioactive heating in the mantle produces warping of the overlying crust followed by lateral spreading under gravity.

But whatever the disagreements over

causes, there is general consent that plate tectonic processes are long term phenomena with characteristic time scales of at least hundreds of millions of years. By contrast, the high seismic activity which defines the locations of plate boundaries is sometimes claimed to have much shorter periodicity of about 11 years (see, for example, Simpson, *Earth Planet. Sci. Lett.*, **3**, 417; 1967). Machado (*Geol. Rund.*, **64**, 74; 1975) has now drawn attention to another example of this supposed periodicity—in the seismicity of the Azores—which he finds 'informative'. What makes the Azores particularly interesting is that they lie at the triple junction of the American, African and Eurasian plates and are thus presumably influenced both by the constructive margin forming the mid-Atlantic ridge and by the destructive margin along the Eurasian–African boundary. Machado finds that the 11-year variation in earthquake frequency is apparently present in data both from the islands of Fayal and Pico and from the islands of Terceira and San Miguel. But there is a difference in that the main seismic swarms on the two pairs of islands alternate, the main Fayal–Pico swarms being associated with crustal expansion (constructive) and the main Terceira–San Miguel swarms being associated with contraction (destructive).

Machado generalises from this example by suggesting that expansion and contraction perhaps alternate within an 11-year cycle everywhere. He then goes on to propose that this alternation could be due to 11-year pulsations in the gravitational constant (G). Indeed, he does more than propose; he claims to show mathematically that gravitational pulsations are a necessary consequence of general relativity within an expanding Universe. The physical effect of such pulsations would be alternate expansions and contractions not only of the Earth's lithosphere but of the whole interior. During an expansion phase, rifting would take place at oceanic ridges and mantle material would rise to fill the fractures; during the subsequent contraction phase, excess lithosphere would be forced downward at subduction zones. The net effect would be a drift of the plate; but as envisaged by Machado, the mechanism avoids the paradox implicit in attempting to explain apparently simultaneous expansion and contraction by a variation in G. In fact, there is no simultaneous expansion and contraction; each process takes place over alternate 5.5-year half cycles.

It is difficult to know how far to pursue an idea such as this. Is there really an 11-year periodicity in worldwide seismicity? And if so, do worldwide constructive and destructive processes alternate over half-cycles

within each cycle? On the other hand, it would perhaps be unwise to reject the idea of short-period gravitational fluctuations out of hand. The idea of a long term decrease in G has a long and distinguished history; and there is still a lingering suspicion in some quarters that gravitational variations may ultimately be found to account for the Earth's mobility as manifested at the surface by activity at the three types of plate boundary.

Folding proteins along the dotted lines

from Barry Robson

THE relation between the amino acid sequence and conformation of a globular protein is as yet imperfectly understood. But the fact that many proteins can spontaneously fold into their biologically active conformations suggests that computer simulation of the folding process would be likely to throw considerable light on that relation. An interesting technique for carrying out such a simulation has been proposed by Levitt and Warshel in *Nature* (**253**, 694; 1975).

The work of Levitt and Warshel may be considered as an extension of the study by Ptitsyn and Rashin (Preprint, Acad. Sci, USSR., 1973; *Dokl. Acad. Nauk SSSR*, **213**, 473; 1973). Certainly both investigations neglect the polypeptide backbone of the protein, and treat the amino acid side chains essentially as simple single-centred structures with interaction energies calculated from amino acid solubilities in ethanol. In both cases, therefore, emphasis is placed on the hydrophobic interaction between side chains as the principal driving force towards a biologically active conformation. The more recent study, however, is considerably more ambitious. Ptitsyn and Rashin confined their attention solely to the amino acid residues within the extensive α-helical regions of myoglobin, and fixed the conformation of these residues as α-helical from the outset. Levitt and Warshel, on the other hand, propose a technique in which the backbone is free to adopt any conformation.

The problem of manipulating the backbone without having to represent it in detail is overcome by the ingenious use of a device due to the Flory school (P. J. Flory, in *Statistical Mechanics of Chain Molecules*, 248–306, Wiley, New York, 1969). Flory replaced the actual molecular bonds of the backbone by virtual bonds connecting the α-carbon atoms at the base of each side chain. Each virtual bond, represented in the publications of the Flory school as a dotted line, substitutes for one fixed

and two rotatable molecular bonds Levitt and Warshel propose that the simplified representation of a protein as a set of side chains connected by virtual bonds between their α-carbon atoms is an adequate model for simulating the folding process In other words, they propose that the computer should literally fold up a protein along the dotted lines

The authors test this representation by simulating the folding of pancreatic trypsin inhibitor, a small protein of 58 amino acid residues and hence 57 virtual bonds Since the most stable conformations of a molecule are those of least energy, a procedure is used which minimises the conformational energy as a function of the angles of rotation around the virtual bonds Unfortunately, the procedure is one which does not allow the folding pathway to cross low energy barriers in the conformational energy surface, barriers which the protein in nature would be expected to negotiate readily To avoid trapping the molecule in a conformational energy well which is surrounded by low barriers, a technique called 'normal mode thermalisation' is used after each minimisation to generate a new random starting point close to the well The authors do not, however,

allow for the possibility that during minimisation the simulated pathway of folding could be confined to a trivially shallow channel, a difficulty which could be avoided by the use of a different kind of minimisation procedure The conformational energy surface of a protein is so complex that the use of certain traditional minimisation procedures may at worst resemble an attempt to plot the potential course of a stream by chasing a free-wheeling locomotive down a railway track Nevertheless, the authors make the exciting point that in some of their simulations, the protein arrives at a conformation close to that of the known, biologically active structure

One of the principal difficulties in this study is that the proposed model for a globular protein is such a drastic simplification As a further check on the validity of their model, the authors confirm that it is apparently stable when set in the biologically active conformation This is not, however, the sole criterion of an adequate model since the energy surface elsewhere may depart considerably from reality Another problem is that only very few different starting conformations for the folding simulations were explored, despite the fact that folding even from

the same initial conformation did not necessarily yield the same final conformation For these reasons there still remains the danger that the approximations to the biologically active conformation obtained by simulated folding are fortuitous, and an artefact of the model and starting conformations chosen

By far the most serious difficulty, however, is that the use of virtual bonds cannot by its very nature be a general solution to the folding problem Neglect of the backbone with its capacity for intramolecular hydrogen bonding means that α-helical regions, and possibly other secondary structure features, lose their intrinsic stability Possible exceptions are those helices with well defined clusters of hydrophobic or hydrophilic side chains on the helix surface, but such helices are by no means ubiquitous It is therefore notable that Levitt and Warshel, like Ptitsyn and Rashin, were obliged to start with the known α-helical region of trypsin inhibitor in the α-helical conformation and although the virtual bonds within the helical region were allowed to vary, the helix was the part of the real protein reproduced least well after folding As the authors point out, the various statistical pre-

The psis and their relations

from David J Miller

—intermediate boson models, 'charm' models or 'colour' models

The charm or 'SU(4)' model (see *Nature*, **253**, 438, 1974, for a brief outline) is still the most popular Various schemes have been suggested to fit the ψ and ψ' into a multiplet representation of the group SU(4) In 1961 Gell-Mann and Nishijima succeeded in explaining many of the properties of hadrons by fitting them into multiplets of SU(3)—sometimes called the 'eight-fold way' because many of the multiplets contain eight particles If the new quantum number charm is allowed, then SU(3) can be extended into SU(4) in a very natural way—just as the previously well established SU(2) scheme of 'isotopic spin' became SU(3) when Gell-Mann added the 'strangeness' quantum number In a simple SU(4) scheme there is an obvious place for one ψ particle, in the same multiplet as the well established vector mesons ρ, ω and φ, though it is not so easy to fit in two If the ψ (3 1) is fitted in, then predictions have been made (by M K Gaillard, Rosner and others) that charmed particles called the F and the D should exist, with masses as low as

2 2 GeV/c^2 The psis could not decay into Fs or Ds, but the Fs and Ds could be produced in pairs with opposite values of the charm quantum number It has been suggested that the bump at 4 2 GeV/c^2 may be due to the onset of F or D production, but there is no direct evidence to prove this

A recent paper by a Toronto group (*Phys Rev Lett*, **34**, 541, 1975) suggests a novel way of fitting both the ψ (3 1) and the ψ' (3 7) into the same SU(4) multiplet as the vector mesons As well as charm, they invoke a new "medium strong" charm-breaking interaction They assume that the ψ' (3 7) is a combination of a charmed quark and a charmed anti-quark—the obvious assignment for a ψ in the vector meson multiplet Their new interaction allows them to make the ψ (3 1) from a different mixture of charmed and strange quarks and antiquarks As in other SU(4) theories, they predict other new charmed particles which should be seen soon, if they exist, if their scheme is correct the new particles should have extremely interesting properties due to the effects of the medium strong force Perhaps this force also has something to do with the medium strong properties of the ψ (3 1) in its decay and in photoproduction (see *Nature*, **254**, 180, 1975, for a discussion of these results)

diction rules so frequently applied to the prediction of helical regions could first be utilised in order to locate the α-helices Nevertheless, the predictions would have to be particularly good because without the capacity for helical hydrogen bonding, the backbone would presumably not be capable of realistically winding or unwinding to compensate for errors in the statistical predictions

These cautionary notes may well seem pessimistic in the light of future studies but the onus is on the authors to provide a more extensive body of evidence for the validity of their model, particularly evidence resulting from a much larger number of folding simulations If the technique can be justified it will undoubtedly prove of very great value for folding the non-helical regions of proteins and bringing preset helices together

The study of Levitt and Warshel reflects the ingenuity and optimism to be found in a number of recent publications relating directly or indirectly to the folding of globular proteins At meetings and in visits to other laboratories, one can readily detect the underlying tension and enthusiasm, there is an exciting smell of sulphur, carbon, nitrogen and oxygen in the air

Michael Levitt and Arieh Warshel reply— ROBSON sees our work as similar to that published by Ptitsyn and Rashin (*Dokl Akad Nauk SSSR*, **213**, 473, 1973) Ptitsyn and Rashin have made a physical model of myoglobin out of nine preformed helical segments connected by pieces of flexible chain They used regular plasticine cylinders for the helices (rather like the simplified models made by protein crystallographers from low resolution electron density maps), and manually searched possible types of packing after making some assumptions about the neighbouring helices along the chain coming together first The interaction energy of a pair of helices was obtained by counting which residues were taken out of water at the contact surface, hydrophobic residues preferring to be buried and hydrophilic residues to be exposed With this model they concluded that an arrangement of helices closely like native myoglobin had both the lowest energy and the most stable intermediates at each stage of the assembly We find Ptitsyn and Rashin's work exciting because of its originality and the unexpectedly clear-cut picture of stable subassemblies when forming myoglobin from helices It is surprising that their work is considered so similar to what we have done Our work is a complete *ab initio* computer simulation of the folding of a whole protein chain based on realistic chain geometry

and interatomic forces derived from studies of small molecules, and including both the dynamics of the chain and randomising effect of temperature In our paper (*Nature,* **253**, 694, 1975), we did not neglect the polypeptide backbone but only omitted the hydrogen bonds between peptides which may be weak in the early stages of folding when the protein has a fairly open conformation in an aqueous environment We said they could be introduced later, along with other detailed interactions It is certainly not true that we are 'obliged to start with the known α-helical region of trypsin inhibitor" (see page 697, column 2 of our article) We include the effect of the solvent using amino acid solubilities but only as part of a realistic energy function with contributions from van der Waals, electrostatic, and torsional forces

We did, of course, refer to Flory's work on the virtual bond approximation, which was designed and used for calculating statistical properties of disordered random coil polymers It was totally unexpected that this simplification could also be used in a complete simulation of protein folding It now seems that the protein chain can be simplified because the peptide group is planar and the two rotatable bonds almost co-linear Each value of our single variable torsion angle α replaces a pair of the usual backbone torsion angles φ and ψ, so that we can halve the number of variables and hardly affect the representation of the protein backbone It is unfair to say that we consider the protein as "side chains connected by virtual bonds" We connect adjacent Cᵅs by a rotatable virtual bond and the side chains then stick out from this backbone (see Fig 1) Omitting the backbone and connecting adjacent side chains by a virtual bond would be a very poor model indeed

We do not believe that the native conformation of a protein necessarily has the lowest free energy, but try to simulate the actual folding process For this one must move smoothly over the energy surface down the energy gradient The minimisation method we use, developed by the Numerical Analysis group at Harwell, has been proven to be very powerful for a wide class of problems, it follows the path down the gradient more efficiently than any other method We are well aware of the so-called "untraditional" non-gradient minimisation methods which could conceivably avoid shallow minima, but these would require between 50 to 100 times as many energy evaluations to reach a minimum What would be worse is that one would lose all physical reality and still have no guarantee of crossing low energy barriers Our normal mode thermalisation

technique uses information gathered at no extra cost while dropping into a minimum to get out again In fact very few shallow minima are encountered (usually about 1 or 2, see Fig 4) in folding from an open to compact conformation This is an expected result of averaging over less important detail, but may well represent, as we wrote, a real property of the first stage of the actual folding process The conformational energy surface of a protein seems rather simple to us, and the analogy of following a freewheeling locomotive is actually a close picture of what we find

Until now nobody has even shown that accepted interatomic forces give rise to a true minimum (net couples less than 10^{-6} kcal mol^{-1} rad^{-1}) near the native conformation of a protein Were we to have used the accepted all-atom representation of pancreatic trypsin inhibitor, our work would have cost more than NASA's Apollo programme, and the results would have been much harder to interpret because of the many shallow minima caused by the minor irregularities of the side chains Throughout this project we have been very aware of the necessity of making the calculations as efficient as possible, we have managed to reduce the calculation time by a factor of about 1,000,000 by (1) considering the most effective variables, (2) averaging over side-chain conformations, (3) using a very efficient minimisation method, and (4) using normal modes in the thermalisation

Since last August when we obtained the results published in *Nature,* we have extended the work considerably We have simulated pancreatic trypsin inhibitor folding including the backbone hydrogen bonds and get as good a fit to the native conformation We have also tested different starting conformations and sets of energy parameters, and still obtain a significant success rate The same methods have been applied to rubredoxin, another small protein, with encouraging results Tests on the "mainly helical" proteins myoglobin and myogen have shown that when peptide hydrogen bonds are included, helices are stable and capable of growth and that several helices can come together as in the native protein Now that we have a new version of the program two and a half times faster (one cycle for PTI in 0 2 s) we will look at bigger proteins, like lysozyme, ribonuclease, and the antibody domains

For the first time it is possible to simulate protein folding by computer study each step of the process in detail and test which forces dominate and which parts fold first A great deal still has to be done, but there is room for some optimism about a general solution to the problem of how proteins fold

review article

Bacterial behaviour

Howard C. Berg*

Bacteria swim by rotating their flagella They back up or choose new directions at random by changing the direction of the rotation The probability of such changes is biased by sensory reception. The bias depends on the way in which the intensity of the stimulus changes with time, so that the bacteria tend to swim up a gradient of attractant and down a gradient of repellent chemicals

BACTERIA move with intent, accumulating in regions which are hot or cold, light or dark, or of favourable chemical content Systematic studies of these phenomena began in the late nineteenth century[1-3], but only recently has it been clear that they can be understood in molecular detail[4] How do bacteria swim? How do they respond to changes in their environment? How do they detect and process sensory information?

Mechanism of propulsion

Bacteria swim by rotating thin helical filaments which project from one or more points on their surface (Fig 1) A filament is joined by a proximal hook to a rod and a set of rings embedded in the cell wall and the cytoplasmic membrane[5] The entire structure is called a flagellum If there are several flagella per cell, the filaments form bundles and move in unison The bundle both pushes (or pulls) and rotates the cell (Fig 1) Butschli[6] realised long ago that this is a natural consequence of the resistance of the medium to the motion of the flagella Whether a flagellum bends in a helical fashion, as in some eukaryotes, or rotates rigidly about its axis, as in bacteria, the effect is the same The forces involved are viscous rather than inertial[7,8], so much so that it is impossible for a bacterium to coast when the flagella stop moving, the cell comes to a standstill (in so far as Brownian motion will allow) within about a millionth of a body length The hydrodynamics of the propulsion of cells with polar flagella are well understood[9-11]

Bacterial and eukaryotic flagella are entirely different organelles The eukaryotic flagellum contains complex bending machinery[12,13], the bacterial flagellum does not[14-17] Its filament is only about 130 Å in diameter It is a self-assembling polymer of a single protein, flagellin, which has no known enzymatic activity Since the filament lacks local means for the interconversion of chemical and mechanical energy, it cannot actively bend How, then, does it do work on the medium in which it is suspended? It has been suggested that helical waves are driven from the base[16,18-20], but it is not clear that a filament propagating such waves could transfer the requisite amount of energy If the filament rotates as a whole, energy transfer is no longer a problem Rigid rotation was noted as a possibility by Stocker[14], proposed[21,22] and later abandoned[23,24] by Doetsch, then adopted[25-27] and later modified[28] by Jarosch Unfortunately, one cannot distinguish wave propagation from rigid rotation simply by looking at a cell[29] This is easily demonstrated with a model of a flagellum made by threading a rubber tube over a spiral wire[7,30] If the tube is fixed at one end and the wire is turned, the tube propagates a helical wave It looks as if it is rotating, but it is not If the wire is held fixed and the tube is turned, the tube revolves around the wire It looks as if

it is stationary, but it is not Unless one is close enough to see what is happening at the surface of the tube, it is impossible to tell that the tube is there

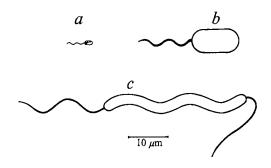
There is now a considerable body of evidence in favour of rigid rotation[31,32] The most dramatic has been obtained by tethering a cell with an abnormally long hook or a straight filament to a glass slide with anti-hook or anti-filament antibodies, when this is done, the cell body rotates, alternately clockwise and counter-clockwise[32] The cell is non-motile when free, but it spins several revolutions per second when the hook or the filament is linked to the glass Similar results have been obtained with anti-filament antibodies and cells with helical filaments[33] In each case, the body of the cell rotates, it does not merely precess or wobble It has been suggested that tethered cells may rotate because the end of the hook or filament in contact with the glass crawls around a circular path as it passes a helical wave (C R Calladine, personal communication) Experiments with polystyrene latex beads[32] are not subject to this argument When they are linked to cells with straight filaments, often several can be seen in tangential contact with (and revolving in synchrony about) a line projecting from the surface of the cell


Fig. 1 Scale drawings of various bacteria *a*, *E coli* (or *Salmonella typhimurium*) About six filaments arise at random from the sides of the cell and form a bundle which appears near one pole The bundle pushes the cell When it changes its orientation, the cell goes off in a new direction *b*, *Chromatium okenii* About forty filaments arise at one pole When they change their direction of rotation, the cell backs up *c*, *Spirillum volutans*, shown swimming from left to right The body is helical About twenty-five filaments arise at each pole Those on the right are in the head configuration, those on the left in the tail configuration When they change their direction of rotation and flip over, the cell swims in the opposite direction In each case, the filaments rotate about 50 revolutions per second one way while the body of the cell rotates more slowly the other, translation occurs at speeds of about 20 cell diameters a second

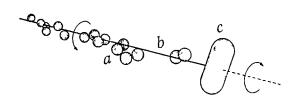
*Address Department of Molecular, Cellular and Developmental Biology, University of Colorado, Boulder, Colorado 80302


Fig 2 An experiment in which polystyrene latex beads (*a*) are linked to a straight filament (*b*) The filament is shown as a solid line, but it is invisible under phase contrast Most of the beads are linked directly to the filament, some are linked by means of other beads They revolve about the axis of the filament in one direction, while the cell body (*c*) rotates about this axis in the other There are no beats or undulations The beads remain fixed relative to one another Every now and again they slow down, stop, and start up in the opposite direction, the cell body changes its direction synchronously The entire assembly slowly diffuses through the medium The cell was derived from *E coli* AW405 (ref 34) by transduction with P1 from the donor W3110 (ref 32) The beads were linked to the filament by a method similar to that of Silverman and Simon[32]

(Fig 2) The flagella do not simply wind up and unwind mutants exist which rotate in one direction indefinitely[33]

If the flagella rotate, it is possible to understand (see ref 31) how cells with flagellar bundles are stopped by bivalent but not by univalent anti-filament antibodies[35,36], why cells with only one filament are inert to such bivalent antibodies[36], how peritrichously flagellated cells are stopped by flagellotropic phages[37,38], how cells with straight filaments may be able to form flagellar bundles[39], and finally, how cells with polyhooks but no filaments can counter-rotate when linked together with bivalent anti-hook antibodies[40] In making the first of these arguments, we noted that adjacent filaments in a bundle will stop when crosslinked by an antibody, because they can no longer rotate relative to one another Calladine[41] has argued that these crosslinks, if sufficiently rigid, could also prevent helical wave propagation by suppressing intra-filament "oscillatory lengthwise rubbing" This assumes that the filaments are inelastic, when, in fact, relatively little work would have to be done to deform them to meet the constraints on wave motion which such crosslinks impose (R A Anderson, personal communication)

A model for the flagellar rotary motor is shown in Fig 3 (see ref 42) The motor utilises as an energy source an intermediate in oxidative phosphorylation rather than ATP itself[43,44] It shares this property with a number of systems for active transport[45] Indeed, it could be driven by the translocation of ions through the M-ring which interact with fixed charges on the surface of the S-ring Some of the dynamic properties of the motor have been determined by following the rotation of tethered cells in the tracking microscope[42] The motor runs in either direction at about the same speed, it changes its direction abruptly, the motion can be remarkably smooth, there is little passive slip between the flagellum and the cell wall, and the amount of torque generated is impressive In *Escherichia coli*, some twenty genes are required for the complete assembly and function of the organelle[46,47], many are homologous to those found in *Salmonella*[48,49] One (*hag*) is the structural gene for flagellin, another (*flaE*) controls the length of the hook, a third (*flaI*) regulates the synthesis of the entire structure A normal *mot* product is required for the motor to rotate, normal *flaA* and *cheA* products are required for it to rotate both clockwise and counter-clockwise Most of the other genes have a non-flagellated mutant phenotype Only the *hag* gene product has been identified

Response to changes in environment

Bacteria have a limited repertoire of movements which vary depending on the size and shape of the cell and the distribution of the flagella (Fig 1) Most swim steadily in almost a straight line, then alter course abruptly *E coli* chooses a new direction

Fig. 3 A model for the flagellar rotary motor of a Gram-positive bacterium The rod is connected to the filament (not shown) by the hook, which serves as a universal joint[31] The torque is generated between the M-ring, which is mounted rigidly on the rod, and the S-ring, which is mounted on the wall The M-ring rotates freely in the cytoplasmic membrane The motor of a Gram-negative bacterium has an additional pair of rings[5] which probably serve as a bushing for the passage of the rod through the multilayered wall[42]

Fig 4 A projection of the track of a wild type *E coli* obtained with a microscope which automatically follows its motion in three dimensions[50,51] The points are 0 08 s apart The cell swims along as straight a path as rotational diffusion will allow (runs), stops and jiggles about (tumbles or twiddles), and then runs again The twiddles occur at random, on the average about once a second

almost at random (Fig 4)[50] *Chromatium okenii* backs up, moves bundle-first several body lengths, then swims forward once again[52], a manoeuvre which Engelmann[53] called a "shock reaction" Cells with a single polar flagellum, such as *Vibrio metchnikovii* (not shown) simply back up, they swim equally well with the flagellum in front or behind[54] *Spirillum volutans* flips its bundles from a head–tail to a tail–head configuration and swims off in the opposite direction[54,55] The probability of the occurrence of these events is biased by sensory reception It was thought for many years that bacteria back up or choose new directions at random on entering regions which are unfavourable that is, that the motor reflex is an avoidance response[53,56,57] This has not proved to be the case for *E coli*[50] When these

bacteria swim up a spatial gradient of an attractant (such as L-aspartate or L-serine), the probability that a twiddle will occur is smaller than it is in an isotropic solution, when they swim down such a gradient, the probability is nearly the same as it is in an isotropic solution Other parameters of the random walk remain constant The bacteria drift up the gradient because the runs are somewhat longer in the favourable direction The same asymmetry has been found in experiments in which a temporal rather than a spatial gradient is formed by enzymatic generation or destruction of an attractant As the concentration increases, the bacteria change direction less frequently, as it decreases, they swim as they do in the absence of a stimulus[58] Similar conclusions have been reached in experiments with *S typhimurium* in which solutions of an attractant at different concentrations are mixed[59,60] If the concentration of the attractant is suddenly increased, the bacteria swim smoothly for a relatively long period of time If it is suddenly decreased, they twiddle more frequently, but only for a relatively short period of time Attractants and repellents have opposite effects[61] The enzyme and the mixing experiments both show that the bacteria make temporal rather than spatial comparisons[56] In the enzyme experiments a response occurs even though the medium is isotropic In the mixing experiments the bacteria are exposed to both temporal and spatial inhomogeneities, they could measure the latter and time-average the results, but then the response would be the same on adding or diluting out the attractant

The motor reflex occurs when the flagellar 'motors' change their direction of rotation This was shown in early work on bacteria with polar flagella by Reichert[54], Buder[52], and Metzner[55] who, however, regarded the change as one in the direction of propagation of flagellar waves The use of the tethering technique has recently made a more direct proof possible for *E coli* Larsen *et al*[33] have shown that mutants of *E coli* that swim smoothly (that do not twiddle) rotate counter-clockwise when tethered to the top of a slide and viewed from above, while mutants that twiddle incessantly rotate clockwise Stimuli which cause the wild type to swim smoothly (or to twiddle) cause such cells, when tethered, to rotate counter-clockwise (or clockwise) Similar conclusions have been drawn from studies of *S typhimurium*[62] The bundle of a peritrichously-flagellated bacterium is able to push the cell but not to pull it, when the motors reverse, the bundle changes its orientation or comes apart[54,63,64], and the cell twiddles[33] The bundle of a bacterium with a polar flagellum is not subject to this instability, it remains intact, and the cell backs up *Chromatium okenii* completes the shock reaction by swimming forward once again, probably when its filaments tangle, a similar mechanism may terminate the twiddle[3,19] In so far as all bacteria able to respond to sensory stimuli are known to change directions spontaneously, it is likely that all bacteria have a "twiddle generator"[50] that reverses the flagellar motors[3] If so, the behaviour of a cell depends on the rate at which the generator fires in the absence of an external stimulus and on the extent to which the firing is enhanced or suppressed by sensory reception Parkinson[65] has concluded from an analysis of a large number of motile but non-chemotactic mutants of *E coli* that the machinery for twiddle generation and suppression involves only three gene products S-adenosyl methionine may be required for its function[4,66-68]

Chemoreception

A renaissance occurred in 1969 when Adler[69] proved that bacteria have specific chemoreceptors, that is, that they sense attractants *per se* There were suggestions of this in the early literature (for example, in Rothert's[56] experiments on competitive inhibition), but the idea never took hold Links[70], for example, proposed that the first (or only) step in the chain of events leading to the chemotactic response is a sudden decrease in the rate of utilisation of energy by the motor apparatus This hypothesis was developed further by Clayton[71,72], who applied it to taxis in *Rhodospirillum rubrum* Adler grew *E coli* on a chemically defined medium, washed and suspended the cells in a medium that supported motility but not growth[73], and then exposed the

cells to spatial gradients formed by the diffusion of attractants, from capillary tubes[74-76] By varying the initial concentrations of the attractant and counting the numbers of bacteria that swam into the tubes in a given period of time, he was able to establish a quantitative dose–response curve Using this method he showed that (1) chemicals that are extensively metabolised need not attract (even if they are the first metabolic products of chemicals that do attract), (2) chemicals that are not metabolised (because they are non-metabolisable *per se* or because the cells have lost the ability to metabolise them) may attract, (3) the response to an attractant is not generally blocked by the presence of structurally unrelated compounds (even if metabolisable), (4) structurally related compounds compete, (5) mutants exist which lack specific taxes (yet metabolise the attractant), and (6) transport of a chemical into the cell is neither necessary nor sufficient for it to attract

Chemoreceptors for amino acids[77], sugars[78], and a number of repellents[61,79] are now known The recognition components for D-galactose, D-ribose and maltose are shockable binding proteins[80] The role of the galactose binding protein in chemotaxis has been studied by Hazelbauer and Adler[80], that of the ribose binding protein by Aksamit and Koshland[81,82], and that of the maltose binding protein by Hazelbauer[83] Genetic analysis has shown that the binding protein for galactose interacts with other components that are specific either for taxis or for transport[84] The recognition components for D-glucose, D-fructose and D-mannitol are sugar-specific enzymes of the phosphotransferase system[78,85] Other components in these systems specific for taxis but not for transport remain to be identified For L-aspartate and D-galactose, twiddle suppression depends on the time rate of change of the fractional amount of chemoreceptor bound[58,86] For D-ribose the duration of the smooth response in a mixing experiment is proportional to the increment in the fractional amount of chemoreceptor bound[87] The cells monitor the status of their chemoreceptors, but the biochemical mechanisms are not known

Signal processing

Neurones integrate excitatory and inhibitory inputs electrically, responding in an all-or-none fashion by generating an action potential It is tempting to think of a bacterium in the same manner[88] and to suppose that the integration of different inputs[61,89] and the coupling between the receptors and the flagella occur through changes in the membrane potential[90] This is suggested, for example, by work on *S volutans* (Fig 1) Ordinarily, the flagellar bundles reverse synchronously[55], they seem to do so even when filmed at 48 frames per second[91] This implies that one end of the cell can signal the other in 10^{-2} s or less If the signalling were done by diffusion of a substance of low molecular weight, either through the cytoplasm of along the membrane, at least 1 s would be required[3] An electrical disturbance could be propagated much more rapidly The signalling can be impeded by the addition of large amounts of salt or blocked by partial deprivation of oxygen in the presence of a photodynamic dye[55] Other substances put the flagella in a head–head or a tail–tail configuration[55,91,92], but they may do so simply by forcing the motors to run in the same direction Some work has been done with drugs known to affect excitable membranes[91-95], but the results are hard to interpret In *E coli* relatively little is known about the mode of coupling between the chemoreceptors and the flagella[4,47] Mutants exist that fail to respond to compounds that use different chemoreceptors, such as D-ribose and D-galactose[84], or L-serine and certain repellents[79], L-aspartate and L-serine signal the flagella by means of different pathways[65] The system may prove to be complex Since both the receptors and the flagella reside in or interact with the cytoplasmic membrane, the latter's involvement is apparent

Experiments in catastrophe

J. M. T. Thompson

Department of Civil Engineering, University College, London, UK

Two new theories of evolutionary instability are outlined When applied to highly optimised engineering structures, they predict that buckling strengths can be dramatically eroded by small unavoidable manufacturing imperfections this is confirmed by tests on stiffened panels of box-girder bridges A related analysis yields a spectacular picture of the hyperbolic-umbilic catastrophe

Two parallel and complementary contributions to our understanding of evolutionary instabilities have recently been presented The first is the widely acclaimed qualitative catastrophe theory of René Thom[1] which has been applied most fruitfully by Zeeman and others to problems in sociology, economics and theoretical biology[2].

The second is the quantitative general branching theory of Thompson and Hunt[3] which has had a major impact on our approach to the instability of elastic solids This is essentially a prototype bifurcation theory for slowly evolving systems in the spirit of Poincaré, and has wide applications across the mathe-

matical sciences in such areas as cosmology, hydrodynamics and crystallography

The two theories have been developed quite independently, but are remarkably similar in form and content, and Hunt and I have just completed a preliminary correlation between them[4] Cross fertilisation between the two disciplines promises to be most rewarding, and catastrophe theorists may be interested to find in ref 3 well developed perturbation schemes for the quantitative analysis of bifurcations and catastrophes, together with a wealth of catastrophe machines akin to that of Zeeman[5]

General theory

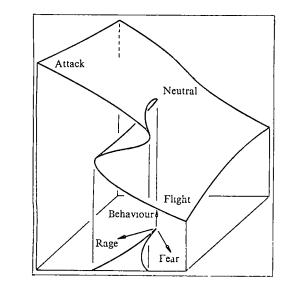
In their simplest form, the two theories relate to any system governed by a potential function $V(Q_i, \Lambda^j)$ where Q_i is a set of n state variables or generalised coordinates, and Λ^j is a set of k externally controlled parameters Stationary values of V with respect to the Q_i are supposed to be necessary and sufficient for equilibrium, while minimum values are supposed to be


Fig. 1 Zeeman's illustration of the cusp catastrophe in the response of a dog subjected simultaneously to fear and rage

necessary and sufficient for stability The n equilibrium equations $\partial V/\partial Q_i = 0$ thus define surfaces[6] in the $k+n$ dimensional $(\Lambda - Q)$ space, while the vanishing of the stability determinant $| \partial^2 V/\partial Q_i \partial Q_j |$ identifies critical equilibrium states at which a loss of stability can be expected

The locus of critical states projected into the k-dimensional control space gives a catastrophe boundary which in elastic stability usually corresponds to an imperfection–sensitivity curve on a plot of the failure load against the imperfection magnitude Usually Λ^j is finally assumed to be slowly varying, and attention is focused on the steady evolution of an initially stable equilibrium solution which can be destroyed by a sudden dynamic snap from one of the critical equilibrium states

The two theories delineate the forms of instability that can occur by classifying the singularities that can arise in the catastrophe boundary, and a powerful result of topology allows Thom to identify seven "ordinary catastrophes" These are the only topologically stable, and therefore the only naturally occurring, forms that can arise in a control space of up to four dimensions ($k \leqslant 4$) no matter how many state variables Q_i there are in the system

This result has significance in developmental biology where the external control parameters of a cell might be its spatial coordinates (x,y,z) and the time t, the former influencing the cell through the spatially varying chemical environment Our conceptual catastrophe boundary now becomes a four-dimensional spatio-temporal boundary of behaviour[7]

Two applications

In the past, bifurcation and catastrophe theorists have tended to view their identical problems in rather different ways, and I can best illustrate this by means of two illustrative examples

An attractive illustration of qualitative catastrophe theory in an inexact science is Zeeman's demonstration of the cusp phenomenon in the psychological response of a dog or a man subjected simultaneously to feelings of fear and rage Here we must think of the intensities of fear and rage as being two controlled variables Λ^j under which we observe the behaviour of the dog as a single coordinate Q We thus expect to have a response surface which Zeeman[8] argues must have the form shown in Fig 1

Under low stimulus we see that the behaviour can vary continuously from flight to attack, but under high stimulus the dog's response varies discontinuously with jumps in behaviour at the fold-lines which project into a cusp in the plan view Clearly it is imperative for the animal that under intense pressure it should not respond in a neutral manner, even if

fear and rage are equally balanced, and correspondingly the inverted fold of the surface represents unrealisable unstable states

By contrast, a quantitative application[9] of the general bifurcation theory is sketched schematically in Fig 2 Here a square sheet of crystal is loaded by a direct force or stress σ_{11} and deforms accordingly into a rectangle with a direct elongation or strain ε_{11} At a certain load, however, a point of bifurcation C is encountered at which a symmetry-destroying shearing deformation ε_{12} develops and the crystal deforms unexpectedly into a parallelogram At this bifurcation load the directly stressed crystal would fail explosively in a homogeneous shearing mode A small constant shearing stress σ_{12} would clearly induce some shearing strain ε_{12} even before the bifurcation, so such a stress would act as an "imperfection" rounding off the bifurcation as shown

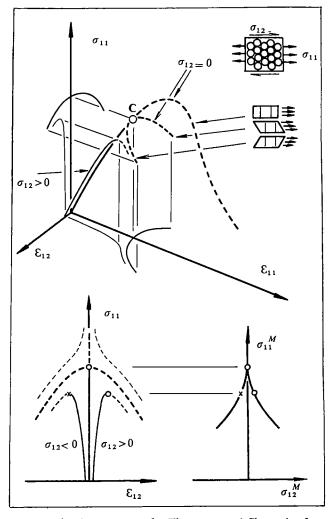
In this example the stresses σ_{11} and σ_{12} are to be thought of as two control parameters Λ^j whereas the strains ε_{11} and ε_{12} are to be identified as two state variables Q_i The first picture shows equilibrium paths in a three-dimensional graph, a significant projection of which is shown underneath on the left hand side The load carrying capacity as measured by the maximum direct stress $\sigma_{11}{}^M$ is severely reduced by the application of even a small σ_{12}, and the locus of critical points is finally projected into the control space to give a cusp-shaped failure stress locus of $\sigma_{11}{}^M$ as a function of $\sigma_{12}{}^M$


Fig. 2 The demonstration by Thompson and Shorrock of a bifurcation in the response of a mechanically stressed atomic lattice A close-packed crystal with Lennard–Jones interatomic potentials is considered and the primary path is shown to lose its stability in a symmetry-destroying unstable-symmetric point of bifurcation at C This gives rise to a cusp on the failure stress locus In an extension of this work we have shown that the crystal exhibits a hyperbolic-umbilic catastrophe in the three dimensional failure space of the planar stresses σ_{11}, σ_{12} and σ_{22}.
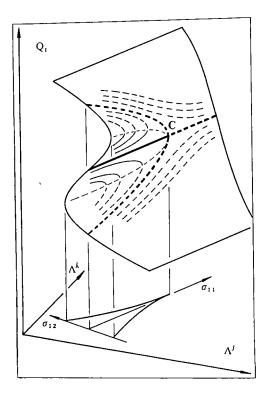

Fig. 3 Paths on an equilibrium surface demonstrating the equivalence between the unstable–symmetric point of bifurcation and the cusp catastrophe One distinction between the examples of Fig 1 and Fig 2 is that in the former the bulk of the surface is stable and the inverted fold is unstable while in the latter the situation is exactly reversed My stable– and unstable–symmetric points of bifurcation are each classified by Thom as a cusp catastrophe

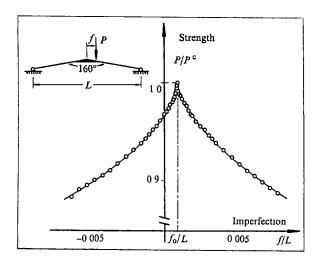
Figure 1, with its emphasis on the whole equilibrium surface, is an example of Thom's Riemann–Hugoniot cusp catastrophe and Fig 2, with its emphasis on equilibrium paths, represents my unstable–symmetric point of bifurcation But in fact these are one and the same phenomenon, as is made clear in Fig 3 in which bifurcating paths are generated simply by slicing the folded equilibrium surface at constant σ_{12}

This cusp, or distinct symmetrical point of bifurcation, which generates a two-thirds power law cusp in Λ space, is by far the most common branching phenomenon and can be found throughout the mathematical sciences, one significant example arising in the instability of rotating stellar masses[10,11]


Elastic arch

This ubiquitous cusp was first studied experimentally by Roorda at University College, London, and one of his many tests is summarised in Fig 4 Here a shallow steel arch pinned to rigid abutments is loaded, nominally at its crown, by a load P which is progressively offset by a small distance f to simulate an asymmetric manufacturing imperfection The behaviour of the arch is elastic throughout, and failure is associated with the dynamic snapping of the arch through asymmetric configurations into an inverted state

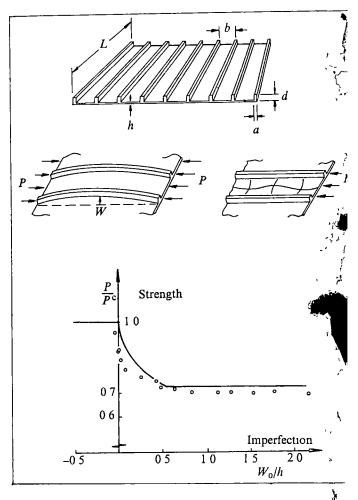
In this example the load P and the offset f are to be regarded as two controlled parameters while the in-plane rotation of the crown, θ, can be viewed as a single generalised coordinate measuring the asymmetric deformation The equilibrium paths


Fig. 5 The sensitivity of the strength of a stiffened panel to manufacturing imperfections W_0 in the overall form The model panel tested was of epoxy plastic with dimensions $h = 0 75$ mm, $b = 57 5$ mm, $a = 4 9$ mm and $d = 10$ mm The graph corresponds to a section through the hyperbolic-umbilic catastrophe of Fig 6 This test is one of a continuing series conducted by A C Walker

of the family of arches generated by varying f have the general form of the unstable–symmetric point of bifurcation shown in the lower graphs of Fig 2 with P replacing σ_{11}, f replacing σ_{12} and θ replacing ε_{12}

The right-hand-side cusp is of particular interest and now represents an imperfection–sensitivity curve on a plot of the failure load P as a function of the simulated imperfection magnitude f The curve determined experimentally is shown in Fig 4 This follows the predicted two-thirds power law, and shows a dramatic deterioration of strength away from the optimum 'design' at $f = f_0$ at which the critical offset f_0 is just cancelling out the unavoidable manufacturing errors in the test specimen (see also ref 3)

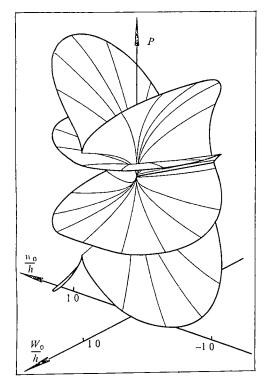
Fig. 4 Test by Roorda on a model arch, showing a deterioration of strength with the controlled asymmetry


Fig 6 The hyperbolic-umbilic catastrophe determined by Hunt (unpublished) in the theoretical response of a stiffened elastic panel The lower region of the surface gives the panel strength as a function of the overall and local manufacturing imperfections[4]

Highly optimised structures

I have just presented an example of an optimum design which is extremely sensitive to unavoidable manufacturing imperfec-tions, and it is my thesis[3,12] that as higher and higher degrees of optimisation are sought, so the severity both of the failure and of the associated imperfection-sensitivity will rise Indeed us is likely to be a feature of any highly optimised system, whether in the field of engineering structures or not

As an illustration of this I consider the elastic buckling of an optimised stiffened panel similar to those employed in box-girder bridges The model panel of Fig 5 is compressed by an axial load P, parallel to the stiffeners, under which the specimen may deflect like a simple column in an overall mode with amplitude W as shown on the left, or may alternatively ripple between the stiffeners in a local mode with amplitude w as indicated on the right

The much used, but potentially dangerous concept of simultaneous mode design[3,12] states that the structure will be optimal when these two failure modes can develop simul-taneously, and I have chosen the length of the panel so that this condition is closely realised A simulated initial deflection of amplitude W_0 in the overall mode represents a manufacturing imperfection, and we[13] have obtained the imperfection-sensitivity curve shown, failure being characterised by a sudden dynamic snap in the range of material elasticity A dangerous erosion of strength with positive imperfection amplitude is indicated, and the experimental points are seen to be in quite good agreement with the curves of a simplified *ad hoc* theoretical treatment

This treatment and more details of the tests are to be re-ported elsewhere[13] They show that highly optimised plate assemblages must be expected to have the severe imperfection-sensitivity characteristics previously associated only with the notorious buckling behaviour of thin shells, a conclusion that will undoubtedly carry over into the plastic range

Hyperbolic-umbilic catastrophe

A similar stiffened elastic panel containing additionally a local imperfection of amplitude w_0 has been analysed more rigorously by V Tvergaard, and his asymptotic equations corresponding to our homeoclinal point of bifurcation have been solved in detail by G W Hunt (unpublished) to give the complete imperfection-sensitivity surface of Fig 6, the lower region of which gives the panel strength as a highly-peaked function of the two imperfection amplitudes W_0 and w_0 This dramatic computed picture has been identified by D Chilling-worth of Southampton University as a hyperbolic-umbilic catastrophe, and this seems to be the first known practical example of this predicted form

Evolution of Precambrian crust from strontium isotopic evidence

S. Moorbath

Department of Geology and Mineralogy, Oxford University, Oxford, UK

The strontium isotope evidence places constraints on the evolution of Precambrian crust Contrary to popular belief, sialic crust cannot, it seems, be "reworked" on a grand scale

MANY geologists believe intuitively that Archaean and post-Archaean gneisses, the ultimate origin of which is not recog-nisable in the field, are somehow derived from "much older" sialic (that is, continental igneous, sedimentary or metamor-phic) crust A particularly popular hypothesis is that continental,

sialic crust can somehow be "reworked" repeatedly on a grand scale (The term reworked is here used in the sense of partial or complete melting leading to mobilisation and reconstitution as an essentially new rock and not in the frequently used, but incorrect, sense of isochemical recrystallisation and/or defor-mation) These views are not compatible with the results of some recently published Sr isotopic data on Archaean and Proterozoic gneisses, and greenstone belt volcanic rocks with associated later granodioritic or tonalitic plutons

The views presented below are an extension of those of

Spooner and Fairbairn[1], who reported low, if somewhat imprecisely determined, initial $^{87}Sr/^{86}Sr$ ratios for several suites of Precambrian pyroxene granulite gneisses In particular, they favoured an igneous origin for such rocks, involving transfer into the crust of a mantle-derived magma of approximately andesitic composition Spooner and Fairbairn suggest that the part that reaches the upper crust will crystallise as normal extrusive and intrusive rocks, but any part that is trapped in the lower crust at about 10^5 KPa will cool slowly to a minimum of about 500 °C and crystallise directly into plagioclase–pyroxene assemblages, characteristic of the granulite facies In this connection, igneous rocks with magmatic features characteristic of fractional crystallisation but with typical granulite facies mineralogy are well known from such areas as Lofoten–Vesteraalen, north Norway, where large quantities of mangeritic and charnockitic magmas were intruded at depths of 20–25 km and at 900–1,000 °C (ref 2)

Geochemistry and isotope data

The geochemistry of major elements of many pyroxene granulite and amphibolite facies gneisses (see, for example, ref 3) suggests strong affinity with igneous rocks of calc-alkaline character, in spite of the characteristic depletion in certain incompatible trace elements such as U, which shows up so particularly well in the present unradiogenic Pb isotope ratios in many high-grade gneisses[4][5] This depletion occurred within the uncertainty of the measured whole rock Pb/Pb age and has been interpreted as an essentially metamorphic phenomenon[4,5] The highest grade gneisses sometimes also show strong synmetamorphic Rb depletion, leading to present unradiogenic Sr isotope ratios[1,6]

Table 1 is a summary of recently reported Rb—Sr whole rock ages and initial $^{87}Sr/^{86}Sr$ ratios of some major Precambrian gneiss complexes Also shown are measurements on basaltic-to-andesitic greenstone belt volcanics and associated (either cross-cutting or presumed later) calc-alkaline plutons from two areas Almost all initial $^{87}Sr/^{86}Sr$ ratios are in close agreement in the general range 0 700–0 702, and fall rather close to the value presumed to be characteristic of the upper mantle for the corresponding age[7]

Figure 1 shows averaged $^{87}Sr/^{86}Sr$ growth lines, calculated from the mean of the measured Rb/Sr values for each individual rock unit in the publications cited in Table 1 The slopes of the lines are proportional to the Rb/Sr ratios, which are mostly within the range 0 2–0 4 for the gneisses and granites listed in Table 1, although each rock unit exhibits considerable dispersion in Rb–Sr values The data for Greenland, Scotland and Rhodesia are plotted in relation to a hypothetically linear upper mantle growth line extending from 0 699 to 0 703 in 4,600 Myr, corresponding to a Rb/Sr ratio of about 0 02 (It is not yet known for certain whether this line is strictly linear, or slightly convex upwards implying nonlinear evolution of upper mantle Sr^7) The positions of all initial ratios fall almost on, or slightly above, the linear upper mantle growth line, and demonstrate beyond any reasonable doubt that later rock units cannot have been derived by the reworking of earlier ones of the type exposed in any given region The same conclusion applies to the North American data, which are not plotted because of the large grouping of ages at around 2,700 Myr and the relative uncertainty in the values for the Minnesota River Valley gneiss

Implications for evolutionary models

The measured ages and initial $^{87}Sr/^{86}Sr$ ratios for unaltered greenstone belt volcanics and later plutons almost certainly relate to the time of crystallisation For a gneiss complex, they could relate to the time of regional metamorphism In that case, linear extrapolation of any given $^{87}Sr/^{86}Sr$ growth line back to the linear upper mantle growth line yields an upper age limit for the precursors of the gneiss complex In most cases this does not exceed about 100 Myr, and in some cases it is less than 50 Myr Since high-grade metamorphism may cause a decrease in Rb/Sr ratios, the first part of the $^{87}Sr/^{86}Sr$ growth line could have been significantly steeper, so that the age difference between formation of the precursors and their metamorphism would be correspondingly reduced A nonlinear upper mantle growth line (convex upwards) would, of course, have much the same effect

Several major Archaean and Proterozoic gneiss complexes, as well as greenstone belt volcanics and associated later plutons, are predominantly juvenile additions to the continental crust at, or close to, the measured age, implying continental growth on a major scale during the Precambrian (Table 1) Furthermore, the

interval between the time of extraction of juvenile igneous material from the upper mantle (and/or subducted oceanic lithosphere) and the time of production of the regional metamorphic characteristics of the derived gneiss complex may be less than 50–100 Myr, which falls within the analytical uncertainty of most age measurements of Archaean and Proterozoic rocks It is possible that during such an "accretion" event, major amounts of juvenile igneous material broadly equivalent in composition to the island arc tholeiite series and, in particular, to the calc-alkaline series, were produced at depth in an ancient proto-island arc regime[8-11] Some of this material came directly to the surface of the pre-existing continental or oceanic crust where it gave rise to the volcanic assemblage characteristic of greenstone belts The remainder crystallised at depth as the hypabyssal and plutonic equivalents of the high level rocks The

volcanic association is probably the early extrusive expression of the subcrustal processes which later led to the intrusion of calc-alkaline plutons into the deforming volcanic-sedimentary pile, as already suggested for the Yellowknife Province by Green and Baadsgaard[12] At depth, the plutonic material slowly crystallises with igneous or metamorphic mineral assemblages, simultaneously undergoing geochemical and petrological differentiation to give a compositionally layered lower crust[13-17], in which the major and minor components of granite (*sensu lato*) migrate upwards to form rocks of the calc-alkaline plutonic association, leaving behind a thick residue of depleted granulite facies rocks at greater depth The resulting crustal layering is gradational and highly complex in detail Under these plutonic conditions the

conventional distinction between what is "igneous" and what is "metamorphic" is no longer clearcut Furthermore, intermediate zones of variably depleted calc-alkaline amphibolite facies gneisses must also be quantitatively important Most of the gneisses in Table 1 are actually of this type

In some cases, upward migrating volcanic and plutonic materials penetrate much older continental, sialic crust (as in Rhodesia) which could have formed in much the same way during an earlier continental accretion episode But this older sialic crust, where present, may contribute little or no "reworked" material (Fig 1), although it may well undergo renewed metamorphism and tectonism (as in the Godthaab area of West Greenland), as well as providing xenoliths and enclaves of many different types in the younger volcanic and plutonic rocks But it seems, in principle, unlikely that relatively low density, continental sialic crust can be buried or subducted sufficiently deeply for really large scale reworking of basement gneisses of the type postulated by many geologists (see, for example, refs 18 and 19) True reworking of older sialic crust may, of course, happen on a limited scale above ancient and modern subduction zones, and it is quite possible that in certain tectonic regimes such as in orogenic belts formed in sites of continental collision with resulting major crustal thickening, sialic crust can be truly reworked on a moderate scale[20] Localised partial melting of ancient, sialic crust may also occur in the zone of heating above large bodies of basic igneous magma introduced into high crustal levels, as for example in the Tertiary igneous province of north-west Scotland[21] All of these complicating factors which involve partial melting of, and assimilation with, ancient sialic crust are clearly exhibited by the complexities of initial Sr isotopic ratios in many relatively high level granites and related rocks of mainly Phanerozoic age[7]

The mechanisms of continental growth and crustal evolution implied by plate tectonics may well be adequate to explain the evolution of major Precambrian crustal units, although there is no final proof At any rate, they are certainly compatible with the Sr isotopic evidence The sequence of events comprises. plate formation—plate separation (ocean floor spreading) —plate convergence—subduction—partial melting of basic lithosphere and/or upper mantle—extraction and emplacement of basaltic and calc-alkaline volcanic and plutonic rock types— accretion of continental crust—geochemical and petrological differentiation of new continental crust The Sr isotopic evidence suggests that this sequence can be relegated for any given cratonic suite, which exhibits close grouping of rock-forming ages and low initial $^{87}Sr/^{86}Sr$ ratios, into a continuous or semicontinuous "super-event" not exceeding 50–100 Myr in duration This value is of the same order as found at present between the most recently formed complementary ocean ridges, island arcs and continental margins

The major conclusions drawn from the Sr isotopic evidence are, of course, unaffected by the particular model chosen for continental growth, whether plate-tectonic or otherwise But for the examples cited here, the process of repeated reworking of significantly older sialic crust with anything like normal crustal Rb/Sr ratios must be rejected

Energy spectrum of diffuse component of cosmic soft γ rays

IN this paper we present new measurements on the diffuse component of cosmic soft gamma rays in the energy range 0 1–4 MeV obtained with a balloon-borne telescope These measurements show that the energy spectrum gradually steepens from $E^{-2\,3}$ to $E^{-2\,8}$ as the energy increases from 100 to 500 keV and becomes less steep thereafter, consistent with the presence of a hump in the MeV region

Previous observations[1–5] of the diffuse gamma ray spectrum obtained both at balloon altitudes and with detectors on board spacecrafts are subject to criticism In the spacecraft observations[6,7], the counting rate in the detectors resulting from radioactivity induced by cosmic ray interactions is comparable to that of the cosmic component of gamma rays at energies above 1 MeV and the corrections for this effect are not free from ambiguity In balloon observations the procedure for deducing the background contribution from secondary cosmic rays by linearly extrapolating the growth curve is not justified for omnidirectional detectors[8–10] These difficulties can be circumvented by employing the "active shutter method" described previously[11]

This experiment is an improved version of the scheme with which a well defined directional response for the gamma ray detection has been achieved previously The central NaI (Tl) counter of 7 5 cm diameter and 7 5 cm thickness is surrounded by a cylindrical NaI (Tl) counter of 10 cm wall thickness and 30 cm height The bottom hole is covered by a CsI (Tl) crystal, 7.5 cm in diameter and 7 5 cm thick A shutter counter made of NaI (Tl) of 7 5 cm diameter opens and closes the entrance aperture at the top for alternate periods of one minute By taking the difference between the counting rates of the open and closed modes, the background caused by the radiation outside the entrance aperture is eliminated The angular response of the detector for this difference is nearly triangular with FWHM of about 40°, as determined by using gamma ray sources [57]Co (122 keV), [137]Cs (660 keV), [60]Co (1 7, 1 33 MeV) and [24]Na (1.37, 2 75 MeV) The geometrical factor at 1 2 MeV is 23 cm^2 sr. The detection threshold of the guard counters and the shutter counter are set at 15 keV The response of the detector to neutrons has been measured using an Am–Be source, the counting rate of the telescope at the ceiling has a negligible contribution from atmospheric neutrons

The gamma ray detector was flown from Hyderabad, India on April 13, 1974 The balloon stayed at the ceiling altitude of 4,300 Pa (4 3 mbar) for about two hours and then gradually

descended to 6,800 Pa over the next three hours The pulse heights measured in the central counter were analysed into 128 channels and telemetred event by event along with the indication of coincidence with the shutter and/or the guard counters The counting rates of the guard counters were also monitored In-flight calibrations of the central and shutter counters revealed showed that the functioning of the apparatus was stable throughout the flight

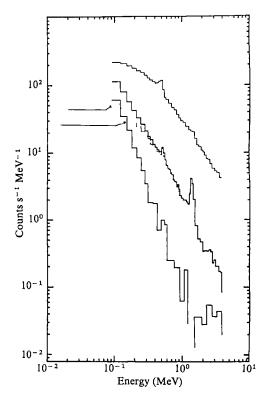
The pulse height distributions observed at the ceiling altitude are shown in Fig 1 for the open and the closed modes of operation of the telescope Their difference, also shown in the same figure, represents the pulse height distribution for the 'forward gamma rays' To determine the gamma ray intensity at the top of the atmosphere the following functional form for


Fig. 1 Observed pulse height distributions of the central counter at the ceiling altitude *a*, Anti-off, open, *b*, anti-on, open, *c*, closed, *d*, difference (open–closed) "Anti-off" indicates guard counter pulses disregarded
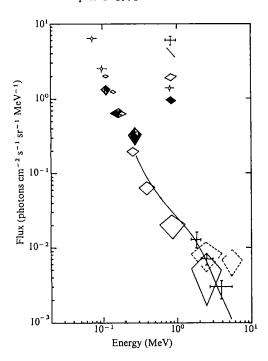

Fig 2 Energy spectrum of soft gamma rays The present result is indicated by open diamonds Dashed diamonds represent the fluxes not corrected for the electron contribution ◆ and O, Our previous balloon observations, +, Schonfelder and Lichti (unpublished, solid line, ref 5)

the growth curve was assumed for altitudes higher than 50 g cm^{-2}

$$C(z) = I_0 F(z) + I_b z$$

where $C(z)$ is the counting rate at an altitude z (in g cm^{-2}), I_0 is the intensity of primary gamma rays, $F(z)$ is the attenuation function of primary gamma rays in air and I_b is the constant The last term is the intensity of the atmospheric component, and its assumed linear z-dependence for the narrow aperture telescope used in the present experiment is supported by Monte Carlo calculations[8-10] $F(z)$ is taken from a Monte Carlo calculation by Horstman and Horstman-Moretti[12]

The energy loss spectrum has been transformed to photon spectrum by the use of response functions obtained for different energies using radio isotopes A comment is necessary for the data above 1 MeV Since the entrance aperture is not protected against charged particles, re-entrant albedo electrons are suspected to give an appreciable contribution in this energy region This has been estimated using the observed electron spectrum[9] The spectrum of the gamma rays thus derived with the utmost correction of the electrons is shown by open diamonds, whereas the flux values without the corrections are shown by dashed diamonds in Fig 2 The effect of the electrons is estimated to be negligible below 1 MeV

The present results are compared in the same figure with our earlier results The filled diamonds are those obtained from a balloon flight made at Hyderabad in 1972 with a similar detector equipped with a plastic guard counter and the open circles are based on a balloon observation from Sanriku, Japan (also in 1972) with a passive collimator and a passive shutter There is good agreement between the various results in the overlapping energy regions The spacecraft results by Trombka et al[5] and the balloon results by Schonfelder and Lichti[13] are also shown in Fig 2 These are in general agreement with our results although their flux values are somewhat higher

Our principal conclusion is that the spectrum gradually steepens in the energy range 100–500 keV and then tends to flatten in the MeV region consistent with a hump around 1 MeV Single power spectra can fit the data points only with confidence

levels lower than 0 001 Detailed description of the experiment and data analysis will be published elsewhere[13]

Neutrino processes and QSOs

PECULIAR jets of matter emanate from some galactic nuclei and QSOs, including the galaxy M87 and the QSO 3C273 It is generally believed that these jets are matter ejected from the central regions of the object[1] As a result of non-conservation of parity in weak interactions, the neutrino processes associated with gravitational collapse of a galactic nucleus in the presence of a strong magnetic field can lead to ejection of matter from the nucleus in one direction I suggest that the jets observed in M87 and 3C273 are the result of this mechanism

The importance of neutrino processes in gravitational collapse depends on the very large mean free path of neutrinos even in extremely dense matter, which enables them to carry away the gravitational potential energy released in the collapse Because of conservation of magnetic flux associated with the "frozen in" magnetic field, a collapsing object can acquire an intense magnetic field[2] In the presence of an intense magnetic field a certain fraction of neutrons in the object will be aligned with spins parallel to the magnetic field, in weak processes involving aligned neutrons the neutrino emission is asymmetrical as a result of non-conservation of parity in weak interactions So the linear momentum carried away by neutrinos is non-zero and must be compensated by a change in linear momentum of the system The degree spin alignment of neutrons depends on temperature T and the strength of the magnetic field H An almost complete spin alignment is possible if $\mu H > kT$ (μ is the magnetic moment of the neutron, k the Boltzmann constant) For a temperature of the order of 10^8 K, this condition is satisfied if $H \sim 10^{15}$ gauss Optical and radio observations probably rule out the existence of magnetic fields of this strength in the outer regions of a galactic nucleus or a QSO But the occurrence of magnetic fields of this strength in the central collapsing regions of the nucleus, where the neutrino processes are important, cannot be ruled out Ginsburg[3] has shown that the magnetic field of a collapsing object

can increase without limit There are also arguments which suggest that highly collapsed matter is 'ferromagnetic' with spins of neutrons aligned in one direction[4] If we assume almost complete spin alignment, the neutrino angular distribution function $W(\theta)$ is proportional to $(1+\alpha\cos\theta)$, where θ is measured from the direction of the magnetic field (for nuclear β decay, α is of the order 0 4) If N neutrinos are emitted with average energy E a simple calculation gives the momentum ΔP carried away by neutrinos as

$$\Delta P = (2NE\alpha/3c)n \qquad (1)$$

where n is unit vector in the direction of the magnetic field Thus if a mass δM is converted into neutrinos, by setting $NE = \delta Mc^2$ in equation (1) the momentum carried away by neutrinos is

$$\Delta P = 2/3\,(\delta Mc\alpha)n \qquad (2)$$

So to conserve linear momentum the object should either recoil or eject matter in the opposite direction For the mechanism to be effective a large fraction of the material of the nucleus must be in the form of neutrons free to decay This requirement can probably be realised In the central regions of a collapsing object matter should exist predominantly in the form of neutrons since at high pressures it is thermodynamically more favourable for protons to capture electrons The presence of few per cent of electrons will ensure that neutrons are stable against β decay But there is no reason to believe that the Fermi energy of these electrons will remain the same throughout the collapse A sudden decrease in Fermi energy will allow neutrons to decay The quantity δM in equation (2) can be a considerable fraction of the mass of the object Since α is not very different from unity, large amounts of matter can be ejected in a direction opposite to n with relativistic speeds The energy released during neutron decay could temporarily convert the contraction into an expansion Repetition of this process will also occur but in every contraction phase ejection of matter will take place in the same direction because of the presence of the "frozen in" magnetic field

The jets associated with most objects have condensations along their length indicating that several ejections have taken place in the same direction This is in agreement with the mechanism I propose It is interesting that no other mechanism could easily explain the occurrence of discrete emissions from the nucleus in the same direction If the jet formation is a magnetohydrodynamic effect there is no reason why the discrete ejections should not occur with equal probability in a direction parallel as well as anti-parallel to the magnetic axis

Time markers in interstellar communication

THE feasibility of interstellar radio communication using existing facilities has been established in principle[1] We can communicate with extraterrestrial civilisations whose technological powers are no greater than ours by concentrating radiated power and receiver sensitivity in a narrow band of frequencies and a narrow field of view

Frequency selection is a problem that seems to be tractable

because there are clearly defined markers, spectral lines of hydrogen and hydroxyl, in the low noise region of the radio spectrum[1,2] Although there may be no single optimum frequency, the number of frequencies that must be considered seems to be quite small

The number of stars that can be considered as possible homes for communicative civilisations, on the other hand, is very large Recent studies[3-6] agree that the chances of two civilisations establishing contact are exceedingly small in the absence of time markers that will tell the two civilisations when to search for one another Here we point out that suitable time markers do exist for binary stars They are the turning points of the stellar orbits, periastron and apastron

Single star civilisations would logically transmit signals to binaries at the observation of periastron and apastron Binary star civilisations would scan single stars at a time $2T$ after periastron and apastron, where $2T$ is twice the signal propagation time between the stars The length of scan need be no longer than twice the uncertainty in T Contact signals from different stars would arrive at different times at the binary system because of differences in the value of T for each candidate This strategy would enable a binary star civilisation to complete a search of nearby stars with a small number of telescopes after only a few orbital revolutions

The same strategy would be followed for transmissions from one binary civilisation to another Contact signals would be sent at the time of observed periastron and apastron of the receiving civilisation Contact signals would be sought at a time $2T$ after local periastron and apastron

The strategy for a binary civilisation attempting to contact a single star civilisation depends on whether the signals are transmitted isotropically or non-isotropically Signals transmitted isotropically from a binary at its own periastron and apastron will arrive at each target star at the observation of periastron and apastron On the other hand, with non-isotropic transmission, individual transmissions must be made to all target stars, necessitating very short transmissions or a very large number of transmitters A solution to this problem would be to delay transmissions by a time known to both civilisations, that is T This would preserve the time markers but spread the calls out in time

It may, on the other hand, be preferable to send the contact signals to single stars at the times when the angular distance between the binary stars as seen from the target star is either a maximum or a minimum These times are known to both civilisations Because they depend on the orientation of the orbit with respect to the line joining transmitter and receiver the times are different for each target star Simultaneous calls to many candidates are therefore avoided by this strategy

Although the optimum strategy may not be immediately apparent, these considerations limit the possibilities to the point where the search in time is no more difficult than the search in frequency For any advantage to be gained from these strategies, however, it is necessary that the number of reasonable contact times, multiplied by the duration of the search period required to accomodate errors in distance and in orbital elements, should not exceed the period of the binary star These strategies therefore require accurate knowledge of stellar parallaxes The strategy of listening for contact signals from binary stars at the times of observed turning points of the orbit or at the times of maximum angular separation does not require knowledge of the distance on the part of the receiving civilisation, however, so it might be advantageous for us The transmitting civilisation does need to know the distance in order to determine when to listen for replies, but binary star civilisations should be able to measure stellar parallaxes more accurately than we can because of the long baseline provided by the binary orbit

There is no shortage of binary star systems that may be the homes of communicative civilisations Of the 100 nearest stars at least 40 are visual binaries, and a total of more than 50,000 visual binaries are known[7] The probability of the existence of habitable planets in binary star systems has been examined by

Dole[8,9] and Huang[10,11] There seems to be no reason why visual binaries should not have habitable planets, provided one or both of the stars is of suitable spectral class and provided their ecospheres have radii considerably smaller than the separation at periastron

In the Worley Catalog of Visual Binary Orbits[12] there are 536 systems with known orbits and periastron dates Of these we have determined that about 300 systems may have habitable planets about one or both components The number of stars in these systems that may support habitable planets exceeds 500 As an illustration of the possibilities we have prepared a partial list of opportunities for the detection of signals from civilisations associated with visual binaries that we judge to be habitable Considering only systems closer than 300 light yr we find 34 opportunities between 1975 0 and 1980 0

If there are communicative civilisations associated with any of the nearby binary stars it should occur to them, as it has to us, to use the orbital motions of their stars as an indicator of when to send and when to look for contact signals There seems to be a reasonably small number of possibilities These considerations could lead to a non-random search programme with some chance of success They could also provide a practical basis on which to initiate our own transmission of contact signals

Upper atmospheric thermal structure in Antarctica

THE mesospheric wind results derived for atmospheric altitudes between 50 and 90 km from meteorological rocket flights carried out at Molodezhnaya station (67° 40′ S, 45° 51′ E) in Antarctica have been discussed in ref 1 The rapid shifts in both zonal and meridional components of the winds during May to July indicated a sudden 'explosive' change in temperature distribution in the upper mesosphere over Antarctica in the winter regime I have investigated this phenomenon and extended the study down to the stratosphere, the results are discussed here The meridional and the zonal temperature gradients at altitudes of 65, 70 and 75 km, derived from the thermal wind equations using the corresponding upper wind and temperature results, have also been studied Atmospheric temperatures up to an altitude of about 80 km were also measured and the accidental root mean square errors in the determinations were as follows in the altitude region 60 to 80 km it does not exceed

7 to 10 °C, at 50 km it is 5 °C, and below 40 km the error is less than 3 °C

Time-height cross sections of the mesospheric temperatures in the region 50 to 80 km are plotted using the conventional interpolation method in Fig 1 Meridional and zonal temperature gradients are derived for altitudes of 65, 70 and 75 km from the corresponding upper wind and temperature results using the thermal wind equations

$$\frac{\partial T}{\partial y} = \frac{fT}{g}\left(\frac{\partial u}{\partial z} - \frac{u}{T}\frac{\partial T}{\partial z}\right)$$

$$\frac{\partial T}{\partial x} = \frac{-fT}{g}\left(\frac{\partial v}{\partial z} - \frac{v}{T}\frac{\partial T}{\partial z}\right)$$

where f is the coriolis parameter, g the acceleration due to gravity, T the absolute temperature at a particular level, x, y, z the eastward, northward and vertical axes, u, v the zonal and meridional components of winds with west and south positive, respectively The horizontal temperature gradients are given in Table 1

Time sections of the upper atmospheric temperatures showing annual variations at the altitudes 30, 50 and 70 km as derived from the successful 1972 rocket soundings are plotted in Fig 2 Corresponding upper atmospheric warming and cooling of more than 15 °C over periods of less than 15 d are given in Table 2 for 5-km altitude intervals during the winter period May to August and early spring

Figure 1 and Table 1 are confined to the mesosphere only, whereas Fig 2 and Table 2 extend the study to the stratosphere Figure 1 shows that in the southern summer months January–February the mesospheric temperatures in the region 50 to 80 km ranged from about 10 to −110 °C, with the summer maximum reached by about January 5 in the lower mesosphere and by about January 26 in the upper mesosphere The disruption of the mesospheric winter regime by a period of stormy winds[1] is clearly shown in Fig 1 In the third week of May and the first week of July the upper mesosphere was subjected to a warming of more than 30 °C in less than a week The temperature distribution returned to normal by early September, but was again disrupted in about the third week

Table 1 shows that the horizontal temperature gradients at 65 km ranged from −37 to 10 °C per 5° latitude with a maximum on September 6 At 70 km the range was −31 to 30 °C with the maximum values on June 28 and May 17, whereas the gradients at 75 km ranged from −14 to 21 °C per 5° latitude with the maxima on September 6 and May 17, respectively Larger gradients were found from May to July, indicating a disruption by stormy winds having large wind shears of about 10×10^{-3} s^{-1} to 30×10^{-3} s^{-1} A similar disruption occurred in September The negative meridional temperature gradients represent a decrease of the zonal winds with altitude (the easterlies increase and the westerlies decrease with height) and the negative zonal temperature gradients represent an increase of the meridional winds with altitude (the northerlies decrease and the southerlies increase with height) On May 17 at 70 km the meridional temperature gradient was 30 4, suggesting a disruption by strong easterlies which decreased with height

Curve C in Fig 2 shows that at 30 km the stratospheric temperatures in Antarctica fall as the Sun sets, and that the minimum −75 °C is reached in June A slow temperature rise begins as the Sun returns, but this becomes much more marked after early September when the Sun's radiation reaches the lower strata Curve B (50 km, around the boundary of the stratosphere and the mesosphere) shows a warming of 23 °C during the second week of May followed by an equal cooling during the third week During the second week of July there was a mid-winter stratospheric warming of 30 °C The temperatures at 50 km ranged from a maximum of 12 °C in early

* °C per 5° latitude

December to a minimum of −45 °C at the end of May Curve *A* (70 km) reveals sudden 'explosive' changes in the upper mesospheric temperature distribution, particularly during the winter period May to July During the third week of May, a warming of 26 °C occurred, and in midwinter there was a warming of 31 °C during the first week of July followed by a 'sudden cooling' of 53 °C during the second week The temperatures at 70 km show a distinct maximum of −12 °C during the first week of July, after which the temperature declines irregularly, attaining a minimum of −93 °C in mid-November Again in September there was a disruption with a warming of 20 °C followed by a cooling of 33 °C after which the temperature distribution returned to the normal summer regime

Table 2 reveals that in May there was a significant warming both in the upper stratosphere and the mesosphere with a 'sudden warming' of 49 °C at 73 km from May 17 to 24 The warming was followed by a cooling of about 30 °C in the lower mesosphere From June 28 to July 5, a warming of 37 °C was detected at 65 km The upper stratosphere and the lower mesosphere were subjected to a warming from July 5 to 19, with a maximum of 38 °C at 55 km, whereas the upper mesosphere underwent a 'sudden cooling' which had a maximum value of 55 °C at 65 km from July 5 to 12 In August and

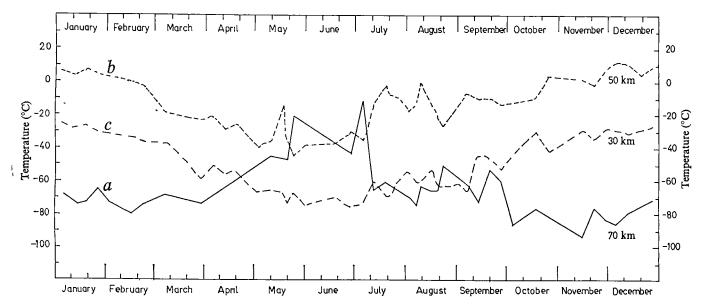
*°C
†Dates

September the warming in the mesosphere was less than 27 °C, while the stratosphere at 40 km experienced a cooling of 26 °C from August 2 to 9, followed by a warming of 32 °C from August 9 to 16 At 40 km there was another warming of 39 °C from September 6 to 20, which was followed by a cooling of 20 °C from September 20 to 27


This investigation of the Antarctic upper atmosphere indicates that the most active period in south polar regions is the winter and the early spring it is marked by large disruptions in the wind and thermal structure The rapid shifts in both zonal and meridional components of the upper atmospheric winds, particularly during the winter period May to July, were accompanied by sudden changes in the temperature distribution as revealed by warming and cooling in Fig 2

Figure 2 shows that the stratospheric warming in May propagated upwards and was followed by the mesospheric warming The stratospheric warming in July followed the

mesospheric warming, indicating downward propagation of the disturbance which started above 70 km This leads to the intuitive conclusion that the polar winter warmings may be caused both by an increase in the supply of energy in the form of a vertical flux of geopotential energy consisting of very long waves, and by radiative and photochemical processes taking place in the upper atmosphere During September, when the winter westerlies changed to the summer easterlies, the upper atmosphere was again disrupted with a warming of 39 °C at 40 km which is attributed to the increase in available heat brought about by the return of sunlight It is thus concluded that sizeable perturbations may occur in the upper atmosphere over Antarctica during the winter regime

Fig. 2 Time section of annual variation of the upper atmospheric temperatures (°C) for the altitudes 30, 50 and 70 km at Molodezhnaya, Antarctica, in 1972

part in the expedition, and giving me the privilege of being the first Indian explorer of Antarctica, which was made possible by the late Professor Vikram A Sarabhai I thank Professor P R Pisharoty for guidance and discussions I also thank my parents for inspiration

Phlogopite stability and the $^{87}Sr/^{86}Sr$ step in basalts along the Reykjanes Ridge

THE relatively sharp step in the $^{87}Sr/^{86}Sr$ ratio within basalts midway along the Reykjanes Ridge may reflect the breakdown of titaniferous phlogopite during variable fusion of an essentially homogeneous phlogopite-lherzolite upper mantle, extending beneath both Iceland and the submarine parts of the Mid-Atlantic Ridge

Schilling[1] detected substantial variation in the concentrations of several elements within basalts collected along the Reykjanes Ridge, south of Iceland To explain this he proposed two magma sources, a primordial hot mantle plume, relatively enriched in large-ion lithophile (LIL) trace elements and radiogenic Sr and Pb isotopes, rising beneath Iceland, and relatively LIL-depleted upper mantle within the low velocity layer beneath the Mid-Atlantic Ridge Mixing of these sources and/or their partial melt products was postulated to produce the chemical variation observed along the Reykjanes Ridge Subsequent work[2,3] showed that the transition from Icelandic (0 70304) to Mid-Atlantic Ridge (0 70270) values for the $^{87}Sr/^{86}Sr$ ratio in basalts was not by a smooth gradation but by a step confined to a zone 200–250 km south of the Reykjanes Peninsula Several other trace elements behave similarly Critics of the two-mantle-source model[4,5] have emphasised that most Icelandic basalts (some of which approach tholeiitic andesite compositions) are very strongly fractionated relative to the compositions of magmas that could conceivably have been generated by partial fusion of any postulated upper mantle material The rare-earth element (REE) patterns reported by Schilling[1] may be fitted adequately to a model invoking variable partial fusion of a single source[5]

The proposals of Schilling's critics do not account for two crucial observations first, the varying Sr and Pb isotopic ratios in the lavas, second, the high rate of magma production in Iceland relative to deep-sea sections of the Mid-Atlantic Ridge, as evidenced by thickening of the crust beneath the former[6] We are reluctant as yet to accept the two-mantle-source model because it is essentially defeatist It may eventually be proved that the two-mantle-source model is correct, but meanwhile the single-mantle alternative should continue to be considered We concentrate here on $^{87}Sr/^{86}Sr$ variation in the basalts, perhaps the most persuasive evidence for the two-mantle-source model, and attempt to show that it is not irreconcilable with a single mantle composition

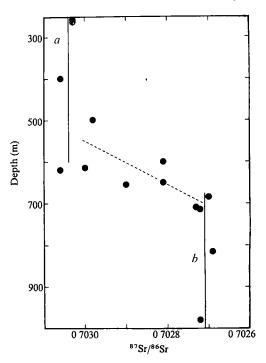
$^{87}Sr/^{86}Sr$ in basalts from the transition zone between the relatively isotopically-homogeneous lava groups of Iceland and the Mid-Atlantic Ridge shows a good correlation with the water depth at each collection site (Fig 1 and ref 3) This reflects local topographical irregularities in the Reykjanes Ridge and is not merely a result of the overall deepening of the Atlantic south of


Fig 1 $^{87}Sr/^{86}Sr$ of Reykjanes Ridge basalts as a function of the water depth from which they were dredged[1,3] The Iceland and Mid-Atlantic Ridge average values[3] of $^{87}Sr/^{86}Sr$ extend for a very much greater range of water depths (~ 0–2,500 m) along the axis of the North Atlantic than that covered by this diagram *a*, Mean $^{87}Sr/^{86}Sr$ for Iceland, *b*, mean for Mid-Atlantic Ridge

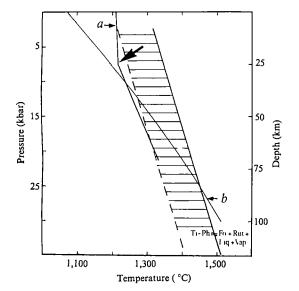
Iceland, there is little correlation of $^{87}Sr/^{86}Sr$ between the points in the transition zone in Fig 1 and their distance from the tip of the Reykjanes Peninsula Hart *et al* [3] attribute this relationship to dynamic interfingering between their two postulated mantle types This proposal seems improbable when the high postulated viscosity of the upper mantle (~ 10^{22} poise) at appropriate pressure and temperature[7] is compared with the small scale of topographical[8] and isotopic variation in the transition zone, lavas with distinctively different $^{87}Sr/^{86}Sr$ ratios are found as little as 2 km apart[3]

There are two alternative explanations of the $^{87}Sr/^{86}Sr$–depth relationship, both coming from discoveries[9,10] that volcanism on the Mid-Atlantic Ridge is essentially confined to the axis of the structure and that, as the European and American plates separate at a constant rate (on the spatial and temporal scale considered here), the thickness of the ridge lava pile, monitored by water depth, is a direct measure of the rate of magma production beneath each ridge segment It follows that

(1) If the system is constrained by assuming constant mantle circulation rates beneath both topographic highs and lows on the Reykjanes Ridge, a greater amount of mantle partial fusion must have occurred beneath the highs than beneath the lows during basalt genesis So the relative ^{87}Sr-enhancement of lavas from the highs may reflect the thermal breakdown of an ^{87}Sr-rich mineral in the upper mantle This phase would remain in the residuum during production of the magmas which give rise to the Mid-Atlantic Ridge basalts and only melt during more intense fusion beneath Iceland and the northern Reykjanes Ridge


(2) If the driving force behind the movement of separating lithospheric plates is independent of mantle turnover beneath mid-oceanic ridges[11], the mantle passively inflowing between them as they part could move at very different rates in different localities If mantle fusion is related to its flow rate through heat generation resulting from viscous dissipation[7], the topographical heights on the Reykjanes Ridge may simply reflect zones of relatively rapid mantle creep beneath them The degree of partial

melting involved in the production of each magma batch might in this case be the same beneath both the Mid-Atlantic Ridge and Iceland Indeed, it may be even less beneath the latter, if enhanced kneading within fast-flowing mantle causes a positive correlation between flow rate and efficiency of magma extraction during partial fusion[12] In this case it is possible that magma generation takes place at greater depths beneath Iceland than the Mid-Atlantic Ridge The $^{87}Sr/^{86}Sr$ step in Reykjanes Ridge basalts may mark the breakdown of an ^{87}Sr-rich mantle mineral with increasing pressure northwards at the site of partial fusion If the Reykjanes Ridge crust is extremely weak, as seems probable from what is known of the strength of thin hot crust elsewhere[13], its topographical irregularities may give rise to small local pressure differences (< 50 bar, see Fig 1) at the level of partial melting below The $^{87}Sr/^{86}Sr$–depth correlation within the transition zone in Fig 1 would then reflect passage of this ^{87}Sr-rich mantle phase in and out of its stability field along irregularities in the isobar marking its maximum stability at depth

Is there a likely upper mantle phase with the chemistry and *PT* stability to satisfy any parts of the genetic models discussed above ? We suggest that phlogopite is the mineral responsible for the $^{87}Sr/^{86}Sr$ step It has been postulated frequently as a minor phase in the upper mantle[14-19] and the suggestion has been made in two recent papers[20,21] that fusion of phlogopite might be important in controlling K, Rb, Ba and ^{87}Sr contents of Icelandic and Mid-Atlantic Ridge basalts But neither discusses the *PT* stability of phlogopite relative to other likely phases in the upper mantle

Experimental studies of the stability of synthetic Ti-free phlogopite[18,19,22] have indicated that, if undersaturated with water at moderate pressures, it would probably be stable up to the solidus of a peridotite upper mantle but would enter the first fraction of liquid formed But the phlogopite that occurs as a primary phase in generally-accepted xenolithic samples of the upper mantle, such as garnet–lherzolite blocks in rapidly erupted volcanic rocks[16], frequently has a substantial Ti content (< 9% TiO_2) Synthetic Ti-phlogopite [$K_2Mg_4TiAl_2Si_6O_{20}$ $(OH)_4$] has a considerably greater thermal stability at all in-

vestigated pressures than its Ti-free analogue[23] Even making allowance for the presence of other mantle phases (extrapolated from the Ti-free phlogopite data), it seems probable (Fig 2) that Ti-phlogopite would remain in the residuum after fusion of a considerable fraction of a peridotite upper mantle at pressures below about 10 kbar Only at higher pressures would Ti-phlogopite enter near-solidus melts

The data of Fig 2 may be applied to upper mantle fusion beneath Iceland and the Mid-Atlantic Ridge, if the geothermal gradients in these areas are known The latter are not easily extrapolated from surface heat-flow measurements in regions of active volcanism, because of magma movement near the surface, and geothermal water circulation Experimental petrology is an alternative way of approaching the problem Kushiro ard Thompson[24] studied the melting behaviour of Mid-Atlan Ridge lavas as a function of pressure One of the most Mg-r ᴗh of the phenocryst-poor basalts (MgO = 9 17%) as yet known from the Ridge shows liquidus coprecipitation of three phases (olivine + pigeonite + plagioclase) at 7 5 kbar The simplest interpretation of this phenomenon[24] is that the basalt formed by fusion of a plagioclase–lherzolite upper mantle at 7 5 kbar and was erupted without significant further modification Fe/Mg of phases near liquidus in the basalt indicate a residual mantle, after Mid-Atlantic Ridge basalt extraction, with Mg/(Mg+Fe) ~ 0 85, in accordance with estimates from other volcanic areas[11,25] Acceptance of a primary magma hypothesis for this lava allows calculation of a Mid-Atlantic Ridge geothermal gradient, fitted to the liquidus temperature (1,215 °C) at the four-phase point The result of 45 °C km^{-1} overall corresponds well with previous estimates by other methods[26,27] Unfortunately, there are no comparable experimental data available as yet to allow calculation of Icelandic geotherms

If the geotherm below the Mid-Atlantic Ridge reaches 1,215 °C at about 7 5 kbar, it is appreciably above the anhydrous solidus at that pressure of either a pyrolite[28] or a Mg/(Mg + Fe) = 0 85 lherzolite[29] upper mantle (Fig 2) But it is approximately at, or slightly below, the extrapolated stability limit of Ti-phlogopite

The two models for the $^{87}Sr/^{86}Sr$ step in basalts from the Reykjanes Ridge may now be reassessed

(1) If the degree of mantle partial fusion during magma genesis increases northwards beneath the Reykjanes Ridge, then the $^{87}Sr/^{86}Sr$ step in Fig 1 and its correlation with thickness of lava pile may reflect the isobaric breakdown of titaniferous phlogopite in the source of the basalts This proposal leads to the surprising conclusion that the relative enrichment of Icelandic basalts in the 'incompatible' elements K, Rb, Cs, Ti, Ba and ^{87}Sr (ref 28) may not be because they originate as lesser fractions of mantle fusion than Mid-Atlantic Ridge basalts At first sight this seems highly improbable, because light REE and P are also concentrated in the Icelandic lavas But phlogopite can be relatively enriched in the light rare-earth elements[30] and its breakdown could contribute these elements to the melt Furthermore, concomitant REE and P variation may reflect the stability relations of apatite in the upper mantle The behaviour of this phase during partial fusion may be as complex as that postulated here for phlogopite Until this is known, or until data are published for LIL elements that are not concentrated in apatite or phlogopite, it seems premature to reject this model for the chemical variation in the Reykjanes Ridge basalts

(2) If the depth of the partial fusion zone increases northwards, the $^{87}Sr/^{86}Sr$ step beneath the Reykjanes Ridge may mark the intersection of this zone with the Ti-phlogopite breakdown curve In this model the degree of partial melting could decrease towards Iceland, so that apatite might then be envisaged as entering the first melt fraction An attractive feature of this alternative is apparent when it is applied to the general problem of the chemical differences between mid-oceanic ridge and ocean island lavas, of which the Iceland–Mid-Atlantic Ridge system is just a facet Ocean islands forming away from the crests of mid-oceanic ridges are composed, in general, of lavas less saturated in Si than those erupted at spreading axes[17,31,32] The available

Fig 2 *P–T* diagram correlating the following data anhydrous solidus of pyrolite[28], a possible model composition for the upper mantle, anhydrous liquidus of Mid-Atlantic Ridge magnesian basalt T-87 (ref 24), upper limit of thermal stability, in conditions free from vapour, of titaniferous phlogopite and extrapolation of this to stability in the presence of other likely upper mantle minerals[23] , "T-87 Geotherm" (see text), — — —, extrapolated stability, *a*, T-87 liquidus, *b*, anhydrous pyrolite solidus Arrow marks four-phase point

experimental data[29,33] indicate that partial fusion of a lherzolite upper mantle at less than 8 kbar, as postulated earlier for Mid-Atlantic Ridge basalts, could not yield nepheline-normative magmas, however low the degree of partial melting The latter have probably been generated at pressures above about 15 kbar (refs 25, 29, 33)

The largest potential weakness in all the foregoing argument concerns [87]Sr/[86]Sr equilibration amongst mantle phases This must be assumed not to occur either before or during partial fusion, if enrichment of magmas with [87]Sr is to be linked with phlogopite stability Most [87]Sr in phlogopite-lherzolite mantle will be generated from Rb contained in the phlogopite Isotopic studies of the minerals within peridotite xenoliths from sub-continental upper mantle sources indicate approximate equilibrium[34] in phlogopite-bearing garnet-lherzolites and disequilibrium within spinel-lherzolites[35,36] The relevance of data derived from material originating in continental parts of lithospheric plates to conditions in the sub-oceanic upper mantle requires further study At present we strongly support the geochemically based model of O'Nions and Pankhurst[21], which postulates lack of isotopic equilibration amongst the solid phases of a homogeneous phlogopite-lherzolite upper mantle, both before and during its partial fusion at sites of magma genesis, as the cause of [87]Sr/[86]Sr (amongst other) differences between Mid-Atlantic Ridge and Atlantic Ocean Island lavas

I L Gibson, M J O'Hara and P Suddaby made detailed constructive criticisms of the manuscript M F J F and H-U S received support from the Deutsche Forschungsgemeinschaft

Note added in proof Our attention has been drawn to a paper by M J O'Hara, M J Saunders and E L P Mercy (*Phys Chem Earth*, in the press) which contains ideas very similar to ours on the postulated major role of upper mantle phlogopite in controlling [87]Sr contents of basalts

Palaeogeotherms and the diopside–enstatite solvus

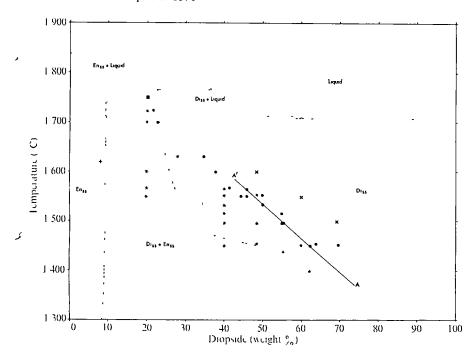
THE precise composition of the solid solutions that develop between diopside and enstatite has provided a basis for estimates of the temperature of equilibration of mineral assemblages from peridotites We report here results of a reinvestigation of these relationships, which demonstrate that the range of solid solutions formed at high temperatures is less than previously believed, and that it is dependent on both pressure and silica activity The stable existence of an iron-free pigeonite has not been confirmed

Garnet-lherzolite xenoliths in kimberlite are widely accepted as xenoliths of the upper mantle They contain olivine, garnet and enstatite coexisting with a clinopyroxene They can be divided into two groups, in one the clinopyroxene is calcic and in the other it is subcalcic The distribution of analyses of the clinopyroxenes is bimodal[1]

Temperatures and pressures of equilibration of the mineral assemblages in individual nodules from the xenoliths have been estimated[2] The palaeogeotherms which existed in the upper mantle immediately before incorporation and transport of the xenoliths by kimberlite eruptions have been derived from data from large numbers of individual xenoliths[2] These geotherms show an abrupt rise in the rate of increase of temperature with depth, coincident with the change in clinopyroxene composition from calcic to subcalcic diopside

The temperature estimates were based on a comparison of the Ca/Ca+Mg ratio of the diopside coexisting with enstatite in the natural rocks, with the Ca/Ca+Mg ratio of diopside coexisting with enstatite in the system $CaMgSi_2O_6-Mg_2Si_2O_6$, as determined by experiments at 30 kbar (ref 3) The procedure assumed this relationship to be independent of pressure The results on the synthetic system indicate that enstatite is in equilibrium with a single clinopyroxene phase over the whole temperature range investigated and that the composition of that diopside solid solution changes continuously with temperature The rate of change of the diopside composition did not, however, vary regularly, and reached a maximum at temperatures close to 1,450 °C (ref 3) A study[4] of the same system at 20 kbar reported an abrupt change of the clinopyroxene coexisting with enstatite at this same temperature, from a calcic diopside at lower temperatures to a pigeonite at higher temperatures Above 1,450 °C a further solvus was reported between the pigeonite and a more calcic diopside The composition–temperature field occupied by a single clinopyroxene solid solution in the results reported[3] at 30 kbar is thus occupied by three fields, of clinopyroxene A (diopside), clinopyroxene B (pigeonite) and clinopyroxene A plus clinopyroxene B in the results reported[4] at 20 kbar

The possibility that the abrupt change from diopside to pigeonite in equilibrium with enstatite might have a bearing on the abrupt change from calcic to subcalcic diopside in the xenoliths from kimberlite, and on the change in slope of the inferred palaeogeotherms, prompted this reinvestigation of the clinopyroxene limb of the solvus at 20 and 30 kbar, the results show that pigeonite is not an equilibrium product in this system at those pressures The position of the equilibrium diopside limb of the solvus at high temperatures is very different from that observed by Davis and Boyd[3] Coexisting diopside and enstatite solid solutions do not have the same Si/Ca+Mg ratio, that is, the join $CaMgSi_2O_6-Mg_2Si_2O_6$ cuts across the tie lines linking coexisting diopside and enstatite solid solutions which depart, in opposite senses, from the ideal 1 1 ratio of Si/Ca+Mg The position of the diopside limb is, moreover, pressure dependent

The discrepancies between these and previous results are predominantly a function of the nature of the starting material Results obtained from glass starting materials yield metastable


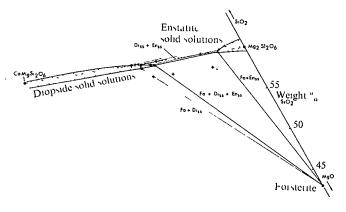


Fig 1 Results obtained at 30 kbar from compositions lying along the diopside–enstatite join, shown in relation to the interpretation by Davis and Boyd[3] (-----) A–A' = The diopside limb of the diopside–enstatite solvus obtained from runs on the gel composition $Di_{40}En_{60}$ weight % Results from gel starting materials ★, bulk composition and temperature of runs which crystallised to a solid solution of diopside plus enstatite, ●, composition of diopside in equilibrium with enstatite, from X-ray measurements, ×, homogeneous diopside solid solution obtained, +, enstatite solid solution obtained, ■, enstatite solid solution plus liquid, ○, liquid, ▲, composition of diopside solid solutions coexisting with enstatite solid solution crystallised from the glass of bulk composition $Di_{40}En_{60}$ weight %, , solidus in present work SS, solid solution (in all figures)

products When very fine-grained crystallised gels are used as starting material they react readily and completely to yield the equilibrium products

A high pressure piston-cylinder apparatus (see ref 5) was used in these experiments Temperatures were measured using Pt/Pt 13 rhodium thermocouples with no correction for pressure effects The starting materials were finely ground gels which had been recrystallised at 900 °C Runs were made both on homogeneous gels ($Di_{40}En_{60}$, $Di_{50}En_{50}$) and on mechanical mixtures of pure diopside and enstatite gels (bulk compositions $Di_{20}En_{80}$, $En_{28}En_{72}$, $Di_{40}En_{60}$, $Di_{60}En_{40}$, $Di_{69}En_{31}$) All compositions are quoted in weight % A glass of composition $Di_{40}En_{60}$ was also used for more direct comparison with the earlier works[3,4] which had used glass starting materials All charges were dried at 1,050 °C for 1 h and sealed in platinum capsules Runs were initially taken to 5 kbar above the desired pressure, the excess pressure being bled off when the required temperature was reached In the temperature ranges 1,450–1,500 °C, 1,500–1,565 °C and above 1,600 °C, the durations of the runs were at least 4 h, 2 h and 0 5 h, respectively, except where stated At 1,450 °C no change in the clinopyroxene composition occurred when experiments were run for longer

Fig 2 Part of the system $MgO–SiO_2–CaO$(weight %) at 30 kbar and 1,550 °C, showing bulk compositions of charges (+), and measured clinopyroxene compositions (●), in relation to inferred variation of SiO_2 in the diopside solid solution field (the extent of which along the join $CaMgSi_2O_6–Mg_2SiO_4$ is taken from refs 6 and 7) Tie lines to inferred enstatite compositions (▲) are shown intersecting the $CaMgSi_2O_6–Mg_2Si_2O_6$ join

than 1 5 h, and it was therefore assumed that equilibrium had been attained in all experiments used for drawing up the diopside solvus

Products were identified by optical and X-ray diffraction methods Attempts made to analyse clinopyroxenes using the electron microprobe failed because of the small grain size (< 5 μm) of the crystals, it was not possible to focus the electron beam on a unique grain, and interference from adjacent crystals produced a wide range of clinopyroxene compositions (for example, $Ca/Ca+Mg = 0 10–0 25$ in one of the coarser grained charges) The X-ray diffraction technique used chromium radiation in an evacuated chamber Compositions of clinopyroxenes were estimated from the relationship reported by Davis and Boyd[3] which our study verified as valid between 20 and 69 weight % diopside Clinopyroxene compositions could be obtained with a precision of ±1% diopside (99 7% confidence limits) The precision is rather less good for charges containing large amounts of enstatite This technique is capable of resolving two clinopyroxenes differing by as little as 10 weight % of diopside Clinopyroxenes which crystallised in equilibrium with enstatite at 30 kbar from the starting composition $Di_{40}En_{60}$ lay along the curve A–A' (Fig 1) irrespective of whether or not the homogeneous gel or the mixed diopside–enstatite gel was used Clinopyroxenes which crystallised from starting compositions $Di_{20}En_{80}$ and $Di_{28}En_{72}$ lay away from this curve by up to 4 weight % diopside towards enstatite, clinopyroxenes from starting compositions $Di_{50}En_{50}$ and $Di_{60}En_{40}$ lay up to 7 weight % diopside away from curve A–A[1] towards pure diopside When 10 weight % of forsterite was added to each of the gels $Di_{20}En_{80}$ and $Di_{40}En_{60}$ at 1,550 °C and 1,565 °C, constant clinopyroxene compositions of $Di_{41 5}En_{58 5}$ and $Di_{42}En_{58}$, respectively, were generated from both compositions This indicates that in detail the parageneses have the form shown in Fig 2

Experiments using glass of composition $Di_{40}En_{60}$ as starting material yielded homogeneous clinopyroxene above 1,440 °C as required by Davis and Boyd's[3] phase diagram which was obtained from runs on glass charges At 1,440 °C and 1,400 °C this starting material crystallised to enstatite and clinopyroxenes which lay exactly on the diopside limb of Davis and Boyd's[3] solvus

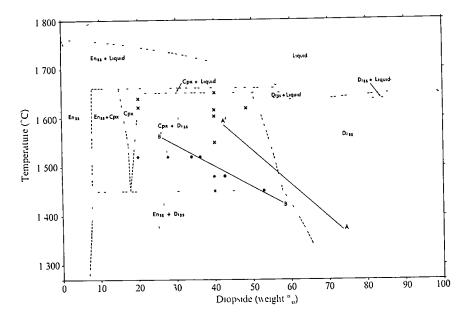
Runs on the homogeneous gel $Di_{40}En_{60}$ at 1,450 °C yielded enstatite and a clinopyroxene Di_{56} after 10 s and a progressively more magnesian clinopyroxene (up to Di_{50}) in longer runs of up to 30 min This trend towards the solvus found by Davis


Fig 3 Results obtained in this work at 20 kbar from compositions lying along the diopside–enstatite join, shown in relation to the interpretation by Kushiro[4] B–B'= Approximate position of the diopside limb of the diopside–enstatite solvus obtained from experiments on gel starting materials A–A', and all symbols as in Fig Cpx, clinopyroxene

and Boyd[3] was reversed in longer runs, as the clinopyroxene changed towards the solvus A–A' (Di_{60} after 50 min, Di_{63} after 90 min), indicating the latter to represent the closer approach to equilibrium The effects may indicate that the exchange of Ca and Mg between the two pyroxenes proceeds more rapidly than the adjustments in silica content implied in Fig 2

Figure 3 shows the results at 20 kbar from compositions lying on the diopside–enstatite join in relation to phase boundaries obtained[4] using glass charges We found that enstatite coexists with a diopside lying close to the curve B–B' (Fig 3) The boundary B–B' at 20 kbar is significantly displaced towards En relative to A–A' at 30 kbar, but this pressure effect is for charges which were not saturated with forsterite The pressure effect is, however, also significant in forsterite saturated charges Forsterite (10 weight %) was added to the mixed gel of bulk composition $Di_{20}En_{80}$ at 1,520 °C The clinopyroxene which crystallised in equilibrium with enstatite and forsterite had the composition $Di_{37.5}En_{62.5}$ When the temperature of the forsterite bearing assemblage at 30 kbar is raised by 30 °C the clinopyroxene becomes 4 weight % richer in diopside The effect of pressure on the diopside solvus (20–30 kbar) at 1,535±15 °C is to increase the amount of apparent diopside by 0 8 weight % per kbar in forsterite saturated assemblages The effect in the stoichiometric join $CaMgSi_2O_6$–$Mg_2Si_2O_6$ is not necessarily the same as this Translated into temperatures this would represent an error of +7 °C per kbar for assemblages equilibrated at a higher pressure than that of the experimental determinations

Material of composition $Di_{20}En_{80}$ yielded a homogeneous clinopyroxene at 1,620 °C and diopside and enstatite at 1,520 °C Kushiro[4] predicted an assemblage of pigeonite plus minor diopside for the 1,520 °C run Material of composition $Di_{40}En_{60}$ yielded diopside plus enstatite at 1,450 °C and 1,480 °C and a single homogeneous clinopyroxene of composition $Di_{40}En_{60}$ at 1,550 °C The two higher temperature runs lie within the reported[4] field of diopside plus pigeonite stability but fail to verify its existence Runs on bulk composition $Di_{40}En_{60}$ at 1,620 °C using homogeneous gel and glass starting materials, and at 1,614 °C using the mixture of diopside and enstatite gels, all yielded a homogeneous clinopyroxene There was again no evidence for the coexistence of two clinopyroxenes as required by Kushiro[4] He reported[4] that he was not able consistently to generate the pigeonite plus diopside assemblage It is possible that the two clinopyroxene field is a quenching phenomenon Deliberately slow quenching of the $Di_{40}En_{60}$ gel, run at 1,620 °C failed, however, to produce two clinopyroxenes,

nor were they obtained from glass or homogeneous ge starting materials of the $Di_{40}En_{60}$ composition when run at 1,620 °C in the same equipment used[4] by Kushiro We conclude that there is no stable field of pigeonite separate from a diopside field on this join at 20 kbar

In the light of these results the temperatures on the geotherm estimated by Boyd[2] may require some revision, and the method should only be applied to olivine saturated assemblages when compared with a diopside solvus determined in the presence of excess forsterite

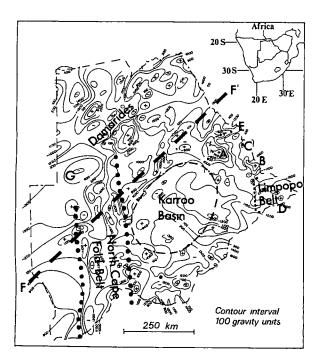
Crustal structures in central southern Africa

WE announce preliminary results from the geophysical reconnaissance of Botswana carried out during 1972 and 1973 Tertiary to Recent sands and sediments in the Kalahari Basin totally obscure the solid geology over 70% of the country, but these new results give exciting first indications of the disposition of geological features in the concealed 'basement' when related to the better known geology of the surrounding territories The new data also suggest the extent of the concealed sedimentary and volcanic strata of Karroo age, and their possible relationship to the recent, if slight, tectonic instability in the heart of the continental plate This work forms part of Botswana's contribution to the International Geodynamics Project[1]

A network of 2,131 gravity stations was established over Botswana's thinly populated 575,000 km² land area, over much of which access and communication by land is difficult and slow A network of gravity base stations at 23 strategic airstrips was established using two LaCoste and Romberg gravimeters


transported by light aircraft[2] and the intermediate stations were reached either by truck or helicopter Altitude control of barometric observations was provided by the 1964 primary triangulation (Directorate of Overseas Surveys) and by more recently completed precise levelling routes (Department of Surveys and Lands, Botswana) Navigation equipment on trucks was essential for position fixing Total-field magnetic observations were made at 1,300 of the gravity stations

A mean negative Bouguer anomaly of about 1,150 gravity units (1 g u $= 10^{-6}$ m s$^{-2} = 0$ 1 mgal) persists over the whole country, reflecting the isostasy of the monotonously flat continental plateau which stands at about 1,000 m above sea level, while locally Bouguer anomalies range in value from -700 g u to $-1,500$ g u

In the geologically better known areas in the east of the country the denser rocks of the isolated greenstone belts or "schist relics"[3] in the Archaean basement produce local positive gravity anomalies By far the largest of these is at Matsitama (A, Fig 1) and smaller ones are found at Tati (B), Vumba (C), Baine's Drift (D) and Maitengwe (E) Similar anomalies over schist belts in both South Africa and Tanzania have been discussed by Darracott[4,5] But even the anomaly over the Barberton Mountainland, South Africa, is much smaller, both in area and amplitude, than that at Matsitama Here causative dense rocks must extend westwards below the cover of Karroo and Kalahari sediments beyond the confines of the exposure mapped geologically and a further, arcuate, extension of the Matsitama anomaly (A–E) runs north, then north-eastwards to link up with the anomaly at Maitengwe The cause of this arcuate structure is entirely concealed by more recent cover, but a connection between the two "schist relics" was predicted on purely geological grounds[3] It is convincingly delineated by the new geophysical evidence which may therefore have considerable economic importance

The gravity 'high' in the area of the northern Transvaal and southern Rhodesia border, recognised in earlier surveys and attributed to the Limpopo Mobile Belt, quickly disappears when traced westwards into Botswana, becoming extinct west of Selebi–Pikwe This corroborates recent thinking[6] that the Limpopo Belt may terminate in this region and does not continue westwards to intersect the Damaran Belt[7] nor swing southwards to join the North Cape Fold Belt

Fig. 1 Bouguer anomaly map of Botswana showing preliminary interpretation

Contour interval 100 gravity units

250 km

In east central Botswana a large featureless area of the Bouguer anomaly map seems to characterise the Karroo Basin and suggests its western and southern limits, where there is no geological control as yet[8] An earlier study of the seismicity of Botswana[9] shows this same area as notably aseismic Together these factors tend to support Green's suggestion[8] that the deposition of the Karroo strata was controlled by epeirogenic movements of a rigid continental plate, rather than by multiple or migratory rifting, at least in the area indicated in Fig 1

The geological significance of a "Kalahari Seismicity Axis"[9], based on recent epicentre data and supported by the disposition of photogeological features, is well supported by the gravity data, where a considerable anomaly gradient follows much of the length of the axis (F–F') Seismic activity may be associated with an abrupt change in crustal thickness or density along this line This might be the edge of the foreland to the Damaran orogenic belt, an incipient Rift, or both, but whatever its significance, the Kalahari seismicity axis divides the gravity anomaly map into areas of distinctly different "texture" South-east of the seismicity axis the gravity anomaly field is largely featureless, devoid of steep gradients and localised anomalies, while to the north-west numerous large anomalies, both positive and negative, are evident Many of the anomalies are elongated in an approximately NE–SW direction, giving an overall impression of a strong north-easterly strike over the entire north-west half of Botswana This area includes the seismically active Okavango Delta where recent seismic refraction studies have shown[10] that some of the faults determining the south-east margin of the delta[9] are downthrown by as much as 300 m to the north-west and probably postdate the Karroo But faulting even on this scale can only make a relatively small contribution to the observed gravity anomalies

The only area of extensive rock outcrop in western Botswana is the Ghanzi Ridge where there is a major gravity "low" (G) Here the rocks are considered to be part of the Damara orogenic belt and, by extrapolation, we suggest that Damarides may underly the entire area north-west of the Kalahari seismicity axis Anomalous density distribution resulting from folding and intrusion could account for the pattern of gravity anomalies characterising this area This, however, contrasts with the findings of Darracott[11] that the Mozambique orogenic belt is featureless in gravity anomalies compared with the adjacent cratonic area in East Africa! We do, however, believe that it is significant that both the Okavango seismicity and the 'Kalahari Seismicity Axis' seem broadly associated with areas we now presume to be underlain by the Damaran orogenic belt

Striking north from the vicinity of Tshabong in southernmost Botswana a clear trend extends that recognised in the gravity survey of South Africa[12], characterised by the large positive and negative anomalies in the vicinity of Olifantshoek in the North Cape Fold Belt On the Bouguer anomaly map of Botswana this trend may be traced as far north as Ghanzi, where it seems to become engulfed in the north-easterly, supposed Damaran, trend A major negative anomaly in the regional magnetic contours south of Ghanzi is coincident with the northerly gravity trend We conclude that the North Cape Fold Belt (10^9 yr) recognised in the Cape Province continues in a northerly direction as far as Ghanzi where it becomes lost in the Damaran remobilisation (5×10^8 yr), the whole being concealed below the Karroo and Kalahari cover

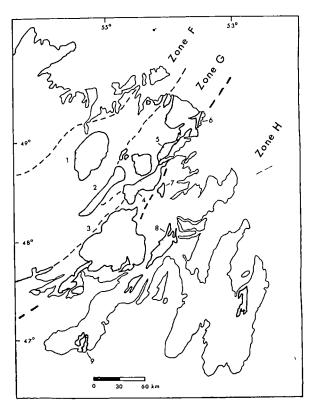
Geochronology of eastern Newfoundland

WHOLE-ROCK Rb–Sr isochrons from granitoid rocks intruded into the easternmost part of the Central Mobile Belt and the Avalon Platform of Newfoundland indicate that the bulk of the plutonic activity took place during Devonian and Carboniferous times Of the nine intrusions that were dated, only one, a Cambrian granite from the Avalon Platform, was significantly older

The Appalachian System in Newfoundland can be divided into three geological provinces, each characterised by a distinct geological history[1-3] the Western Platform, the Central Mobile Belt and the Avalon Platform Volcanic rocks of Early Palaeozoic age (the Central Mobile Belt) are sandwiched between two blocks of Precambrian basement and Palaeozoic platformal sedimentary rocks A more refined subdivision may also be possible, with the island divided into eight zones (designated A to H), each characterised by a distinct Ordovician and/or pre-Ordovician history of deposition and folding[4] The northern and western parts of the island have been studied in detail, and the geology of those areas has furnished some of the basic observational information used to synthesise models for the evolution of orogenic belts[5] and the origin and emplacement of ophiolite complexes[6] The central parts of the island have not been so well studied

Granitoid rocks make up a significant proportion of the total volume of rocks exposed in Newfoundland and contribute (Map 1231A, Geological Survey of Canada) about 40 per cent of the total area of granitoid rocks exposed in the Canadian Appalachians The ages of a few of the intrusions are known from stratigraphic evidence, and some K–Ar measurements have been made on others, but the timing of the magmatic activity remains obscure These K–Ar ages are mostly single determinations on single mineral phases, and must be interpreted with caution The isotopic ages obtained so far range from 330 to 450 Myr, with the bulk of them between 340 and 400 Myr These granites have been related to the Devonian Acadian Orogeny and the K–Ar ages seemed grossly in agreement with this opinion Other intrusions, however, are believed to be significantly older[7]

Here we summarise results of a geochronological study of granitoid rocks from Zones F, G and H in eastern Newfoundland Full details will be published elsewhere Nine intrusions were dated by the Rb–Sr whole-rock method (Fig 1)


Rb–Sr ratios and concentrations were determined by X-ray fluorescence The ratios and the concentrations are considered to be accurate to $\pm 3\%$ (95% confidence level) of the quoted value Sr isotope ratios were measured on a 15-cm, 90°, solid-source mass spectrometer Our reproducibility is one part in 700 at the 99% confidence level Measurements of the Eimer and Amend Sr carbonate standard gave an $^{87}Sr/^{86}Sr$ ratio of 0 7077 $\pm$ 0 0003

The whole-rock Rb–Sr ages (Table 1) are calculated on the basis of the $1 47 \times 10^{-11} yr^{-1}$ decay constant for ^{87}Rb They indicate that (1) Of the nine granites sampled, six are either Silurian or Devonian according to the 'absolute' time scale,

and thus could fall within the generally accepted time span associated with the Acadian Orogeny (2) Bearing in mind the uncertainties assigned to each age, it seems that in Zones F and G, granite magmatism had started by the Silurian and continued into the early Carboniferous Plutonic activity on the Avalon Platform (Zone H) extended much further back, at least into Cambrian times (3) None of the granites in Zones F and G that were analysed are of pre-Middle Ordovician age This is surprising because many of the foliated leucogranites, particularly those associated with the metamorphic terrain, were considered to be that old on geological grounds[7]

Two models have been suggested for the geological evolution of eastern Newfoundland Kennedy and McGonigal[7] divided the region into three distinct terrains a basement or gneissic terrain of possibly Precambrian age, a metasedimentary terrain of pre-Middle Ordovician age, and a Middle Ordovician sedimentary and volcanic terrain Kennedy and McGonigal suggest that the gneissic rocks not only underlie the eastern part of the Central Mobile Belt but that they may also form a sialic basement to the Avalon Platform This relationship between the underlying basement and the Gander Lake Group (redefined to include only the metasedimentary terrain) resembles that of the Precambrian (in part Grenville) rocks of the Western Platform and the overlying Cambro-Ordovician sequences A similar relationship also exists between the basement gneisses of the western flank of the Central Mobile Belt and the overlying Fleur de Lys Supergroup A correlation of the newly-defined Gander Lake Group and the Fleur de Lys Supergroup is considered in terms of two sedimentary units that form continental prisms thickening from the eastern and western platforms on to the central belt

By contrast, the plate tectonic model of Strong *et al*[9] involves a south-easterly-dipping subduction zone, with the Avalon Platform forming a continental margin, and with the plutonic rocks of the Gander Lake Metamorphic Belt (Zone G) inter-

Fig 1 Sketch map (after Strong *et al*[10]) of the granitoid rocks of eastern Newfoundland The numbered granites are 1, Mt Peyton, 2, Middle Ridge, 3, Ackley City, 4, Freshwater Bay, 5, Middle Brook, 6, Cape Freels, 7, Terra Nova, 8, Swift Current, 9, St Lawrence

Table 1 The analytical data

Locality	Normative composition[10]	Petrographic notes[10]	No of points	Age (Myr)	Mean square of weighted deviates (MSWD)†
St Lawrence	Granite	Alaskite granite–rhyolite porphyry–abundant veins and fracture fillings of fluorite	4	315 ± 10*	3 2
Terra Nova	Granite	Coarse-grained granite—also microcline, megacrystic variety	4	335 ± 20	0 3
Ackley City	Granite–quartz monzonite	Orange to red, coarse-grained porphyritic biotite granite, irregular masses of alaskite and aplite	4	345 ± 10	1 8
Freshwater Bay	Granite	Megacrystic microcline granite, in parts schistose-foliation trending NE–SW Inclusions of metasediment and migmatite	4	360 ± 15	0 9
Middle Ridge	Granite	Pink medium-grained and central garnetiferous leucocratic phase	4	370 ± 10	3 8
Mt Peyton	Granite–granodiorite	Syenite, granite, diorite, monzonite	4	375 ± 15	12 7
Cape Freels	Granite	To east, homogeneous megacrystic granite—to west, augen gneiss	4	400 ± 15	0 3
Middle Brook	Granite–granodiorite	Microcline megacrystic granite—metamorphic texture in parts, augen gneisses	6	435 ± 35	3 1
Swift Current	Granite–diorite	Pink equigranular medium-grained granite, also contaminated variety with granitised volcanic and sedimentary rocks	4	510 ± 20	7 7

*95% confidence level

†This quantity gives some idea of the goodness of fit of the points to a straight line, and in the ideal case approaches a value of one if the points fit the line within experimental error[8] In practice, the MSWD is strongly dependent on the precise estimation of the analytical uncertainties, and on the total number of points used to define the isochron, so that for our results any MSWD less than about five probably represents a suitable fit of the points to a straight line Only the results from Mt Peyton show any real sign of a deviation from 'ideal' behaviour

preted as Palaeozoic intrusions above the subduction zone The metamorphic belt running along the eastern part of the Central Mobile Belt is related to the same subduction zone, and reflects metamorphic activity above a down-going plate sometime during the Palaeozoic The direction of subduction from northwest to south-east is supported by some gross geochemical trends (in particular a definite eastward increase in the average K content of the granitoid plutons of eastern Newfoundland) and by a zonation of many Newfoundland mineral deposits

To distinguish unequivocally between either of these two models by using both the geological information and the data in Table 1 is difficult, but the Rb–Sr ages provide certain important constraints Perhaps the most important finding is that most of the granites that were sampled are 400 Myr old or younger The prediction that several of the foliated granites intruded into the gneissic terrain may be of either Precambrian or pre-Middle Ordovician age is difficult to reconcile with the new data even though the higher mean square weighted deviates (MSWDs) associated with some plutons may indicate that the Rb–Sr system was disturbed sometime after intrusion The intense foliation associated with at least two of the megacrystic granites, the Cape Freels and the Freshwater Bay, suggests a much younger (post-400 Myr) period of intense deformation and/or metamorphism On the other hand, a variation in age across an ocean-arc and continent system, which would be intuitively expected from a simple model of subduction as suggested by Strong *et al*, is not at all apparent from our data, although any igneous phenomena associated with a downgoing plate are not going to be straightforward in terms of either age or spatial distribution

We thank A R Berger, D F Strong and H Williams for discussions and D F Strong for samples T J S Cole and D P Menagh were responsible for the mass spectrometer, and J S Stevenson and P F DeWolf provided technical assistance This work was supported in part by the NRC and the President's Fund of Carleton University

Origin of gasoline range alkanes in the deep sea

IT is believed that C_4 to C_7 hydrocarbons in petroleum are formed by the cracking of organic matter at depths generally exceeding 1,000 m at temperatures in excess of 50 °C (refs 1–3) Also, none of the alkanes in the butane–heptane range are formed biologically as far as is known at present Consequently, it is thought that they do not occur in shallow, Recent sediments In 1962, I analysed 22 samples of Recent sediments from 7 different environments and verified that these hydrocarbons were not present at the p p m level[4] although traces of a few hydrocarbons such as butane, isobutane, isopentane and n-heptane have been found[5-8] No identification of individual hexanes or heptanes has been reported except when there has been clear evidence of seepage from deeper source sediments[9]

Using more sensitive techniques I have detected the widespread occurrence of practically the entire suite of C_4–C_7 alkanes of petroleum at the ng g^{-1} level in shallow, low temperature marine sediments The yields generally correlate with organic carbon This suggests that diagenetic reactions which form traces of C_4–C_7 hydrocarbons are occurring much earlier and at much lower temperatures than most geochemists had expected

The analytical technique[10] consists of placing frozen core material in a metal container completely filled with water and then introducing a known volume of helium to form a gas cap After thawing, the container is placed in a boiling water bath, then agitated and a sample of gas is withdrawn and analysed on a gas chromatograph fitted with a 200 foot, 0 01 inch internal diameter hexadecene-hexadecane-Kel F capillary column Each peak was identified against a known standard.

* Exact well locations and core descriptions are published in the Leg Reports of the DSDP, US Government Printing Office, Washington, DC DSDP core numbers indicate in order leg-hole-core-section

† Parts per 10^9 by weight, or ng per gram of dry sediment

About 5% of the samples analysed so far, mostly from abyssal plain areas, have shown no detectable hydrocarbons even though the method is sensitive to 5 parts per 10^{12} in a 100 g sample This indicates there is no continuous source of contamination at the levels studied

Table 1 shows the yield of C_4–C_7 alkanes from 14 deep sea samples The samples range in age from Pleistocene to Palaeocene and in sediment depth from 28 to 769 m Organic carbon contents vary from 0 04 to 4 8% Nannofossil chalk (Table 1, no 4) had the lowest yield, and oozes and clays from the outer continental margins (Table 1, nos 1–3, 6, 9–13) had the highest yields The yield of C_4–C_7 alkanes generally increased with increasing organic carbon content except in the vicinity of Tasmania where very high yields in the range of 1,000–6,000 parts per 10^9 were obtained These high yields are associated with a basalt intrusion which occurs at a depth of about 520 m in Hole 280A Previous studies[11,12] have shown that the high temperatures caused by igneous intrusions can generate large quantities of hydrocarbons from the organic matter in adjacent shales Distribution of these hydrocarbons can be erratic because of variations in migration pathways, but yields are invariably higher than average The three deepest samples near Tasmania have a mean yield of 3,211 μg alkanes per gram of carbon, which compare with a mean yield of 22 μg alkanes per gram of carbon for the rest of the samples This suggests that some of the alkanes in the deep Tasmanian samples have migrated from sediments heated by the intrusion

When factors such as temperature are relatively constant, a correlation between hydrocarbon yields and the total organic carbon content of the sediment indicates that the alkanes are autochthonous although there is no way to prove conclusively that this is so When the yield of C_4–C_7 alkanes is plotted against organic carbon, excluding the three deep Tasmanian samples, the correlation coefficient is +0 75 This indicates that those alkanes are autochthonous There is apparently no correlation with lithology, age or depth The deepest sample in any one hole generally has the highest yield Marked increases in yield, however, occur over very short distances, as in the first two samples of Hole 34 These differences cannot be a

result of the temperature increase with depth The highest temperature to which these samples have been exposed is estimated to be about 45 °C for the sample from the deepest part of the Bengal Basin Most samples have never been above 25 °C More likely, differences in yield, as in Hole 34, are related to variability in the type of organic matter A few samples were treated with HF and HCl to remove the mineral matter, and the organic residues were examined microscopically Organic matter in the deep sea samples was generally amorphous whereas the clays from basins along continental margins contained woody fragments, spores and pollen The Indian Ocean sample from Hole 254, which is over 1,500 km from any continent, showed a surprising amount of woody material. Palynological studies[13] showed, however, that these sediments were deposited in a shallow lagoon during Miocene times

Individual hydrocarbon yields for eight representative samples are shown in Table 2 Results to date indicate that certain hydrocarbons form very early during diagenesis, whereas others form very late The earliest formed hydrocarbons are generally the butanes, pentanes, 2- and 3-methylpentanes and methylhexanes, *n*-hexane, *n*-heptane, and methylcyclohexane The hydrocarbons that seem to form latest are 2,2-, 2,3- and 2,4-dimethylpentanes, 1,*cis*-3 and 1-*trans*-2-dimethylcyclopentanes, and 3-ethylpentane About 1 sample in 20 contains a trace of 2,2,3-trimethylbutane A few samples contain olefins which are now being examined using mass spectrometry Large anomalies in individual hydrocarbon yields are scattered erratically through the samples For example, *n*-pentane constitutes 43% of sample 7 and 42% of sample 6 Sample 13 contains 31% 2-methylhexane When it is realised that an individual hydrocarbon represents only 0 0001% of the organic matter, it is understandable that such anomalies can be attributed to a very small part of the organic matrix For example, sample 13 may contain a few easily reducible compounds with 2-methylhexane chains from the original plant material It can be expected that such anomalies would disappear when the organic matter was buried to sufficient depth to generate large quantities of a variety of hydrocarbons by thermocatalytic reactions

* Sample numbers as in Table 1.
Abs = Absent

Hydrocarbon ratios even at this early stage of generation are similar to those in crude oil for some, but not all, hydrocarbon pairs. For example, the ratio of 2- to 3-methylpentane in crude oil averages 1.7 (ref. 14). The mean ratio in the samples of Table 2 is 1.9. The ratio of 1-trans-2- to 1-cis-2-dimethylcyclopentane is about 2.7 in crude oils and 3.3 in these samples. Between methylcyclohexane and cyclohexane the ratio is 2.5 in crude oil and 4.4 in these samples, excluding sample 9 which has almost no cyclohexane. An inverse relationship is noted in the ratio between 2 and 3-methylhexane; it is 0.8 in crude oils and 1.1 in these samples, excluding the anomalous sample 13.

All studies to date indicate in general that some hydrocarbons form earlier than others. When yields at specific locations are compared, however, it seems that some organic matter forms a wider spectrum of hydrocarbons more readily than others. Thus, the Pleistocene sample from a depth of 28 m in the Gulf of Mexico contains 5 more hydrocarbons in the C_4–C_7 range than the Oligocene sample from a depth of 109 m south of Tasmania, even though both samples have a total of 18 ng of hydrocarbon per gram of sediment.

The occurrence of these gasoline range hydrocarbons in shallow marine sediments may be an early indicator of the capability of sediments to generate petroleum. On the other hand, a significant point of this study is that time and the particular nature of the organic matter are not alone sufficient to ensure the generation of commercial quantities of petroleum hydrocarbons. A higher temperature is required than the 15–45 °C range recorded here. For example, the Eocene clays associated with the Lake Maracaibo oilfields in Venezuela have about 1 mg of C_4–C_7 alkanes per gram of carbon at about 75 °C compared with the 18 µg per gram of carbon in the shallow Eocene samples of this study[4]. In the Jurassic sediments of the Paris Basin, there is[3] about a 100-fold increase in the C_4–C_7 alkanes in going from sediments at about 35 °C to those at about 100 °C.

I thank the Scaife Family Trusts and the National Science Foundation for support of this project.

Acoustic observations of suspended particulate matter in the ocean

CLOUDS of suspended particulate matter in the ocean have been observed by satellite[1], sensed by nephelometers[2], and sampled by water bottles. We present here evidence that it may be possible to observe oceanic suspended particulate matter acoustically. The particulate matter discussed is thought to have arisen from a dredging operation. It is also thought that the suspended matter is present at lower concentrations than any in any other case recorded acoustically[3]. Certain questions, as yet unresolved, regarding acoustic scattering strengths are also discussed.

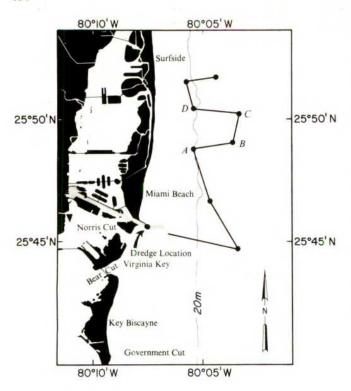
An experiment to determine the feasibility of acoustic surveys of suspended sediments was conceived during field testing of a 20-kHz LODAR echo-sounding system. The LODAR system has a downward-looking acoustic beam of 12° by 18° and a pulse duration of 2.2 ms. Initial acoustic records of a cloud-like feature were coincident with visual sightings of suspended sediment down-current of a working dredge. During this initial experiment, the dredge was operating for five days out of eight and data were taken on both incoming and outgoing tides. In conjunction with the LODAR records, measurements were made with expendable bathythermographs (XBTs) and a continuous recording light beam transmissometer (LBT).


Fig. 1 Typical trackline in area of investigation (May 22, 1974, RV Virginia Key). A–D indicates locations shown on Fig. 2.

On the five days when the hydraulic suction dredge was working, a visible cloud of suspended sediment and the acoustic 'cloud' were observed down-current of the dredge. On incoming tides the sediment flowed into the bay where the water is too shallow to operate the LODAR system. On outgoing tides the suspended sediment flowed out of the channel; the surface manifestation disappeared between 200 and 600 m seaward of the channel, depending on the state of the sea. Figure 1 is a typical trackline and Fig. 2 is the acoustic record from part of that track. The same general trackline was traversed each day. The minimum volume of the cloud estimated from acoustic records was about 60,000 m³. During the three days when the dredge was not in operation, clouds were not observed either by the acoustic equipment or by visual observation of any surface manifestation.

The continuous recording LBT records the percentage transmission of a beam of white light 2 cm in diameter over a 1-m path; filters maximise the sensitivity at 475 nm. Although the light transmission characteristics involve more than one parameter[3,4], the instrument is useful for obtaining approximate particulate concentrations and distributions. LBT station depths were limited by the length of telemetering cable aboard,

but shallow casts (less than 100 m) indicated a reduction in transmittance of between 10% and 15% in the upper regions of the cloud. The developed cloud occupied a region between inflection points on the XBT temperature traces (Fig. 3). A volumetric concentration on the order of 0.01–1%, obtained from the acoustic data, enabled us to carry out a first-cut check of acoustic and transmissometer readings. For the LBT used[5], a reduction in transmittance from 85% to 60% implies a particulate concentration of roughly 0.03%, so that the acoustic and transmissometer devices are consistent.

The observed acoustic 'cloud' cannot be accounted for either by temperature anomalies or by a package of contaminated bay water which would occur independently of dredging operations (see ref. 6). Temperature anomalies, however, seem to influence the location in depth of the acoustic cloud which occupies a region between inflection points on the XBT records (Fig. 3). This observation is consistent with the finding that temperature-induced density gradients are an important controlling factor in the transport of fine-grained sediment[7]. Large biological reflectors cannot account for the cloud as there is no evidence of point source reflectors on the records. The possible role of small biota in producing such a cloud requires further investigation. Although unlikely, the stirring up of bottom nutrients by the dredging operation may have produced a short-lived bloom of microscopic biota.

It is unlikely that the cloud results from microbubbles produced by organic processes in the sediment and released by the dredging operation. An extraordinary amount of decay of organic matter would have to occur to produce clouds of the magnitude observed on every outgoing tide when the dredge was in operation. Such extraordinary quantities would have been observed as seeps emanating from the bottom when the dredge was inoperative.

The observed behaviour and properties of the acoustic cloud support our interpretation that it is the product of acoustic scattering from suspended sediment particles in the water column. The nature of a suspended sediment cloud and its movements would be affected by the tides, temperature-induced density gradients, and the northward flow of the Gulf Stream current. The observed cloud varied in size, shape, and location corresponding to the changes in dredging operations and tides. The tides affect both the direction of flow in Government Cut and the flow of warmer bay waters out to sea on outgoing tides, thus inducing the density gradients at the outflow of the cut. Also, the observed acoustic clouds moved to the north on leaving the cut, with the easternmost extent of the cloud approaching the Gulf Stream.

How is it, though, that particles with diameters that may be of the order of 1–100 μm can reflect detectable sound signals at 20 kHz? The present hypothesis is that the sediment cloud may have regions of relatively high particulate concentration which are detectable but not resolvable using the acoustic system described here. Studies are under way to determine the validity of that hypothesis.

Theoretical work and further field work are under way to

Vertebrate localities in the Karroo System of the Luangwa Valley, Zambia

PROLIFIC vertebrate localities within the Karroo System of the northern part of the Luangwa Valley in Zambia have been known since Dixey's investigations of 1928 and 1935[1]. They were the subject of extensive collecting in 1960–61 by the then Geological Survey of Northern Rhodesia[2], and again in 1963 by a joint British Museum (Natural History)–University of London expedition[3]. Two fossiliferous horizons are recognised in the Luangwa Valley, the Madumabisa Mudstones corresponding to the Upper Permian *Daptocephalus*-zone of South Africa, and the Ntawere Formation which is regarded as a little older than the Manda Formation of Tanzania and corresponds approximately to the Beaufort–Stormberg boundary of the Karroo System. In 1972 members of the Geological Survey of Zambia investigated the middle Luangwa Valley in and around the game reserves, discovering two new, potentially important localities. The first lies in the Munyamadzi Corridor between the northern and southern game reserves and is an exposure of the Madumabisa Mudstones yielding abundant therapsid and some pareiasaur remains. The fossils

are, however, preserved in calcareous mudstone nodules which lack the extensive, hard ferruginous covering which makes the specimens from the Upper Luangwa so difficult to prepare. The second is an exposure of the Ntawere Formation in the northern game reserve and yielded archosaur-like teeth along with the bivalve *Unio karrooensis*. As a consequence of these discoveries members of the Oxford University Museum were invited to participate in an expedition during the summer of 1974, to collect fossil vertebrates from the series of new localities in the middle Luangwa Valley.

North of the Munyamadzi River extends a nearly flat alluvial plain, beyond which the terrain rises about 70 m in 6–7 km. This hilly belt is dissected extensively by stream beds and eight localities were found within the 'donga' type erosion system associated with these streams. Most of the localities lay just below a remnant of horizontal grit or sandstone on an interfluve and consisted of small gullies cutting through the soil and soft rock, which often coalesce to form wide, shallow, bare hollows. The fossiliferous rock is a near-horizontal, brown and grey, fine-grained calcareous mudstone, with frequent nodules that are of the same rock type but are more calcareous, and in which the fossils themselves occur. Large amounts of bone have weathered out and lie strewn over the surface but numerous good specimens were found still *in situ*.

A basically similar locality was found on the Musina River some 18 km further north, apparently in the same geological horizon. The specimens collected from these Madumabisa Mudstones were characteristic of the *Daptocephalus*-zone of South Africa. They consisted of abundant dicynodont skulls often with postcranial bones associated, about a dozen gorgonopsid skulls including one with much of the postcranial skeleton, two whaitsiid-like therocephalians, a complete procynosuchid skeleton resembling *Parathrinaxodon proops*[4], a pareiasaur skull and partial postcranial skeleton and, at one particular locality, numerous remains of fishes, including hybodont-like fin spines, palaeoniscid scales and the partial skull of an *Acrolepis*-like palaeoniscid. All these specimens have since proved very suitable for the acetic acid method of preparation.

Two localities along the Lokokwa River in the northern game reserve were also investigated. They seem to be exposures of the Ntawere Formation and consist of a sequence of mottled red-brown and greenish mudstones and siltstones with some thin, light grey, flaggy sandstones and lenses of intraformational conglomerate of calcareous pellets. Vertebrates were, however, extremely scarce and the only specimen of likely value is a piece of the conglomerate containing part of a small archosaur skeleton. Otherwise only a few surface fragments of labyrinthodont and dicynodont nature, and a large archosaur tooth were found, along with abundant *Unio karrooensis* specimens.

Fig. 1 Karroo localities of the middle Luangwa Valley. ●, Madumabisa Mudstones; ▲, Ntawere Formation.

The collection is now in the Oxford University Museum where it is under preparation. I express my gratitude to the staff of the Geological Survey of Zambia, particularly Dr Alan Drysdall for the initial invitation and Mr and Mrs Colin Kerr, for their cooperation throughout the expedition. I also thank the Wildlife Department and the Monuments Commission of Zambia for the necessary permits, and the Royal Society for a grant. Mr H. P. Powell of the Oxford University Museum and Mr C. D. Kerr of the Geological Survey of Zambia accompanied me during this expedition.

Do children draw men with arms coming out of the head?

CHILDREN'S drawings raise formidable taxonomic problems. Consider the two extremely common drawings in Fig. 1. There are good reasons for selecting the 'conventional man' as a standard against which to assess the 'tadpole man' but we do not know how to do it. It may be that the tadpole man is lacking a trunk[1-4] or that it has the trunk amalgamated with the head[4,5] (and at least two other descriptions are also plausible). In practice, authors have tended to opt for the following subset of possible hypotheses: (1) the trunk is omitted and the arms attached according to a rule 'attach arms to head'; (2) the trunk is omitted and the arms drawn on the head by default even though the child has a rule specifying

the trunk as a locus of insertion for limbs; (3) the trunk is not differentiated from the head, and therefore the rule 'attach arms to trunk' is not violated. The present experiment was designed to test the plausibility of such accounts. Children were given incomplete figures and asked to draw limbs. The results show that the tendency to attach arms to the head or the trunk can be brought under lawful control in such a way as to discriminate against the above hypotheses in favour of one based on the concept of a 'production error'.

As in any binary-choice experiment, the primary goal is to find a set of stimuli which will reliably affect the relative strengths of the two responses under examination, namely, attaching arms to the head or to the trunk, at the same time as satisfying the condition that the stimuli occur at approximately equal intervals on an underlying scale. Such a set is series *a* in Fig. 2, in which each stimulus pair sums to the same overall height, with the central pair being of equal size to give a point of objective and subjective equality (as established in a pilot study). From a classical psychophysical standpoint, series *b* is experimentally somewhat neater since it is based on the method of constant stimuli, in which a fixed 'standard' is paired with varying 'comparison' stimuli. In the present case, one of each pair of circles is held constant, at a diameter of 3 cm, with the other circle varying on an equal interval scale, although this allows for covariance in the overall height. Both series were used in the present experiment. Similarity of the results obtained from the two series will therefore produce confidence in the assumptions involved in the scaling procedures adopted.

Children (140) in local playgroups aged between 2, 3, and 4 yr (mean = 3.8, s.d. = 0.7) were each asked to draw a man on A4 paper. They were then individually asked to complete a drawing consisting of a head. Then each was presented with a booklet containing a random ordering of one of the series shown in Fig. 2 and asked to complete each drawing before turning the page to the next. The locus of insertion of the arms was noted, and the results conditionalised on the spontaneous drawings by dividing subjects up into groups according to whether they spontaneously drew conventional men, tadpole men, or scribbles.

Fifty-four subjects drew a conventional man (group M), 33 drew a tadpole man (group T) and 35 produced scribbles (group S). The remainder, who largely produced disjointed conventional men, were ignored for present purposes. Analysis of variance showed that group M were reliably older than groups T and S (mean = 4.0, 3.7, and 3.4 yr, respectively) at the 5% level of significance. Groups M and T tended to be consistent when given the predrawn head in that 48 out of 54 of group M turned it into a conventional man and 28 out of 33 of group T turned it into a tadpole. Interestingly, none of group S scribbled, and 20 of them produced a tadpole man, whereas 15 produced a conventional man. When given the series of incomplete drawings, every child put the legs on the trunk. The results for arm attachment is shown in Table 1. Clearly group M remained relatively consistent in attaching arms to the trunk. The results for groups T and S seem to resemble one another. Calculation of Cochran's *Q* confirms

Fig. 1 Drawings of a man (*a*) conventionally, (*b*) as a tadpole figure, by two preschool children.

the unequal distribution of locus of attachment across the conditions, and linear contrast on proportions[6] is significant for group T (95% confidence limits being 3.68–1.68 for series *a*, 3.56–0.36 for series *b*). For group S, the linear trend just fails to reach acceptable significance (95% confidence limits being 2.00 to −0.12 for series *a*, 3.64 to −0.28 for series *b*). Thus there is clear evidence that for the individuals in group T, the larger the head in relation to the trunk the greater tendency to draw arms on the head. Thus group T can attach arms to the trunk but equally can be led to ignore the trunk. The same may well be true of group S, but the evidence is equivocal.

The results for group T are evidence against the operation of the stable rules 'attach arms to head' or 'attach arms to trunk' which hypotheses (1) and (2) promote. With regard to hypothesis (3), the results show that a trunk-attachment rule may be violated. In other words, any putative rule operates only in interaction with the particular graphic configuration. Therefore, rather than regarding the drawing as a direct expression of the child's conceptual knowledge[7], we should consider what kind of performance factor could result in the

Table 1 Proportion of each group of subjects who attached arms to the head rather than the trunk of an incomplete figure, as a function of head–trunk ratio

		Group M (n = 27)	Group T (n = 17)	Group S (n = 13)
Series *a*

	1.7	0.07	0.53	0.44
	3.8	0.19	0.73	0.81

observed lawful variation. We suggest that a useful concept is 'production error', namely a characteristic defect in an executive routine, according to the following argument.

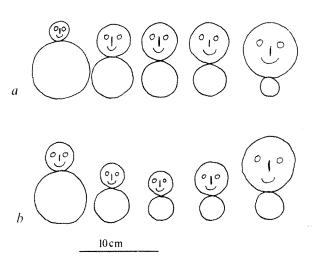
The child has the task of constructing a complex spatial array by bringing into relationship graphical elements which can only be produced in serial order. Typically children and adults talk about, and draw, a man in rather a fixed sequence: head, trunk, arms, legs. Published surveys on drawings[8-11] suggest that if a drawing is incomplete, it tends to be the trunk and arms which are partially drawn or omitted. Note that the trunk is the second element in the pair head–trunk. With regard to the limbs, it was observed in the present experiment when group T produced a spontaneous tadpole man that 80% of the sample drew the limbs in the order legs–arms ($\chi^2 = 5.12$, 1 d.f., $P < 0.05$), that is, the opposite way round to conventional description. Thus for this group of subjects, we propose that their production sequence would typically be head–trunk, legs–arms, and that irregularities are prone to occur in the second element of each pair, that is, the children are liable to sample from the first element in each category, resulting initially in a head plus legs. This means that the child produces a centralised drawing in which the pencil is brought back to a central configuration rather than continuing on a vertical path. (It is this process that the incomplete drawings elicit.) This analysis accords both with Kellogg's[12] classification of drawings (though she overinterprets centralisation as radial symmetry) and with recent evidence[13] showing that for young children, local configurational constraints may preclude them from effectively planning vertical orientation in human figure drawing. The reason why legs are the preferred limbs may be attributable to an early bio-mechanical bias towards vertical strokes, revealed in free scribbling[14], since in simple drawings


Fig. 2 Freehand incomplete drawings presented for completion. Series *a* constructed by holding overall size constant, series *b* by varying size around a constant component.

such "postural propensities are powerful enough to assert themselves"[15].

Thus we suggest that the tadpole man is associated with production problems in programming spatial layout rather than with any peculiar conceptual scheme. Note that group S, the scribblers, were also prone to head-attachment of the arms. In following up some individual scribblers we have found that they are prone to this variability for some months before they produce a recognisable conventional man or tadpole (in one case for over a year). This suggests that such drawing phenomena[16] may be indices of general production problems, rather than being simply specific solutions which arise through repeated 'near misses' in drawing a man. The general problems may well be ones of serial-order programming. In this case, the common practice of scoring a single human-figure drawing may be unsuitable as a method of assessing conceptual intelligence in children of the age range studied here, in that the face validity of the draw-a-man test is challengeable and the completion task permits abilities to be shown by scribblers which they cannot show simply on the demand "draw a man".

Discrimination between parasitised and unparasitised hosts in the parasitic wasp *Pseudeucoila bochei*: a matter of learning

THE female of the parasitic wasp *Pseudeucoila bochei* (Hymenoptera : Cynipidae) lays her eggs in larvae of different *Drosophila* species, and only one parasite emerges from each host. The parasite is able to discriminate between parasitised

and unparasitised host larvae[1], but this ability does not completely prevent super-parasitisation. On investigating the probable causes of super-parasitisation, we discovered that the female wasp has to learn to discriminate, learning being that process which manifests itself by adaptive changes in individual behaviour as a result of experience[2].

Six possible causes were analysed, two of which proved to play an important role in the explanation of super-parasitisation (see Table 1). One of these—which must be related to the

Table 1 Possible causes of super-parasitisation by *Pseudeucoila*

Cause	Importance
1. A female lays more than one egg at an oviposition	—
2. A female does not recognise hosts parasitised by another female	—
3. A female lays a second egg after the first oviposition within the period which is needed for building up the factor which causes avoidance of super-parasitisation	±
4. Two or more females lay eggs simultaneously in one host	±
5. A female's tendency to oviposit increases when she encounters only parasitised hosts for a long period; she will lay eggs in these	+
6. A female has not yet learnt to discriminate	+

—, Never found.
±, Not important.
+, Important.

variation in the tendency of the wasp to oviposit—will be discussed in more detail elsewhere. Here, we report that in certain conditions this tendency may be strong and thus cause a high degree of super-parasitisation. This may happen when the parasite–host ratio is very high and/or when the time during which the hosts are exposed to the parasite(s) is very long.

The other cause, that the wasp has not yet learnt to discriminate, would very easily lead to a high degree of super-parasitisation. During experiments, parasitised larvae were offered to parasites which had never laid eggs before. The inexperienced parasites accepted these unsuitable host larvae (Table 2) as easily as unparasitised hosts (Table 3). The total number of contacts with, and rejections of, the parasitised larvae (Table 2) was tested against the total number of contacts with, and rejections of, the unparasitised larvae (Table 3): $\chi^2 = 1.4, P > 0.05$. Note that the general frequency of contacts was lower in the tests with parasitised larvae. The explanation of this phenomenon will be published elsewhere.

Inexperienced wasps may parasitise many already parasitised hosts in succession and thus waste a large number of their eggs. The parasites did refuse some of the larvae, although this also occurred in the control experiment, in which only unparasitised hosts were presented (Table 3).

If a batch of unparasitised larvae is presented first, and a batch of parasitised hosts thereafter, the wasps will almost completely avoid ovipositing in the latter (Table 4:

Table 2 Number of contacts with and rejections of hosts by inexperienced wasps during three or five tests of 30 min

Female	No. of tests	Total no. of contacts	Total no. of rejections
1	3	43	1
2	3	33	6
3	5	75	11
4	5	58	9
5	5	66	0
Total	21	275	27

Host larvae containing one parasite egg were offered in each test. The average number of contacts and rejections per test was about the same. After an oviposition the host was removed and replaced by a new, once-parasitised host.

Table 3 Number of contacts with and rejections of hosts by inexperienced wasps during five tests of 30 min

Female	No. of tests	Total no. of contacts	Total no. of rejections
1	5	98	5
2	5	72	4
3	5	142	6
4	5	95	21
5	5	110	1
Total	25	517	37

Unparasitised host larvae were offered in each test. The average number of contacts and rejections per test was about the same. After an oviposition the host was removed and replaced by a new, unparasitised host.

$\chi^2 = 47.3, P < 0.005$). The age of the wasps has no influence on their ability to discriminate; the only factor that matters is whether or not they had oviposited in an unparasitised host. From then on the parasites are able to distinguish parasitised from unparasitised hosts. These experiments show that the wasps have to learn to discriminate between parasitised and unparasitised larvae.

We discovered another phenomenon, which is probably related to the former. The inexperienced wasps may learn to discriminate, even when they encounter none but parasitised larvae containing for example one or two eggs. In this case they distinguish between hosts with one egg and hosts with two eggs, and avoid oviposition in the latter. As soon as the wasps encounter mainly hosts containing two eggs they leave the site.

We have shown previously[1] that the wasps not only discriminated between parasitised and unparasitised hosts, but also distinguished hosts with different numbers of eggs. At that time the functional significance of this ability remained rather obscure. In view of our present findings, however, learning may

Table 4 Number of contacts with and rejections of hosts by inexperienced wasps during 30 min of observation

Female	Test no. 1 Unparasitised		Test no. 2 Parasitised	
	No. of contacts	No. of rejections	No. of contacts	No. of rejections
1	8	0	38	36
2	23	1	34	34
3	16	0	31	30
4	14	0	24	24
Total	61	1	127	124

Unparasitised host larvae and once-parasitised host larvae were offered in succession. After an oviposition the host was removed and was replaced by an unparasitised host (test number 1) or a parasitised host (test number 2).

be seen as an important adaptation: if inexperienced wasps arrive at sites in which only parasitised larvae containing one egg are present, they do not continue laying (and thus waste all their eggs!), but leave the site when they have gradually encountered more and more larvae with two eggs. If, as we assume, at each oviposition some 'marking' substance is injected into the host (or is produced by the host), the wasp seems to be able to distinguish different concentrations of this substance, and not just notice its presence or absence.

We have presented[1] some mathematical models on the distribution of parasite eggs over the hosts. These models were based on a large number of egg distributions found in experiments. The majority of these experiments, however, were made with inexperienced wasps. We found substantial super-parasitisation in quite a number of cases, one of the causes of which may be that the inexperienced wasps used in the experiments did not start to parasitise at the same time. Since in each vial more than one wasp was present, wasps that started to parasitise later would have a better chance of meeting, as their first hosts, already parasitised larvae. These larvae

would most probably have been parasitised again by these inexperienced females.

Clearly, the larger the number of inexperienced wasps present in each vial, and the larger the differences in starting time of parasitisation between them, the higher the degree of super-parasitisation will be.

At that time we assumed that super-parasitisation was caused mainly by a strong tendency to lay eggs. In view of these new findings it seems that this would certainly apply to experienced wasps but that most of the super-parasitisation by inexperienced females should be attributed to the fact that they had not yet learnt to discriminate.

Evolution and distribution of left-handed and planispiral coiling in snails

MOST extant snails (Gastropoda) are characterised by dextral (right-handed) coiling of the shell. Sinistral (left-handed) and planispiral (bilaterally symmetrical) coiling are uncommon among gastropods, particularly in the sea[1]. The preponderance of one type of asymmetry over another contrasts with the approximately equal numbers of right-handed and left-handed stocks of conispirally coiled fossil nautiloid and ammonoid cephalopods[2,3], and the roughly equal occurrence of inequivalve bivalves in which either the left or the right valve is larger[4].

There is no evidence that right-handedness is functionally superior or inferior to left-handedness. Here I attempt to explain previously unrecognised anomalies in the ecological and geological distribution of left-handed and planispiral coiling in gastropods by specifying some conditions of reduced stabilising selection under which the mechanisms giving rise to these coiling types could operate. My discussion is restricted to shells of adult snails. Limpet-like forms with bilateral symmetry as well as exceptional instances of sinistral coiling in otherwise dextral species are not considered.

Planispiral coiling is the presumed primitive condition in gastropods[5,6], but it has also been derived secondarily from dextral or sinistral forms in at least nine stocks of archaeogastropods (all pre-Tertiary marine), five or six stocks of freshwater and marine mesogastropods, one line of terrestrial Neritogastropoda, one line each of marine Thecosomata and Entomotaeniata, more than two lines of freshwater Basommatophora and eight planispiral stocks of terrestrial stylommatophorans (Table 1). No planispiral neogastropod is known.

Large size (2–10 cm in diameter) among planispiral shells is attained only among certain Recent land and freshwater forms (Corillidae, Systrophidae, Ariophantidae, Planorbidae, Pilidae) and among pre-Tertiary marine gastropods. All Recent marine gastropods with planispiral shells are less than 10 mm in diameter.

Topographically sinistral coiling may arise in any of three ways: First from a primitively planispiral ancestor; second by hyperstrophy from a dextral form, usually involving a planispiral intermediate phase, or third, by reversed symmetry from a dextral form. The developmental process of torsion, involving delayed appearance of the left compared with the right larval retractor muscle[8,9], predisposed primitive gastropods to dextral rather than sinistral coiling[10]. Hyperstrophic shells are characterised by an apex which is sunken below the apical edge of subsequently formed whorls, and by a base which protrudes as a false spire. Thus, while the shell is externally sinistral, the soft parts within are still dextral in organisation. Reversed symmetry

occurs when both shell and soft parts change in direction of coiling.

Excluding some slightly asymmetrical Bellerophontacea, very conservative estimates suggest that topographically sinistral coiling has independently arisen seven times among archaeogastropods (all but one lineage pre-Tertiary), four times among mesogastropods, six times among the marine neogastropods, twice in the Basommatophora (in one case leading to a major radiation of freshwater forms), and nine times among the land Stylommatophora (Table 1). An additional lineage contains primitive euthyneurans with sinistral larval shells together with the Thecosomata which retain sinistrality as adults. Within several lines of primitively sinistral freshwater Planorbidae, hyperstrophy has led to the evolution of pseudodextral coiling[13,14].

A necessary condition for the attainment of hyperstrophy appears to be the presence in the ancestral stock of an umbilicus, a cavity in the base of the shell created by the incomplete overlapping of adjacent whorls. Nearly all planispiral shells, most archaeogastropods, and most freshwater and land snails, are umbilicate; while most neogastropods and higher mesogastropods are not. It may be argued[15,16] that incomplete whorl overlap renders a shell more fragile than a similarly shaped non-umbilicate shell of equal thickness. In the sea, all but the smallest snails are potentially exposed to vigorous water movements and, especially in the tropics, to shell-breaking predators[17]. Small snails can often occur in the boundary layer at the water–substrate interface, where water movements are diminished, or live among algae or in other habitats where shell-breaking predators can find prey less effectively[1,17]. Hyperstrophy, involving a phylogenetic lowering of the true spire concomitant with an increase in umbilical width, should thus be rare among larger Recent marine gastropods because of an overall reduction in shell strength; but incipient hyperstrophy leading to a planispiral condition might still arise in small-shelled stocks.

In pre-Cretaceous seas, selection among large snails for strong shells may have been less intense than it is today since crabs and teleost fishes, which are among the most effective shell-breaking predators on Recent marine gastropods, were rare[18] or absent[19] before the Cretaceous. Data based on compilations from Knight *et al.*[20] suggest that about 74% of conispiral genera in the largely Palaeozoic Pleurotomariacea (Archaeogastropoda) have umbilicate shells, while calculations based on all known genera of Trochacea (Triassic to Recent)[20] and on all Recent North American genera[21] of this archaeogastropod superfamily yield estimates of 60% and 58% umbilicate genera respectively. The mostly non-umbilicate neogastropods and higher mesogastropods became important elements in the fauna only in the Mesozoic and especially the Cainozoic. Thus secondarily planispiral and hyperstrophic stocks could have evolved in pre-Tertiary times even among large-shelled gastropods.

The shells of many freshwater and land snails are fragile compared with those of marine forms. Many freshwater snails (notably Basommatophora) are annuals, and may adapt to predation by maintaining high reproductive rates rather than by developing impenetrable shells. This may also be true among many land snails, which in addition need not contend with water waves or currents. As in pre-Tertiary marine snails, selection against umbilicate shells is likely to be much reduced among freshwater and land snails, and hyperstrophy is more likely than among large Recent marine forms.

The taxonomic distribution of reversed symmetry may be explained partly by considering methods of larval dispersal. All 18–19 Recent lineages of gastropods with true sinistral coiling, except the Triphoridae and Thecosomata, develop without a planktonic stage. Since reversed symmetry becomes evident at cleavage[10], and as most mutations affecting events at such early developmental stages are associated with harmful side effects, the maintenance in a population of a mutant gene for reversed symmetry is unlikely except possibly in some small

populations in which stabilising selection has been relaxed[6]. Left-handedness in normally dextral snails is often associated with aberrant shell shape[12,23-25]. The general reduction in dispersability associated with loss of a planktonic stage may lead to a higher probability of geographic isolation of small populations. The greater the number of such populations, the higher is the overall probability for reversed symmetry to arise. Reversed symmetry is thus most likely and most widespread in groups such as the Neogastropoda, containing many lineages with direct development, and especially the hermaphroditic and often locally distributed Stylommatophora.

Several anomalies in the distribution of gastropod coiling types are unexplained. All sinistral neogastropods occur or are inferred to have lived in marine soft-bottom environments, none being known from hard substrata. Among land Stylommatophora, sinistral coiling is rare in Africa, Australia and the Americas, but quite common in Europe and especially South Asia and the Pacific islands. The near absence of sinistral species in the three or four stocks of terrestrial prosobranchs, and the evolution of only one small lineage of planispiral forms in this group, are additional enigmata.

Intense stabilising selection may preclude the evolution of planispiral, hyperstrophic, and sinistral gastropods from dextral ancestors because the mechanisms altering coiling direction are normally selected against. This does not mean that all coiling types are adaptively interchangeable[6]. It has been suggested[12] that hyperstrophy in benthic snails renders crawling more difficult than in dextral or sinistral types. The benefit of improved locomotory efficiency with planispiral compared with asymmetrical coiling may in some cases out-

weigh the disadvantage of a weaker shell. Relaxation of selection for strong shells or for efficient locomotion could thus allow other, sometimes opposing, selective pressures to fix and maintain new coiling types.

Prolonged eggshell thinning caused by DDE in the duck

ALTHOUGH eggshell thinning induced by 2,2-bis-(p-chlorophenyl)-1,1-dichloroethylene (DDE)—has been studied in many species (see review by Cooke[1]), the long term effects of this pesticide have not been investigated. Its duration of action is of great environmental significance since it will determine the effect of any pesticide ingested before the breeding season. In this respect, the finding of continuing high levels of DDE and thin eggshells in the Alaskan peregrine falcon (Falco peregrinus) in areas free from direct spraying[2] argues for a prolonged effect, but direct controlled studies have been lacking. In fact, 18 d is the longest period to date during which thinning has been monitored (in mallards given single oral doses of 500–2,000 mg DDE kg^{-1}) and little recovery of shell thickness was observed[3].

We report here the changes in eggshell thickness in the white Peking duck (a domesticated mallard) during 27 weeks following a brief exposure to dietary DDE. Ducks approximately 6 months old were divided into experimental and control flocks (three birds in each) and maintained as before[4]. The experimental flock was fed 250 p.p.m. DDE for 10 d and then control duck feed (provided by Agway Inc.) for the rest of the experiment. A rough calculation from the rate of food consumption shows that experimental ducks (body weight 5–6 kg) ingested about 0.5 g DDE during the 10 d. Approximately 2 months later, when all birds began laying, eggs were collected daily and frozen, and the shells were cut at the equator, that is, approximately midway between the ends. Eggshells were washed in warm water and dried overnight at 45 °C. Twenty measurements of shell thickness, ten per half, were made near the equator of the egg using an Ames micrometer. Each bird produced an average of three or four eggs per week, except for a moulting period of about 7 weeks, when none was laid (weeks 14–20, Fig. 1). As Fig. 1 shows, eggshells from ducks fed DDE were approximately 20% thinner than controls, which agrees with the maximum thinning

reported before[4]. Recovery of shell thickness was slow, being less than half-way at the end of 27 weeks. DDE residues in the yolks were analysed as previously described[5]. Initially, levels were greater than 150 p.p.m. dry weight (Fig. 1) and after 27 weeks, residue values had declined only to about 90 p.p.m. In contrast, levels of DDE residues in a control egg yolk (from week 5) were 0.23 p.p.m. Based on the values of residues shown in Fig. 1, we have calculated the approximate amount of DDE lost by a bird through its eggs. Using a value of 150 μg DDE per g of dried yolk, and assuming that 75 eggs were laid during the 27 weeks, each containing 18 g of yolk (dried weight), roughly 0.2 g DDE or 40% of the original dose would be lost. This calculated clearance parallels the measured decrease in residue levels, that is, approximately 40% decrease in yolk DDE in 25 weeks (Fig. 1). Likewise, Tucker and Haegele[6] found significant loss of DDT through the eggs of mallards. Thus, in the duck, the egg is the major route of excretion for DDE. Naturally, in the wild, the loss would be much less since many fewer eggs are laid.

Earlier work on the white Peking duck demonstrated the rapid onset of eggshell thinning, which is essentially complete within 4 d of exposure to 40 p.p.m. of DDE in the diet[4]. Our study now shows that although the egg is a major route of excretion of DDE, loss through this mechanism is relatively slow, as is recovery of eggshell thickness. Thus, DDE-induced eggshell thinning has a rapid onset and is essentially irreversible.

Fig. 1 Eggshell thickness as function of time for control (○) and DDE-fed (●) white Peking ducks. Experimental birds were fed 250 p.p.m. DDE only during the time indicated. Each point represents the mean thickness for all eggs collected during the 1 week (approximately 11 eggs per flock per week). Variability, when large enough, is shown as standard error bars. Also shown are DDE residues in randomly selected egg yolks from ducks fed DDE. Values are given as p.p.m. dry weight in individual egg yolks. (These values can be converted to p.p.m. wet weight by multiplying by 0.23 or to p.p.m. lipid weight by multiplying by 1.7.)

Acclimation in arctic lichens

USING a new gas exchange method, we have followed the seasonal response of net assimilation rate (NAR) in Arctic lichens and have found rapid acclimation to temperature, light and thallus moisture content. This suggests that these organisms can adjust reversibly their patterns of physiological response to suit the atmosphere of their rather stressful habitats.

Although there is increasing evidence of temperature acclimation of net assimilation rate (NAR) in various plants, both in the field[1-3] and as responses induced under laboratory conditions[4,5], investigations with higher plant systems are complicated by a combination of acclimatory response with variations of NAR resulting from seasonal production of new shoots, flowering and senescence of leaves. Lichens do not undergo seasonal growth of this sort and thus are an excellent system in which to study acclimation.

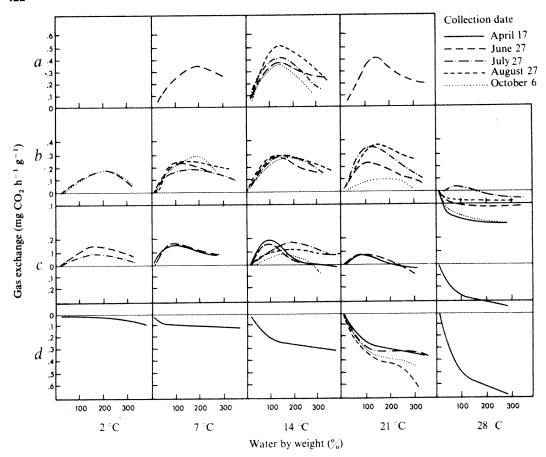
Infrared gas analysis can be used to measure NAR of plant tissue as a change in CO_2 concentration within a flowing gas stream before and after it passes over the experimental plant material, which is enclosed in a special assimilation chamber. We have found that the gas flow networks and environmental control systems which are necessary are too costly and complex to permit use of more than one or two assimilation chambers. Since only one replicate sample can be included in the chamber at once, any adequately replicated experiment is very time


Fig. 1 Seasonal response of NAR in *Cetraria nivalis* Rates of assimilation (μeinstein m^{-2} s^{-1}): *a*, 250; *b*, 150; *c*, 50; *d* 0. Each line is the mean of four or five replicates with s.e.m. less than ± 0.02 mg CO_2 h^{-1} g^{-1}. All collection dates are from 1974.

consuming. Although such methods have been used to investigate gas exchange characteristics of lichens[3]–[5], the time required to study the basic responses to light, temperature and moisture has frustrated many attempts to demonstrate rapid acclimation in these plants[6,7].

We have conducted parallel experiments on various lichens from Arctic tundra using both a standard ventilated system[9] and a new method involving sealed gas exchange cells. We found that unlike the situation with higher plants, ventilation does not influence rates of CO_2 exchange by lichens, and that the concentration of CO_2 around the thallus may fall as low as 150 p.p.m. without any change in the rate of depletion of CO_2 from the vessel. Our results suggest that in these lichens, rates of net assimilation are so low that no strong CO_2 gradients appear within the thallus. It is also important that gas exchange can occur freely across the thallus since stomata are absent. Small samples of lichen (0.25 g) were placed in clear gas exchange cells, sealed and incubated under specified conditions of temperature and radiation within a walk-in growth chamber. After incubation for a specified time the change in CO_2 concentration within the gas exchange cells was measured by injection of a sample into a carrier gas stream flowing through an infrared gas analyser. The value obtained was standardised to yield a value of mg CO_2 h^{-1} g^{-1} dry weight of the thallus. This was plotted against the water content of the thallus—the primary controlling factor of carbon assimilation in lichens— which was measured by weighing before and after each incubation. Rates of net assimilation for *Cetraria nivalis* and *Parmelia caperata* found using this system were the same as those previously obtained by standard methods[4,8,10].

We have used our system to follow the seasonal response of NAR to three variables in *Cetraria nivalis* collected from Arctic tundra at East Pen Island, Hudson Bay. In Fig. 1 data appear as a 'physiological matrix' of responses to all thallus moisture levels, five temperatures and four light levels, measured five times during 1974. Basic gas exchange response changed con-

tinuously throughout 1974. The extent of these changes was considerable: for example levels of assimilation achieved at 250 μeinstein m^{-2} s^{-1} (1 einstein is 1 Avogadro's number (6.023×10^{23}) of photons, and 1 μeinstein is approximately equal to 50 lx) and 14 °C in June were only about 15% higher than at 150 μeinstein m^{-2} s^{-1}. Conversely, by July and August, levels of assimilation at 250 μeinstein m^{-2} s^{-1} were 60% higher than at 150 μeinstein m^{-2} s^{-1}. By October, after the first snowfall, the maximum NAR at 250 μeinstein m^{-2} s^{-1} was again only 15% higher than at 150 μeinstein m^{-2} s^{-1}.

At 50 μeinstein m^{-2} s^{-1} and 14 °C in April NAR in *Cetraria nivalis* was optimal at 100% water by weight; by July and August the response to thallus water content was much flatter, with an increase in NAR at higher levels of thallus water content. By October, the response had decreased and indicated a return towards the response found in the spring.

At 150 μeinstein m^{-2} s^{-1}, the optimal temperature for NAR was near 14 °C in June, near 21 °C in July and had shifted back towards 7 °C in October. In October NAR at 21 °C was about 70% of its value in late August.

It is not known whether the capacity for rapid acclimation demonstrated here is restricted to lichens collected from extreme environments such as East Pen Island or whether temperate or tropical species have equal facilities for acclimation. This could be tested by comparing ecotypes of species such as *Cladina mitis*, the distribution of which extends from high latitude sites like East Pen Island to temperate pine woodland. Although samples of this species collected in Wisconsin[11] showed no significant ecotypic or seasonal variation in response to light intensity, very different patterns can be expected from this species collected from tundra sites.

Our experimental system, with lichens as the experimental material, provides evidence that acclimation occurs very rapidly, is not restricted to shifts in temperature optima and may involve changes in response to light intensity and water content. We are investigating how the assimilation rate of lichens

acclimated to cold, dark and dry conditions is reversed after transfer to warm, bright and wet environments. On the basis of available evidence we suspect that such acclimation can be induced in a matter of days.

Petroleum-degrading achlorophyllous alga *Prototheca zopfii*

ONE of the objectives of this research programme is to enumerate and identify petroleum-degrading microorganisms occurring in Chesapeake Bay, to assess the potential of these microorganisms to degrade petroleum *in vitro* and *in situ* and to determine the types of petroleum degraded[1]. We are sampling two locations in Chesapeake Bay at monthly intervals. One is Colgate Creek, an oil-contaminated site in Baltimore Harbour, the other is an area south of Parson's Island in Eastern Bay, a non-polluted shellfish harvesting region of Chesapeake Bay. The presence of petroleum in Colgate Creek and its absence in Eastern Bay has been confirmed by computerised low-resolution mass spectrometry analysis of benzene extracts of sediments collected at both sites[2,3]. We have routinely isolated petroleum-degrading bacteria, yeasts and filamentous fungi from Colgate Creek and Eastern Bay, but during April and May 1973, and again in 1974, an unusual organism, believed to be an algal species, was isolated from sediment of Colgate Creek. Corresponding isolates have not been isolated from Eastern Bay.

Routine environmental parameters measured during April and May 1973 and 1974 yielded similar data for both years:

air temperature 18–21 °C; dissolved oxygen, 9–12 p.p.m.; water temperature, 12–17 °C; pH 7–8, and salinity, 6–8 ‰. The unusual organism was isolated at a time of year when significant petroleum biodegradation occurred in Colgate Creek[4].

The organism was isolated, in axenic culture, on silica gel oil medium, supplemented with streptomycin and tetracycline which inhibited growth of petroleum-degrading bacteria[5]. The significant feature of our isolate is that it degrades petroleum hydrocarbons. When the organism was grown in 100 ml estuarine salts solution[1] overlaid with 1% (v/v) of a South Louisiana crude oil, we observed significant degradation of the oil, after 30 d of incubation at 25 °C in quiescent culture, compared with the uninoculated, weathered control sample of oil (Fig. 1).

The isolate has been identified as *Prototheca zopfii* (Table 1), following the description provided by Arnold and Ahearn[6], as well as by photomicroscopy (Fig. 2), and electron microscopy (Fig. 3), as recommended by Nadakavukaren and Mc-Craken[7] for differentiating *Prototheca* from fungi. As well as crude oil, the isolate utilised petroleum hydrocarbons in a 17-component mixed hydrocarbon substrate[8], after 14 d of incubation under the conditions described in Table 2. The mixed hydrocarbon substrate permitted determination of the

type of petroleum hydrocarbons utilised by this unusual algal isolate.

Growths of a *Prototheca* sp. on *n*-alkanes has been described[9], but this is the first report of the degradation of oil by an algal species. Although the significance of algae in this process has yet to be assessed, they were previously not considered capable of degrading petroleum hydrocarbons. The role of algae in the microbial degradation of oil must now be examined.

This research was supported by an Office of Naval Research contract and a grant from the US National Science Foundation.

Multiple labelling technique used for kinetic studies of activated human B lymphocytes

IDENTIFICATION of distinct cell surface receptors which could be viewed in the scanning electron microscope would allow unambiguous identification of subpopulations of cells and quantitation of receptors on individual cells as well as permitting kinetic studies of the membrane changes following the binding of a ligand with its receptor. Labelling techniques using one or two markers have been developed for transmission electron microscopy (TEM)[1,2]. But scanning electron microscopy (SEM) offers several advantages over TEM for analysing membrane receptors in that it does not require serial sectioning of material[3] and therefore allows rapid viewing of the surfaces of large numbers of intact cells with a minimum of preparation. Here I describe new labelling techniques for SEM using three distinct markers conjugated to antibodies specific for the immunoglobulins IgA, IgG and IgM.

Previous labelling techniques developed for SEM[4-6] have several limitations. First the techniques use only one marker, restricting visualisation to only one type of receptor[4-6]. Second, with one exception[4], the techniques utilise a large, spherical (130–230 nm diameter) marker which obscures the cell surface preventing precise localisation and quantitative analyses of receptors. Third, the marker has a hydrophobic surface which makes it stick nonspecifically to many surfaces and molecules, and the absorbed protein can dissociate from the marker at physiological salt concentration and pH (ref. 6).

This study was undertaken to determine the feasibility of employing a tri-label technique for SEM. The SEM markers, which were selected for their size and distinctive shapes, were the cylindrical molecule, keyhole limpet haemocyanin (KLH), the icosahedral non-plaque forming simian virus 40 (SV40) and the hexagonal-headed T2 bacteriophage (T2). Antibodies specific for immunoglobulins (Ig) A, G or M were conjugated to individual markers[11], and human B cells carrying Ig were then selectively labelled with these reagents. Surface changes associated with activation were followed during kinetic studies to try to resolve the controversy concerning the appearance

Fig. 1 Lymphocytes were separated from heparinised human blood on "Lymphoprep" (Neygaard and Co.)[12], washed three times in a 1:1 mixture of the decomplemented, autologous serum and PBS, pH 7.4 and resuspended in Medium 199, pH 7.4, at a concentration of 1×10^6 cells ml^{-1}. Macrophages were removed by adherence to glass. Sheep red blood cell (SRBC) rosettes were formed by a modification of previous techniques[10,14]. Briefly, autologous heat inactivated serum, which had been absorbed against SRBC at 4 and 37 °C, was added to the lymphocyte suspension so that the final serum concentration was 20%, and the cells were incubated for 60 min at 37 °C. Washed SRBC were then added and the suspension layered on "Lymphoprep" at 4 °C and centrifuged at 400g for 15 min at 24 °C. The non-rosetting B lymphocytes which comprised about 20% of the total peripheral blood lymphocytes were collected from the top of the gradient, washed three times with Medium 199, and 0.1 ml pipetted on to 12 replicate glass coverslips inside plastic Petri dishes (Falcon). All three SEM marker conjugates were added to each coverslip. Controls consisted of unconjugated markers added to six coverslips. For kinetic studies, cells were incubated for 2 min at 37 °C or for 15, 30 or 45 min at 4 °C, fixed for 30 min with 1% GA and then for 4 h with 2.8% GA[10], dehydrated[10], CO_2 critical point dried, and coated with 5 nm of gold–palladium. Specimens were viewed for between 4 and 8 h in an Hitachi HHF 2R SEM operated at 20 kV. A minimum of 2,000 cells in each preparation were studied. *a*, Control untreated B cell. The surface is not labelled and is smooth except for microvilli. *b*, Elongated macrovilli are labelled with KLH-anti-IgA (between arrows; 2 min after label). Inset shows KLH as a rectangle when viewed sideways and as a circle when viewed on end (high magnification of area adjacent to right arrow ×31,350.) *c*, At low magnifications, T2-anti-IgM appears as 'fuzz' on the cell surface which is covered with elongated macrovilli (×5,225). A 'cap' has formed on the upper left of the cell (15 min after label). *d*, High magnification of the area between the arrows in *c* (×37,400) demonstrating T2 (black arrows indicate junction between the head and tail of T2). White arrow indicates another T2 of which both head and tail are visible. Because of the density of marker, generally only T2 heads or tails are visible as in the upper right of the micrograph. Apparently, the phage was osmotically shocked during the conjugation procedures because most of the heads are round rather than hexagonal. *e*, SV40-anti-IgG labelled B cell with undulate surface (15 min after label). *f*, B cell labelled with T2-anti-IgM at 30 min. Lamellae cover the surface, and the marker which is too dense to count has 'capped' on the upper part of the cell. Marker is also in scattered areas on the surface. Inset is high magnification (×75,900) of T2 from areas at the tip of the arrow. Magnification line equals 500 nm.

of human B cells under SEM. Previously, human B cells have been reported to be either highly undulate[8], highly villous[8,9] or sparsely villous[10], and this controversy has precluded the use of SEM as a simple method for distinguishing between B and T cells.

Markers were fixed in 1% glutaraldehyde (GA) for 2 h to preserve their structure and then dialysed overnight against phosphate buffered saline (PBS), pH 6.9. One ml of IgG fraction of goat antiserum directed against human IgM (3.4 mg ml^{-1}), IgG (15.2 mg ml^{-1}) or IgA (7 mg ml^{-1}) was added to 2 ml of T2 (Miles Lab), SV40 or KLH, respectively, so that the ratio of antibody molecules to marker was 1:1. The antisera were specific for the Ig against which they were made as determined by immunoelectrophoresis and double diffusion in agar. An 8% solution of GA was added dropwise with agitation until its final concentration was 0.1%. Marker labelled antisera preparations were then incubated at 20 °C for 2 h with agitation[11], and dialysed against PBS, pH 7.4, overnight at 4 °C. Conjugates were purified by column chromatography on Agarose A 1.5 m (Biogel 100–200 mesh). The first millilitre containing aggregates

was discarded. The conjugate was present in the first peak, unconjugated marker in the second, and unconjugated gamma globulin in the third.

In preliminary experiments, it was found that the amount of a marker present on a labelled cell was the same at a given incubation time irrespective of whether 1, 2 or 3 markers were used whereas the percentage of B cells labelled increased as more than one marker was used ($1 < 2 < 3$). The relative number of cells labelled with T2-anti-IgM, SV40-anti-IgG, or KLH-anti-IgA varied with the individual whose cells were tested (some had a preponderance of B cells carrying IgM while others had a preponderance of IgG cells). No cells were double labelled. When B cells were treated with a mixture of unlabelled and marker labelled anti-Ig, labelling was drastically reduced. These results confirmed the specificity of the marker-anti-Ig conjugates. "Stacking" of the marker was observed when conjugates were added to live cells but not when the marker was added to cells prefixed with 1% GA and washed in buffer. Moreover, aggregates were not observed when conjugates alone were scanned. This shows that the "stacking"

is not a result of the presence of aggregates in the conjugates. Rather it requires a viable cell membrane, suggesting that membrane fluidity may be responsible.

Incubation times and temperatures for the kinetic studies were selected on the basis of results from preliminary experiments using 1, 3, 6, 9, 12, 15 or 30 min at 37 °C, and 5, 15, 30, 45 or 60 min at 4 °C. All morphological changes observed with SEM occurred within 6 min at 37 °C which is sooner than can be detected with light microscopy. Since this was much too rapid to enable careful analysis of these cellular changes, most experiments were performed at 4 °C to slow membrane movement. It was found initially that cells incubated at 4 °C for 60 min, but not 45 min, showed subtle changes in surface ultrastructure including occasional contraction and collapse of some villi and lamellae; therefore 45 min was selected as the maximum incubation time at 4 °C.

B cells in the untreated control preparations had fewer than 100 microvilli per cell, evenly distributed on the surface (Fig. 1a). Within 2 min of addition of marker-antisera conjugates at 37 °C, the microvilli on labelled cells had migrated to one pole of the cell forming a 'cap', while the elongated macrovilli and lamellae formed at the other (Fig. 1b). An average of 10 markers were visible on each labelled cell. The inset on Fig. 1b shows clearly the marker, KLH, on the elongated macrovilli. KLH is also present on the 'capped' microvilli. By 15 min, elongated macrovilli and lamellae covered the surfaces of 70% of the B cells (Fig. 1c and d) and an average of 300 markers were visible on each labelled cell. Figure 1e shows an IgG-producing B cell labelled with SV40 anti-human IgG. Within 30 min, the surfaces of 50% of the labelled B cells were extensively covered with lamellae, and the marker had again 'capped' (Fig. 1f). No difference was observed in the surface appearance of IgA, IgG and IgM cells. When kinetic experiments were repeated using unconjugated Ig, the same sequence of membrane changes were observed indicating that these are not artefacts resulting from binding of a heavy marker.

These results indicate that unstimulated B cells have microvilli on their surface but do not have elongated macrovilli or lamellae. When activated by anti-Ig receptor reagents, B cells respond first with the formation of elongated macrovilli and then lamellae. Simultaneously with the appearance of macrovilli, the number of Ig receptors present on the surface increases by at least tenfold (from approximately 10 to 300 receptors per cell). This is a minimum estimate because (a) only 1/2 to 3/4 of any individual cell can be seen at any one time with SEM, (b) the marker may be bound in layers or may have entered the cell and (c) some of the marker may have been removed during critical point drying. In spite of these limitations, SEM analysis of surface events, and binding of labelled molecules in particular, is more accurate than TEM analysis which depends on the plane of section (that is, a typical 30 to 60 nm section of a cell may or may not be through an area where the receptors are present in a proportion representative of the whole cell).

Some authors have shown previously that human B cells have relatively few microvilli[3] while others have contended that they have highly villous[12] or undulating surfaces[1]. As is evident from the results of these experiments, the surface appearance of B cells depends on their stage of activation. Those who described B cells as having relatively few villi had incubated them in PBS without antibody or complement[10,13], whereas those who described them as "highly villous", used non-autologous pooled Type AB serum which had not been previously absorbed with the lymphocytes used in the experiment[8,9]. Those who described B lymphocytes as "villous" and "highly" undulate had incubated lymphocytes for 60 min at 0 °C with complement-coated human red blood cells[7]. These conditions can activate B cells and initiate the surface changes described. Although it might seem that these investigators were each describing a different type of cell, the results of the present study would indicate that they were actually describing different stages of activation of B cells. This suggests that conditions for

evaluating peripheral blood lymphocytes as 'T' or 'B' should be standardised.

A study of mouse T and B cells obtained from lymph nodes, incubated in basal salt solution, and fixed before addition of antisera conjugated to latex spheres by the method of Lo Buglio[6] agrees with our first report that human T cells have highly villous surfaces while B cells had relatively few microvilli[10]. It seems that surface characteristics of unstimulated T and B cells of mice and men are remarkably similar.

I thank Dr T. Makinodan for helpful discussion and criticism, Ned Manti for providing non-plaque forming SV40, Park Trefts for contributing the KLH, Helga Johnson for providing the antisera, and Hideo Naito, Mike Shinohara, and Masauro Tamura for their technical assistance.

Regulation of cell size in fish of tetraploid origin

ALTHOUGH what precisely determines the characteristic size of the cell is still unknown its regulation must have been of enormous significance during evolution[1,2]. Bigger cells have a relatively lower metabolic rate than smaller ones so that the reduction of cell size is of adaptive value when changing environmental conditions requires an increase in metabolism and *vice versa*[1,2]. A decrease in cell size, however, must be accompanied by a corresponding loss of DNA if the nucleo-cytoplasmic relationship, which is fundamental in cell biology, is to be maintained.

We have reported on phylogenetically tetraploid Cyprinid fish, which still keep the tetraploid genome, but exhibit a reduction of cell size, compared with the expected value in tetraploid cells[3]. This reduction cannot be ascribed to loss of nuclear DNA. We therefore postulated a regulatory mechanism which acts at the level of specific genes. It is known that fish cell size, to some extent, parallels the amount of $(28S+18S)$ ribosomal genes[4]. In a group of closely related plant species the number of ribosomal genes is also reduced with increasing DNA content[5,6]. Since ribosomes are required for the translation of all RNAs specified by structural genes, a loss of ribosomal genes during the evolution of the tetraploids might well be responsible for a lower synthetic output of the cell, and, in consequence, for the reduction of cell size. In the present investigation we have determined the number of $(28S+18S)$ rRNA genes in the diploid and the phylogenetically tetraploid Cyprinid fish species (Fig. 1).

Surprisingly, a clear-cut 1:2 ratio of the number of $(28S+18S)$ ribosomal genes exists between the diploid and the tetraploid group amounting to a mean number of 272 and 544

Table 1 Cellular parameters in diploid and phylogenetically tetraploid Cyprinid fish species

	2n				4n		
	Rutilus rutilus	Tinca tinca	Abramis brama	Leuciscus cephalus	Barbus barbus	Cyprinus carpio	Carassius auratus
DNA content per nucleus (% of human leukocytes)[7]	28	30	36	38	49	50	53
Erythrocyte volume (μm^3)	202.0	203.8	182.0	186.0	190.8	181.6	180.6
Soluble protein content per erythrocyte (pg)	60.1	70.4	63.0	66.7	70.8	64.7	64.9
Nucleolar area (% of nuclear area)	3.7±0.6*	3.4±0.3	3.5±0.6	3.7±0.4	2.1±1.0	1.6±0.4	1.5±0.2

The erythrocyte volumes were determined with the haematocrit method and the protein content was measured according to Lowry et al. (for further details see Schmidtke and Engel[3].). The relative nucleolar size in 20 cells of each species was determined from smears of fin epithelial cells fixed in Carnoy, and stained with acridine orange.
*Mean ±s.d.

respectively. Although heterologous (28S + 18S) rRNA from HeLa cells and not homologous rRNA from fish cells was used, the observed values approximate the true number of ribosomal genes in the Cyprinid fish species very closely. When DNA of Carassius auratus was hybridised with homologous (28S + 18S) rRNA a saturation value of 0.00054 (rRNA/DNA) was observed[4]; using HeLa rRNA we found a mean saturation value of 0.00052 in this species. These results imply far-reaching homology between fish and human (28S + 18S) rRNA cistrons.

It is clear that in the diploid–tetraploid system dealt with in this investigation there is no correlation between cell size and the number of (28S + 18S) rRNA genes. It could be assumed, however, that, referring to the expected tetraploid cell size, the reduction to the diploid level was achieved by

diminishing activity of the ribosomal genes during evolution nucleolar size measurements point in this direction (Table 1) The diploid and the tetraploid Cyprinids have nucleoli of very similar size, which suggests similar synthetic rates of rRNA. This is being studied at present.

Fig. 1 The number of (28S + 18S) rRNA cistrons per diploid genome in diploid and phylogenetically tetraploid Cyprinid fish species; a, Rutilus rutilus; b, Tinca tinca; c, a natural hybrid from Rutilus rutilus and Abramis brama; d, Abramis brama; e, Leuciscus cephalus; f, Barbus barbus; g, Cyprinus carpio; h, Carassius auratus. Each column represents the mean of about five specimens. DNA was isolated from erythrocytes lysed with Triton X-100, followed by treatment with Pronase and a SDS-concentrated saline mixture, several extractions with phenol, in the presence of m-cresol and 8-hydroxychinoline, and chloroform, and precipitation with isopropanol. Alkali-denatured DNA was loaded on Sartorius nitrocellulose membrane filters (35 μg per filter). DNA was hybridised at 65 °C in 6 × SSC-50% formamide essentially as described by Birnstiel et al.[8] with ^{3}H-labelled (28S + 18S) rRNA isolated from ribosomes of HeLa cells as described by Bross and Krone[9]. Specific radioactivity ranged from 40,000 to 50,000 c.p.m. μg[-1]. Saturating RNA concentration (> 5 μg ml[-1]) and saturating time course (4 h) were determined experimentally. The calculation of the number of 28S and 18S ribosomal genes was based on a molecular weight of fish rRNA of 1.51×10^6 and 0.7×10^6 respectively[10], and a diploid DNA-content of the human genome of 7.3×10^{-12} g (ref. 11).

Abnormal development of preimplantation rat eggs after three days of maternal dietary zinc deficiency

Dietary deficiency of zinc in pregnant rats causes congenital malformations of high incidence in multiple organ systems[1,2]. These teratogenic effects of zinc deficiency seem to be related to impairment of nucleic acid synthesis[3-6]. We now report that dietary zinc deficiency in the first few days of pregnancy results in abnormal cleavage and blastulation in preimplantation eggs, as early as day 3 of gestation in the rat.

Virgin female Sprague–Dawley rats were mated and fed a purified diet, either complete (100 p.p.m. Zn) or zinc-deficient (< 0.4 p.p.m. Zn), from the beginning of pregnancy. The day of finding sperm in the vaginal smear was considered day 0 of gestation. Diet composition and details of environmental control have been published previously[2]. Females were chloroformed on day 3 of gestation, the reproductive tract was removed, and the oviducts were isolated and flushed with saline introduced into the fimbriated ostium and collected in a watch glass from the distal end. On day 4 of gestation the uterine horns of anaesthetised females were distended slightly with calcium-free Krebs–Ringer solution containing 0.002% collagenase and 0.002% hyaluronidase introduced by cannula through an incision near the vaginal end. A ligature prevented escape of this fluid. Fifteen minutes later, the reproductive organs were removed to a saline bath, each horn was flushed from the vaginal end through a small incision near the tubo-

Table 1 Preimplantation rat eggs on day 4 of gestation as affected by maternal dietary zinc deprivation

Group	Females No.	Corpora lutea No.	Eggs Flushed		Normal Morula		Normal Blastula		Uncleaved		Abnormal Morula		Abnormal Blastula	
			No.	%	No.	%	No.	%	No.	%	No.	%	No.	%
Control (100 p.p.m. Zn)	9	131	101	78*	0	0	99	98†	2	2†	0	0	0	0
Deficient (<0.4 p.p.m. Zn)	12	142	113	80*	5	4†	19	17†	9	8†	34	30†	46	41†

$*\dfrac{\text{Embryoblasts recovered}}{\text{No. of corpora lutea}} \times 100.$

$†\dfrac{\text{Type of embryoblast}}{\text{Total no. of embryoblasts}} \times 100.$

uterine junction, and the flushings were collected in watch glasses. The procedure yielded approximately 80% of the anticipated embryos, as based on correlation of the number of recovered eggs with the number of corpora lutea in the corresponding ovary (Table 1).

Cleaving eggs obtained by this method responded normally to supravital staining, retained the zona pellucida for more than 7 h in normal saline at pH 7.4[7], and seemed to be identical morphologically to a small number of samples obtained from deficient and control animals by the methods of Nicholas[8]. Specimens were examined and photographed in saline.

In tubal flushings from seven control rats on day 3 of gestation, all eggs were in the eight or 16 cell stages (Fig. 1 *a* and *b*). In 11 zinc-deficient rats, 68% of the eggs on day 3 of gestation were in the eight-cell stage and appeared to be normal. However, the remaining eggs had either failed to cleave and were undergoing necrosis with disruption and fragmentation of the cellular contents, or consisted of three to seven blastomeres lacking normal orientation and showing variation in size (Fig. 1 *c–f*).

On day 4 of gestation, only two of 101 eggs recovered from control females had failed to undergo cleavage, while all remaining eggs were in the blastocyst stage (Table 1 and Fig. 2 *a* and *b*). Eggs from three of 12 zinc-deficient females were normal morulae or blastulae; all remaining preimplantation embryos from zinc deficient females were abnormal (Table 1 and Fig. 2 *c–f*).

These results clearly show that dietary zinc deficiency in the pregnant rat rapidly produced abnormal development of preimplantation embryos. This is the first time to our knowledge that abnormal development of cleaving eggs has been shown to result from a nutritional deficiency of the maternal diet. It is generally thought that embryos are insensitive to environmental influences before implantation and that exogenous teratogens are either lethal or without lasting effect during this period[9,10]. In the case of zinc deficiency in rats given a deficient diet only from day 0 to day 5 of gestation, preimplantation losses were minimal, and foetal malformations at term were only slightly increased over those of controls[2]. Thus it is possible that the morphologically abnormal blastocysts described here may recover to develop normally but this question remains to be answered.

The uterine fluid of rabbits has recently been found to contain significant amounts of zinc, approximately twice the concentration of the free-lying blastocysts[11]. Uptake of zinc by uterine fluid was, however, slow as compared with that of other reproductive tract components such as the endometrium[11]. It is therefore possible that with a maternal dietary deficiency of zinc, the milieu of the conceptus (the oviductal and uterine fluids) becomes inadequate in zinc as a consequence of competition with tissues having higher avidity for available zinc supplies in the face of the low maternal plasma zinc levels, which are known to occur[12]. The finding of abnormalities in cleaving eggs on day 3 of gestation suggests that intraluminal zinc may be reduced to critical levels before this time under these conditions.

Recent work has shown that cleaving mammalian eggs

Fig. 1 Examples of embryos obtained from the oviducts of control (*a* and *b*) and zinc deprived (*c–f*) female rats on day 3 of gestation. Note the presence of an intact zona pellucida in all examples. All embryos of both control and deficient dams were stained successfully with neutral red following photography. *a*, Control, eight-cell stage; *b*, control, sixteen-cell stage; *c*, abnormal embryo with three large intact blastomeres and the cellular debris of a fourth; *d*, abnormal seven-cell embryo containing one excessively large blastomere; *e*, abnormal embryo, cell boundaries lacking between blastomeres giving the appearance of a syncytium; *f*, abnormal embryo, showing derangement of orientation and great variation in size of blastomeres.

Fig. 2 Examples of embryos obtained from the uterine horns of control (*a* and *b*) and zinc deprived (*c–f*) female rats on day 4 of gestation. Note the presence of an intact zona pellucida in all examples. All embryos of both control and deficient dams were stained successfully with neutral red following photography. *a*, Control, early blastula stage; *b*, control, normal blastula; *c*, abnormal morula showing variation in blastomere size; *d*, early, blastocyst from zinc deficient female showing derangement of blastomeres and beginning of blastocoel (×); *e*, abnormal blastulation with dissociated blastomeres and a degenerating mass of cytoplasm. Blastocoel indicated by arrow; *f*, abnormal, lateral continuation of blastocoel cavity (arrow).

incorporated labelled precursors of DNA and RNA[13] and that mitotic inhibitors or compounds which suppress RNA synthesis adversely affected blastogenesis[14-16]. Thus, the abnormal development of preimplantation eggs reported here may result from impaired synthesis of nucleic acids, a zinc-requiring process.

Temperature-sensitive expression of differentiation in transformed myoblasts

NUMEROUS studies have dealt with the replication of tumour viruses in fibroblasts, but little is known about the mechanisms by which such viruses interfere with the control of specific functions in fibroblasts or in differentiating cells. It is known that tumour viruses can transform cells from differentiated tissues[1-7]. Chick embryo myoblasts can be transformed by Rous sarcoma virus (RSV), (refs 2 and 3); transformation, or at least infection, prevents neither formation of myotubes nor the biochemical changes which ordinarily follow myoblast fusion[8]; Easton and Reich did not, however, purify infected cells by serial passage. We report the *in vitro* transformation of chick embryo myogenic cells with a temperature-sensitive mutant of RSV. We show that transformed myoblasts, after serial passage, lose their ability to differentiate at the permissive temperature (36 °C) but will differentiate to form myotubes—if transformation is blocked by a shift to the non-permissive temperature (41 °C).

Chick myoblasts derived from thigh muscles of 11-d-old chick embryos were infected with the Schmidt–Ruppin *ts*68 strain of RSV (ref. 9) and incubated at 36 °C (permissive temperature). On day 2 after infection, the presence of myotubes could be detected in all the Petri dishes with no obvious differences between mock-infected cultures and RSV-infected cultures. On day 3 after infection, there was still no difference between the mock-infected cultures and RSV-infected cultures. On day 4 after infection, some clumps of rounded cells began to appear in the infected cultures.

In the mock-infected chick embryo myoblasts (Fig. 1*a*) after 5 d in culture, most of the mononucleated cells have been replaced by long myotubes, each containing numerous nuclei. There are also a number of mononucleated cells which are believed to be fibroblasts. These cells form a monolayer and are never found in clumps or large aggregates. In the RSV-infected cultures after 5 d (Fig. 1*b*) the number of myotubes in the plate is reduced and many aggregates of rounded cells are found; most of these are attached to myotubes. This situation is in good agreement with results described previously[2,8], although it is not clear whether all the rounded cells are transformed cells or clumps of dead cells. It is likely that these rounded cells are indeed transformed cells, since no such cells ever appeared in RSV-infected cultures maintained at 41 °C (Fig. 1*c*). We also found, as did Easton and Reich[8], that infected myoblasts will form myotubes and that these myotubes are not stable and will disappear on further incubation.

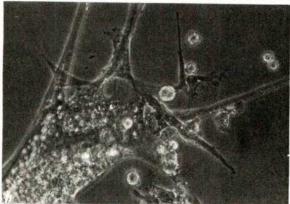
The clumps of rounded cells (Fig. 1*b*) were allowed to grow for a few more days, then dispersed with trypsin and distributed into new Petri dishes. The medium was changed to a mixture of Dulbecco's modified Eagle's MEM and Medium 199 (5:2); 10% foetal calf serum and 1% chick embryonic extract were also


Fig. 1 Phase contrast photographs of chick embryo myoblasts infected with RSV *ts*68. *a*, Mock-infected culture on day 5 after infection. *b*, Infected culture maintained for 5 d at 36 °C; clumped cells have appeared. *c*, Infected culture maintained for 5 d at 41 °C. Chick embryo myoblasts were prepared by a modification of Konigsberg's method[16]. Thigh muscles from 11 day embryos, dissected free of skin and bones, were minced with scissors and incubated at 37 °C in phosphate-buffered saline (PBS): NaCl 137 mM, KCl 2.6 mM, Na_2HPO_4 8.1 mM, KH_2PO_4 1.4 mM for 15 min. The fragments were dispersed by pipetting through a Pasteur pipette and the dispersed cell suspension was centrifuged at 500g for 1 min. The upper nine-tenths of the supernatant was removed, diluted with complete medium (Dulbecco's modified Eagle's MEM containing 10% horse serum and 2% chick embryonic extract) and preplated at $5-10 \times 10^6$ cells on gelatin-coated Falcon tissue-culture Petri dishes (100 mm) to remove fibroblasts. (This procedure usually yields a 90% or better pure myoblast population.) After 15–20 min at 37 °C in a 5% CO_2 incubator, the unattached cells were transferred to gelatin-coated tissue culture Petri dishes (100 mm) at a plating density of 2×10^6 cells and the plates were incubated at 37 °C. Five hours later the cells were washed once with PBS and infected with 2 ml of RSV *ts*68 containing 10^6 focus-forming units ml^{-1}. After adsorption for 60 min at 36 °C, the cells were overlaid with complete growth medium and incubated at 36 °C in 5% CO_2 in air. Many multinucleated myotubes can be seen.

present. The cells were serially passaged with a starting density of 5×10^5 cells per tissue-culture Petri dish (100 mm) and trypsinised when the plates reached confluency (about $8-10 \times 10^6$ cells per plate). During these manipulations, one of the dishes was accidentally left too long and became overcrowded. The sheet of cells detached from the dish and the remaining cells were overlaid with fresh medium. A few clones had grown after a further 10 d; three of them (cl-1, cl-2, cl-3) were picked and further maintained in culture. After about ten generations, one Petri dish of each of the three clones and one Petri dish of the uncloned parental culture were shifted to the non-permissive temperature (41 °C). A change in the morphology of the cells was evident, 24 h after the shift, in all Petri dishes. The cells were more flattened and more dispersed, and some cells had lost the spindle shape characteristic at 36 °C. Figure 2*a* illustrates the changes which occurred after 3 d at 41 °C in both the uncloned parental culture and in cl-3. Numerous myotubes could be seen among a layer of mononucleated cells. In cl-1 and cl-2, no such myotubes could be seen even after a longer period of time at 41 °C.

On the other hand, at 36 °C, no formation of myotubes could be observed in any of the cultures. A more quantitative study, using the parental uncloned culture, is presented in Table 1. It is clear that after the shift to 41 °C there is a change in the overall composition of the population. Whereas at 36 °C, 99% of the cells remain mononucleated, after the shift up to 41 °C, 60% of the cells become polynucleated. It is, however, striking to observe that only 12% of these polynucleated cells contain more than ten nuclei as compared with 71% when primary chick embryo myoblasts are used (Table 1). This was taken to reflect the fact that the RSV-transformed myoblast population contains fewer cells which are able to fuse than do the primary myoblast populations. From this experiment it is clear that RSV-transformed myoblasts can be isolated and that these myoblasts, after serial passage, are prevented from further differentiation. Nevertheless this function is not lost, since following a shift up to the non-permissive temperature they will regain this function and will differentiate to form myotubes.

The nature of the cells which do not fuse at 41 °C remains to be elucidated. The most likely explanation is that these are transformed fibroblasts since the starting primary culture consists of 90–95% myoblasts and 5–10% fibroblasts. One must also consider that some of the mononucleated cells are transformed myoblasts which have definitively lost their ability to differentiate since clones of myogenic cells which do not fuse have already been described[12] (N. Teng, unpublished). A clear demonstration of either one or both of these hypotheses will require the isolation of morphologically pure clones of cells.

Finally, there is a striking difference between the myotubes which appeared after infection and the ones which were formed after the shift to 41 °C, since the latter are very stable and remain on the dish as long as would myotubes in an uninfected culture.

Fig. 2 Morphology of transformed myoblasts at 41 °C. Photomicrograph of the uncloned parental culture maintained for 3 d at 41 °C.

Table 1 Myotube formation by RSV-transformed myoblasts at 36 and 41 °C

	% Mono-nucleated cells	% Polynucleated cells 2–3 nuclei	4–10 nuclei	>10 nuclei
RSV-transformed myoblasts at 36 °C	99	1		
RSV-transformed myoblasts at 41 °C	40	12	36	12
Primary myoblasts at 36 °C	8	3	18	71

RSV-transformed myoblasts were seeded at 36 or 41 °C Primary chick embryo myoblasts, prepared as described in the legend to Fig 1*a*, were incubated at 36 °C Four days after seeding, one Petri dish of each culture was fixed and stained with haematoxylin (A minimum of 500 nuclei were counted in each plate)

In conclusion, we have shown that it is possible to isolate transformed chick embryo myoblasts in which the expression of differentiation is under the control of a viral gene It is too soon to make any speculation about the mechanism of control, especially since nothing is known as yet about the other changes which usually follow the event of fusion such as myosin synthesis[11], appearance of cholinergic receptors[12,13] and regulation of various enzymes[14,15]

Diffusible mating-type factors induce macrocyst development in *Dictyostelium discoideum*

IN cellular slime moulds the formation of multicellular macrocysts constitutes an alternative pathway of development to that of fruiting bodies In appropriate conditions macrocysts form in certain strains of *Dictyostelium* and *Polysphondylium*[1] The existence of mating types in cellular slime moulds was suggested when certain combinations of amoebae of different strains resulted in macrocyst development[2,3] Since the aggregation of cells which leads to fruiting body formation in *D discoideum* is mediated by cyclic AMP[5,6], we decided to investigate whether the interaction between mating types is also mediated by a small, diffusible molecule Our results indicate that such a diffusible

mating factor does indeed regulate macrocyst formation in *D discoideum*

Stock cultures of two complementary, haploid mating types of *D discoideum* (strains NC-4 and V-12, given by Dr D W Francis) were maintained on *Escherichia coli* (strain B/r) on 0 2% Cerophyl agar These strains can from macrocysts when mixed but not when cultured separately[3] The general macrocyst-forming conditions of Nickerson and Raper were used in all experiments[7]

In the first set of experiments, a suspension (5 0 ml) of bacteria and spores of one strain of *D discoideum* in distilled water was pipetted into sterile dialysis tubing (pore size 4 8 nm) The tubing with ends tied was placed in a culture plate An equal volume of spore suspension of the opposite strain (experimental) or the same strain (control) was distributed uniformly over the tubing and the agar The plates were stored in light-tight metal cannisters at 23 ± 1 °C In every experiment separate cultures of V-12 and NC-4, which never produced macrocysts, and a mixture of V-12 and NC-4, which always produced macrocysts, were run as controls Macrocyst formation was assessed by microscopic (× 25–50) examination of plates after 7 and 14 d Whenever macrocysts formed they conformed in structure to that described before[1,2-4,7]

Table 1 summarises the results of these experiments When NC-4 was placed in the dialysis tubing and V-12 was outside, macrocyst formation was induced in eight out of 21 cultures Many macrocysts formed along the outside of the dialysis membrane, but few formed further than a few centimeters from the tubing The reverse combination, with V-12 inside the tubing and NC-4 outside, yielded no macrocysts Under the conditions used either macrocysts developed fully and were evident after 7 or 14 d, or no development began Small numbers of fruiting bodies appeared on all culture plates Thus cell contact between opposite mating types of *D discoideum* is not essential for macrocyst formation

Table 1 Induction of macrocysts across a dialysis membrane

Experimental situation	No of cultures	No of cultures with macrocysts NC-4	V-12
NC-4 alone	9	0	NA
V-12 alone	9	NA	0
(NC-4) × NC-4	7	0	NA
(NC-4) × V-12	21	0	8
(V-12) × NC-4	18	0	0

When dialysis tubing was used the cells contained within the tubing are listed first within brackets NA, not applicable

A second series of experiments was carried out to determine whether the continual presence of the opposite mating type was essential for macrocyst induction Each strain was cultured separately in macrocyst-forming conditions After 18 h, the cells were dislodged from the agar surface with a bent glass rod and the suspension was centrifuged at 2,000*g* for 5 min to pellet the whole cells The supernatant was filtered through a sterile Millipore filter and the final sterile, cell-free supernatant (conditioned medium) was poured over a fresh culture (0 h culture) of the opposite strain After 7 or 14 d, cultures were examined for the presence of macrocysts For controls, the supernatant of one strain was added to cells of the same strain and distilled water instead of supernatant was added to individual cultures of each strain

Table 2 shows that NC-4 supernatant induced macrocyst formation in V-12 66% of the time, but the reverse combination never resulted in macrocyst formation These data agree with the results of the first set of experiments and emphasise that cell contact between mating types is not essential for complete macrocyst formation Furthermore, the data indicate that a stable inducing factor (molecular weight about 12,000) was released by NC-4 very early under macrocyst-forming conditions The fact that V-12 supernatant did not induce a response in NC-4 cells suggests that this factor was unstable or possibly non-

Table 2 Effect of extracellular medium on macrocyst induction

Experimental situation	No of cultures	No of cultures with macrocysts
NC-4 supernatant to NC-4 cells	6	0
V-12 supernatant to V-12 cells	4	0
NC-4 supernatant to V-12 cells	35	22
V-12 supernatant to NC-4 cells	25	0
Distilled water to NC-4 cells	13	0
Distilled water to V-12 cells	13	0

existent The ability easily to induce V-12 to form macrocysts with NC-4 supernatant provides an excellent bioassay system for use in the purification of the mating factor

Macrocyst development might be divided into two events aggregation of single cells to form multicellular clumps, followed by differentiation of the aggregates into mature macrocysts It is unlikely that cyclic AMP is the small molecule that is involved in the formation of macrocysts of *D discoideum*, for fruiting bodies appeared in isolated cultures of NC-4 and V-12 when macrocysts could not form Furthermore, it seems that once macrocyst aggregation is induced, the events of differentiation must also be triggered since macrocyst development always went to completion

Although our results suggest that one strain (NC-4) could be an initiator or dominant strain in a sequential induction system, it is possible that the inducing factor from the opposite mating type (V-12) is simply less stable under our conditions

Effects of progesterone and EDTA on cyclic AMP and phosphodiesterase in *Dictyostelium discoideum*

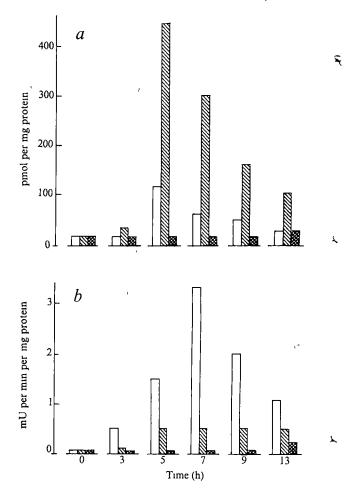
WHEN *Dictyostelium discoideum* amoebae are nutritionally deprived, they undergo a developmental programme which results in the formation of fruiting bodies composed of spore and stalk cells Early events in this cycle are marked by the aggregation of previously individual amoebae During this process they become elongated, and establish specific intercellular contacts, resulting in the formation of cell streams[1] Orientation of cell movement during this period is thought to be directed by an external gradient of cyclic AMP (ref 2) This compound elicits a chemotactic response from starved cells but not from growing cells[3,4] and can induce a period of coordinated movement in nutritionally deprived cells[5] A phosphodiesterase is also excreted by aggregating cells[6,7] activity of which modulates the cyclic AMP gradient Thus, a general model for communication between cells during aggregation is available Little is known, however, about the regulation of metabolic events which result in the differentiation of growth phase cells into aggregation-competent, cyclic AMP-sensitive cells, and in particular, the influence of cyclic AMP on these processes Since in other eukaryotes, changes in internal cyclic AMP are thought to mediate the actions of a variety of hormones, and regulate cell growth and


Fig 1 Intracellular cyclic AMP (*a*) and phosphodiesterase (*b*) levels (which includes both cytoplasmic and membrane-bound activities) in *D discoideum* cells incubated at 22 °C in buffer (open columns), buffer plus 10^{-3} M EDTA (hatched columns), buffer plus 3×10^{-5} M progesterone (cross-hatched columns) $1\ 4 \times 10^7$ Ax-2 amoebae, an axenic haploid strain[9], were plated on to 100×20 mm Falcon tissue culture dishes in 5 ml mM buffer [5 mM 2-(N-morpholino)-ethane sulphonic acid, pH 6 2, 10 mM KCl, 5 mM $MgCl_2$] with or without EDTA or progesterone[8] For studies in which cyclic AMP was measured, the media from four plates was aspirated at the indicated times and cells were immediately harvested in 5% cold TCA Samples were further prepared by the procedure of Maganillo and Vaughan[11], except that Dowex chromatography was performed at pH 6 Aliquots were assayed at three dilutions for cyclic AMP using the method of Gilman[11] For measurement of phosphodiesterase activity, cells were harvested in their media, centrifuged at 3,000g for 2 min and washed once with 50 mM Tris, pH 8, 4 mM $MgCl_2$ The pellet was frozen, then thawed in 1 ml 50 mM Tris, pH 8, 4 mM $MgCl_2$ and dialysed overnight against the same buffer Aliquots were assayed at 30 °C using the method of Brooker[12] Protein determinations were performed according to Lowry *et al*[13] Values represent the average of four experiments
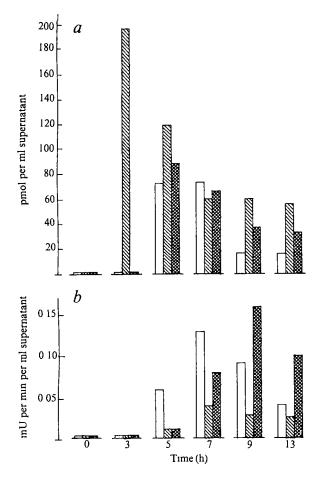

development, we investigated the possible intracellular role of this nucleotide in *D discoideum*

It is generally agreed that abnormal aggregation occurs if amoebae produce an improper chemotactic signal If changes in intracellular cyclic AMP affect processes critical to cell differentiation, however, it is also possible that abnormal aggregation occurs because cells have not been 'induced' to respond properly to a signal A recent study of the effects of various compounds on *D discoideum* revealed that cells treated with either EDTA or progesterone aggregate abnormally[8] In the presence of 10^{-3} M EDTA, a concentration below that of the magnesium ion concentration in the media, cells undergo extensive clumping and very limited streaming This abberant aggregation is completed within the normal period of time, 9 h In contrast, 3×10^{-5} M progesterone causes cells to

remain dissociated and not exhibit any of the morphological changes observed during starvation, even after 18 h incubation When the steroid is removed from the media, cells proceed to aggregate normally Since these two compounds inhibit cell aggregation in markedly different ways, we were interested in determining the level(s) at which they act Here, we report their effects on both intracellular and extracellular cyclic AMP and phosphodiesterase and relate these findings to cell morphology

Figure 1 shows that the intracellular cyclic AMP concentration of amoebae increases by six to eightfold approximately 5 h after transfer on to Petri dishes in non-nutritive media At this time, cells become elongated and establish specific cell–cell contacts typical of the early aggregation phase Similar qualitative changes in cyclic AMP levels in amoebae developing on Millipore filters have been reported[14] The increase in cyclic AMP content is followed by an eight to tenfold induction of phosphodiesterase activity The kinetics of enzymic stimulation correlate well with the decrease in cellular cyclic AMP observed after 7 h Addition of 10^{-3} M EDTA, which enhances the formation of small cell aggregates, produces over a 40-fold stimulation of the cellular cyclic AMP content Even after 11 h, when the cyclic AMP concentration of untreated cells has returned to almost the basal level, that of EDTA-treated cells

Fig 2 Cyclic AMP (a) and phosphodiesterase (b) excreted during starvation by control (open columns), EDTA- (hatched columns) and progesterone-treated (cross-hatched columns) cells Amoebae were incubated as described in the legend to Fig 1 At the indicated times, the media which was aspirated from the cells used for intracellular determinations was either made 1% in TCA and prepared for cyclic AMP assays or dialysed for 5 h against 5 mM Tris, pH 8, 4 mM $MgCl_2$, and then overnight against 50 mM Tris, pH 8, 4 mM $MgCl_2$ The latter samples were then assayed for phosphodiesterase activity
Values represent the average of four experiments

is still greatly elevated This prolonged elevation can be explained by the fact that no increase in phosphodiesterase activity is observed under such conditions Treatment with 3×10^{-5} M progesterone, which results in cells retaining their growth-phase appearance, inhibits both the rise in cyclic AMP and phosphodiesterase activity

The kinetics of cyclic AMP excretion are shown in Fig 2 In the case of untreated amoebae, the concentration of nucleotide in the media increases after 5–6 h of starvation and then decreases This decline is associated with a corresponding increase in an extracellular phosphodiesterase Cells incubated with 10^{-3} M EDTA excrete a large excess of cyclic AMP and do so several hours earlier than control cells During the next 12 h there is a gradual decline in the cyclic AMP level but not a return to that of control cells The small increase in extracellular phosphodiesterase activity seen in EDTA-treated cells is probably responsible for this gradual decrease It therefore seems that EDTA increases the levels of cyclic AMP by inhibiting its intracellular and extracellular degradation Since the extracellular nucleotide is detected early, when cells are incubated with EDTA, it is also possible that synthesis of the nucleotide is stimulated under these conditions Surprisingly, progesterone does not inhibit the appearance of either cyclic AMP or phosphodiesterase in the media, and may, in fact, enhance this process The contrasting effects of progesterone on the internal and external cyclic AMP and phosphodiesterase patterns may be explained by the existence of two systems, only one of which (intracellular) is progesterone sensitive A simpler explanation, however, would be that progesterone stimulates the cellular excretion of both cyclic AMP and phosphodiesterase Other experiments (C K and P B, unpublished) tend to support this model

The variations in the extracellular cyclic nucleotide concentrations are basically unchanged when cells are incubated with steroid Since the changes in extracellular cyclic AMP concentrations occurring in a cell population probably reflect the changes which occur at the individual cell level, this result suggests that the chemotactic signal, thought to orientate cell movement, is unaffected Progesterone probably prevents amoebae from responding to, rather than producing, the chemotactic signal This insensitivity to the chemotactic signal may be directly related to the inability of cells to accumulate cyclic AMP in the presence of steroid The 'inactivated' amoebae therefore tend to remain as isolated cells This interpretation of the intracellular role of cyclic AMP is compatible with the morphological changes seen in the presence of EDTA, that is, the formation of numerous small aggregates EDTA, which greatly increases the cellular levels of cyclic AMP, would produce highly 'activated' amoebae, metabolically prepared to respond to a proper orienting signal Measurements of extracellular cyclic AMP and phosphodiesterase suggest that these amoebae do not produce a proper chemotactic signal They do not stream normally, but instead form small aggregation centres This model predicts that high concentrations of exogenously added cyclic AMP (which would both accummulate within the cells and perturb the extracellular signalling pattern) should mimic the morphological effects seen with EDTA We have found that cells incubated in our conditions with 2×10^{-4} M cyclic AMP form many aggregates without visible streaming (C K and P B, unpublished) Chemotactic assays[4] used as an independent measure of cell differentiation, show also that progesterone-treated cells resemble growth-phase amoebae, whereas EDTA-treated cells behave as differentiated amoebae (C K and P B, unpublished) Obviously, a more extensive analysis must be undertaken to determine the specificity of action of progesterone and EDTA on *D discoideum* These experiments, which include determining their effects on adenyl cyclase, general RNA and protein synthesis, and cellular excretion, are in progress and should help clarify the processes involved in cell aggregation and the levels at which cyclic AMP influences this phenomena

Carbohydrate binding proteins involved in phagocytosis by *Acanthamoeba*

THE soil sarcodinid *Acanthamoeba castellanii* grows readily in axenic culture[1,2] or in monoxenic conditions with a variety of bacteria as food organisms[3] The reduced growth of this organism in the absence of particulate material[4] suggests that even under axenic conditions the formation of phagocytic vesicles is important in the uptake of nutrients, as in *Tetrahymena*[5] We present evidence that the preferential uptake by *A castellanii* of horse red blood cells over those from other sources[6] is caused by binding of these cells to carbohydrate sensitive sites on the surface of the amoebae, and that these sites may function in the same way in the amoeba's natural habitat

When horse erythrocytes were mixed with logarithmic phase cultures of *A castellanii*, massive mixed-cell agglutination resulted Such a reaction was absent in mixtures of amoebae with human (all ABO groups) or sheep red cells A range of carbohydrates were tested for their ability to inhibit this agglutination (Table 1) The sensitivity of this reaction is similar to that of haemagglutination caused by bacterial type 1 fimbria[7,8] Pretreatment of the horse red cells with concanavalin A (con A) (0 16 mg ml⁻¹) or with phytohaemagglutination (PHA) (Wellcome), did not abolish the mixed cell agglutination, although in the PHA-treated cells simple haemagglutination occurred

The effect of mannose on the preferential uptake of horse red blood cells was investigated by incubating horse and sheep red blood cells with amoebae in a glucose medium and horse red blood cells in a similar medium containing mannose (Fig 1) Clearly the inhibition of the agglutination reaction also inhibits the preferential uptake of horse cells

Carbohydrate-binding proteins have been implicated in many biological activities Rosen *et al*[9,10] have described such proteins on the surface of slime-mould amoebae and have suggested that they are important in the aggregation of these amoebae during plasmodium formation

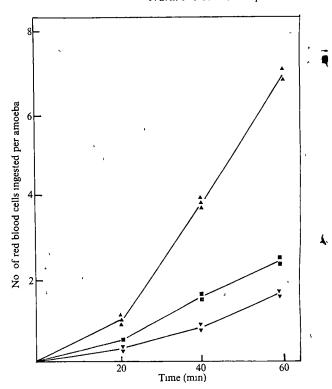
We suggest, therefore, that *A castellanii* possesses mannose-sensitive carbohydrate binding sites on its surface and that the attachment of particles to these sites facilitates their phagocytosis In contrast Allen *et al*[11] have reported that exogenous lectin (con A) will bind bacteria to the surface of mouse macrophages but this does not lead to phagocytosis, indeed, bound lectin will inhibit the attachment of opsonised bacteria This is not the case in *A castellanii*, in which lectins increase phago-


Fig 1 Phagocytosis of horse and sheep red blood cells by *A castellanii* Amoebae from a log phase culture were washed in 0 9% (w/v) NaCl and 1 ml of a suspension put in each of six flasks Medium (7 ml) containing proteose peptone 0 75% (w/v) and yeast extract 0 75% (w/v) were added to each flask, and glucose or mannose was added to a final concentration of 1 5% (w/v) Uptake of horse cells in glucose (▲) and in mannose (▼), is compared with uptake of sheep cells in glucose (■) Uptake was measured spectrophotometrically following hypotonic lysis of uningested red cells and acetic acid extraction of the haemoglobin from the amoebae as described[6]

cytosis[12] The implication of the binding sites which we describe here to the ecology of the amoeba has been investigated by testing a variety of potential food organisms for their ability to form mixed cell aggregates with *A castellanii* and to support monoxenic growth (Table 2) The ability of these particles to attach to the surface of the amoebae, thereby forming aggregates, correlates well with the occurrence of mannose in the

Table 1 Inhibition of mixed cell agglutination of *A castellanii* and horse red blood cells by various carbohydrates

Carbohydrate	Minimum concentration inhibiting mixed cell agglutination
α-Methyl-D-mannoside	3 mM
D-mannose	3 mM
D-fructose	3 mM
Mannan (yeast)*	0 2%
D-glucose	not at 100 mM
D-galactose	not at 100 mM
D-arabinose	not at 100 mM
n-Acetyl glucosamine	not at 100 mM
Sucrose	not at 100 mM
Trehalose	not at 100 mM
L-sorbose	not at 100 mM
Melebiose	not at 100 mM
Inositol	not at 100 mM

Series of double dilutions of the carbohydrates were prepared in a salts solution containing (g l⁻¹) NaCl, 4 0, KCl, 0 2, MgSO₄, 0 05, CaCl₂, 0 07, NaHCO₃, 0 018 and 50 mM phosphate buffer, pH 7 2 A suspension (0 1 ml) of *A castellanii* (10⁸ ml⁻¹) and 0 1 ml of a horse red blood cell suspension (10% v v) were added to each well on a depression plate containing 0 4 ml of the carbohydrate solution The plates were incubated at 30 °C and agglutination results read 20 min later All carbohydrates were obtained from Sigma
*Mannan from *Candida albicans* (a gift from E G V Evans) agglutinated *A castellanii* in the absence of red blood cells

Table 2 Mixed cell agglutination of *A castellanu* and monoxenic growth

Organism particle	Mixed agglutination with *A castellanu*	Supports monoxenic growth
Horse erythrocytes	++++	—
Sheep erythrocytes	—	—
Human erythrocytes	—	—
Saccharomyces cerevisiae CMD 53	++++	+
Saccharomyces carlsbergensis IMI 80178	+++	+
Candida utilis CMD 39	++	+
Shizosaccharomyces pombe	+	+
Pseudomonas aeruginosa PAO 1	—	—
Aerobacter aerogenes NCIB 418	±	+
Bacillus subtilis NCIB 8057	—	—
Stapylococcus aureus CMD 99*	—	±
Polystyrene spheres 9 μm diameter	—	—

Agglutination was tested as described in Table 1 All the organisms were spread on to non-nutrient agar plates and allowed to dry, the plates were inoculated at their centres with drops of log phase culture of *A castellanu*, incubated at 30 °C and examined daily All the agglutination reactions described were sensitive to D-mannose, α-methyl-mannoside and fructose

cell walls of the four yeast species tested Although, under the conditions of our tests, organisms not so bound will support growth of the amoebae, they are present in greater numbers than would be food organisms in the natural environment of *Acanthamoeba* At the lower temperatures and cell populations normally found in the soil, we suggest that phagocytosis would be greatly facilitated by preliminary binding of food organisms to the amoeba It seems likely therefore that yeasts or mannan-containing fungi would form an important source of food for this soil amoeba

Some strains of *Acanthamoeba* will cause menigoencephalitis in experimental animals[13] and humans[14-16] Stevens and Kaufman[17] have already compared binding sites for con A in virulent and non-virulent strains It would therefore be interesting to compare such strains with respect to the lectin-like activity which we describe here

We thank Dr A J Griffiths and Mr I J C Macintosh for discussions, and help in preparing the manuscript R C B is in receipt of a grant from the MRC as a postdoctoral research associate

Visual adaptation in butterflies

THE brilliant glow appearing in the compound eye of butterflies has intrigued investigators of insect eyes since the observations of Exner[1] Miller and Bernard have presented a convincing optical interpretation of the butterfly glow, that the tracheole basal to the rhabdom is modified in such a way as to act as a quarter wavelength interference reflection filter (see refs 2–4) On light adaptation, the eye glow vanishes rapidly[1] Miller and Bernard have conjectured that this is caused by a distal migration of pigment granules in the pigment cells surrounding the crystalline cone[2]

Both the basal reflection theory and the pigment migration hypothesis have been challenged by Swihart et al[5] (highlighted recently[6]) They concluded that the phenomena can be attributed to reflections from corneal processes and photomechanical changes in the retinula cells[5,7], respectively Comparison of our studies on the pupil mechanism of flies[8-10] with similar investigations on the visual adaptation of butterflies[11] suggests that most of the data of Swihart et al[5] strongly support the earlier theories, if these are modified in one important respect—that the distal migration occurs not in the pigment cells but within the retinula cells themselves

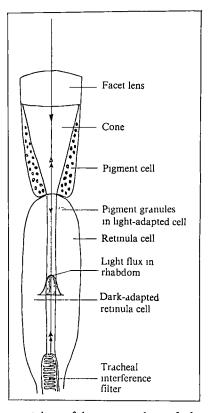
This view is presented diagrammatically in Fig 1, showing an ommatidium of a butterfly Since the rhabdom functions as an


Fig 1 An ommatidium of the compound eye of a butterfly The dioptrical apparatus consists of a transparent facet lens and a cone which are surrounded by heavily pigmented "screening" pigment cells The photoreceptor cells feature a specialised membrane structure, the rhabdomere, which contains the visual molecules Within each ommatidium the rhabdomeres join in a fused rhabdom, an entity which functions as an optical wave guide[11-13] Proximal to the rhabdom an invaginated structure of the tracheal system creates a reflection interference filter So light which enters the ommatidium through facet lens and cone after being propagated by the rhabdom is partially reflected by the basal reflection filter and so can by the same route leave the eye again Obviously a fraction of the light propagated in the rhabdom is absorbed by the visual molecules but owing to the waveguide properties of the rhabdom light is also propagated outside the rhabdom boundary as indicated by the bell-shaped curve, representing schematically one of the possible light distributions Hence pigment granules, existing in the photoreceptor cells as follows from electronmicroscopy (J Tinbergen, unpublished), if localised near the boundary of the rhabdom, can also diminish the light flux, that is, by absorption as well as by scattering By variation of the amount of pigment granules near the rhabdomere the light flux in the butterfly rhabdom can be regulated in an identical way to that occurring in other insects[8-16] In the dark-adapted state (Fig 1, left) the pigment granules are dispersed through the visual cell soma On light adaptation (Fig 1, right) the pigment granules will move towards the rhabdom until an equilibrium situation is reached (see refs 8, 12, 15, 16 and 22)
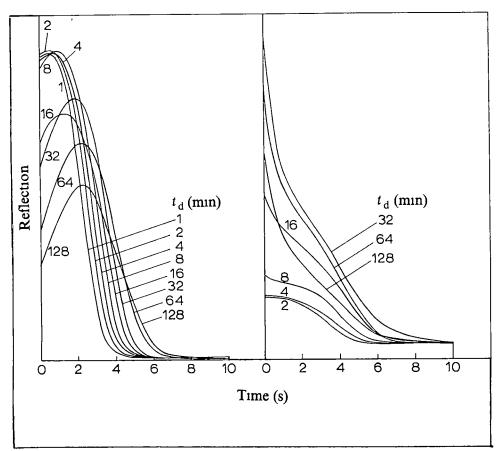

Fig 2 Reflection of the compound eye of the small Tortoiseshell (*Aglais urticae*, Nymphalidae) The curves represent the responses to 10 second pulses of intense light subsequent to a variable dark time t_d, which in turn followed just such a 10 second pulse Irradiation of 584 nm (Fig 2a) and 488 nm (Fig 2b) was applied The initial changes are caused by photochemical events, followed by reflection decreases which are probably due to the migration of absorbing pigment granules towards and against the butterfly rhabdom, thus fulfilling a pupil action The pupil opens during the dark within 0 5-1 min So the initial value of the reflection indicates the state of the visual pigment It proves (Fig 2a) that after prolonged dark adaptation the initial reflection value falls, pointing to dark regeneration of a green rhodopsin This regeneration occurs with a biphasic process, since in the blue the initial reflection first increases but later on decreases again when the dark adaptation time rises above about half an hour (Fig 2b) Possibly a violet absorbing intermediate is involved in the dark regeneration process

optical waveguide the light flux reaching the visual molecules can be controlled by the pigment granules in the photoreceptor cells through regulation of their number near the boundary of the rhabdom (see refs 8-14), a pupil function is in this way fulfilled As a result of the interference reflection filter created by the tracheole basal to the rhabdom, a fraction of the incident light will leave the eye again after a double passage through the rhabdom This fraction of light is the glow visible in the butterfly eye An implication of the outlined conception is that reflection measurements provide knowledge concerning both the visual pigment processes and the pigment migration inside the visual sense cells

The butterfly glow and its disappearance are best seen in the centre of the deep-pseudopupil[1,14], using a vertical-illumination microscope The observations (ref 14, Fig 18) convincingly support the view that the glow is in fact light leaving the rhabdom, and these results disagree completely with the recent proposal[5] that the glow represents reflections arising from the ring of corneal processes surrounding the cone[6,7]

The experimental reflection curves shown in Fig 2 were obtained from the small Tortoiseshell butterfly, *Aglais urticae* (Nymphalidae) A saturating illumination (10 s) of wavelength λ was given after a variable dark-adaptation time t_d, which in turn followed a similar 10 s pulse Figure 2a and b represent the superimposed recordings of the reflected light during light adaptation at λ=584 nm and λ=488 nm, respectively An initial reflection increase (a) or an initial decrease (b), which becomes more prominent as t_d is increased, is followed in both cases by a considerable reflection decrease, the time course of which becomes longer with longer t_d

These observations parallel transmission measurements from blowfly photoreceptors[15] In the latter, intense illumination causes initial transmission changes resulting from photochemical processes in the visual pigment, and subsequently

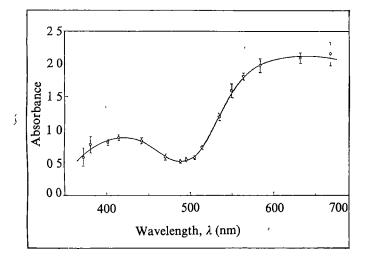
there is a decrease in transmission which is the consequence of absorbing and scattering pigment granules accumulating near the rhabdomere acting as a light guide[8-16] In the fly, the rate of fall in transmission also slows down with prolonged dark time t_d

Mutatis mutandis, it is reasonable to assign the initial reflection changes in Fig 2 to photochemical processes and to interpret the subsequent fall in reflection as induced by retinula cell pigment granula gathering near the boundary of the butterfly rhabdom, in agreement with the hypothesis stated above Swihart *et al*[5] remark that "should the basal theory be correct, one would imagine that the basal reflections would increase in apparent intensity as the visual pigments were bleached"[5]

Yet, bleaching, implying photolysis of visual pigment, cannot be the correct explanation for the initial events of both Fig 2a and b Rather the transients can be interpreted as representing photochemical conversions of a green-absorbing rhodopsin P525 into a blue-absorbing metarhodopsin M480 and vice versa as has been concluded for the related moths[17,18], similar visual pigment processes have been reported for other invertebrates[19,20]

A photochemical equilibrium between the two pigment states will be established at light adaptation This equilibrium, however, is obviously not maintained during the dark The initial value of the reflection at 584 nm continuously decreases with increasing dark time t_d which implies an increase in absorption at that wavelength, or a regeneration in the dark of the green rhodopsin Although this is not apparent at 584 nm (Fig 2a) the dark process must involve two stages, since at 488 nm (Fig 2b) the initial value of the reflection increases with t_d only during the first half hour of darkness and decreases again after a longer period in the dark

The biphasic dark process can be explained by several

alternatives, such as the blue absorbing metarhodopsin being a quasi-thermostable photoproduct being converted by way of a violet-absorbing intermediate into the native rhodopsin, a blue and a violet metarhodopsin could coexist, each state having its own dark conversion rate, dark conversions of other rhodopsins than that absorbing green could be involved The decision as to which alternative must be ruled out requires a detailed analysis, but the unequivocal establishment of the dark-conversions of the butterfly visual pigment(s) would provide a valuable example of the very scantily known *in vivo* dark processes of invertebrate visual pigments[21]


The assumed existence of a green rhodopsin in butterfly eyes is in good agreement with Swihart *et al*[5] that the action spectrum for the extinction of the butterfly glow points to a visual pigment absorbing most strongly at 520–540 nm Hence, the pupil of butterflies could be driven by a force coupled to the receptor potential in the retinula cells in a manner corresponding to the pupil mechanism of flies[8,12,15,16,22]

A further parallel between fly and butterfly pupils may be put forward Illumination of fly photoreceptor cells with intense blue light predominantly converts fly rhodopsin P495 into metarhodopsin M580, resulting in a delayed dark adaptation, which is counteracted by the opposite photopigment conversion[22,23] Furthermore, the pupil of flies absorbs most strongly at just those blue wavelengths which most effectively delay dark adaptation[9,22] We therefore conclude that the fly's pupil not only controls the light flux in the photoreceptor but also its spectral distribution, so as to improve the speed of adaptation

Antagonistic effects of visual pigment conversions on the adaptation of photoreceptor cells have been reported also for the barnacle[20], having a green rhodopsin P532 which is photo-interconvertible with a metarhodopsin M495 In the barnacle it is red light, favouring conversion of rhodopsin to metarhodopsin, which seems to be most effective in delaying dark adaptation of the visual sense cells In the butterfly delayed dark adaptation can also be induced with intense red illumination (D G S, unpublished) Hence, from our knowledge of the pupil of flies we might expect that the butterfly's pupil absorbs extremely in the red to improve the speed of dark adaptation in those photoreceptor cells possessing a green rhodopsin

The absorbance spectrum of the pupil of the small Tortoiseshell butterfly (Fig 3) shows little absorbance in the blue and extreme absorbance in the red, confirming the stated prediction Since we have observed in other butterflies pupil spectra as well as photochemical processes very similar to those reported above, we conclude that, although the visual pigments and the pupil of butterflies and flies seem to have quite different spectral properties, in at least these insect species the pupil may have an

essential function in the speeding up of the dark adaptation after intense illumination It also seems that the butterfly experiments can be satisfactorily interpreted by a combination of the basal reflection theory with the hypothesis of the intracellular pupil

Evidence for hormonal control of integumentary water loss in cockroaches

The susceptibility of terrestrial insects to desiccation is minimised by extremely effective integumentary waterproofing, which results from the presence of remarkably impermeable epicuticular lipids[1] and, it is suggested, from the properties of the underlying epidermal cells[2] On the basis of rather limited information[3,4] it has, in addition, been suggested that the rate of integumentary water loss may be regulated, the degree of permeability depending on the ambient humidity[2]

We now have evidence that integumentary waterproofing may be hormonally controlled Weight loss is more rapid in decapitated cockroaches than in normal ones or in those in which nervous connection with the brain has been severed (Fig 1) The involvement of a blood-borne factor is also indicated by the significant reduction in apparent water loss after injection of brain extract (Fig 2), or to a lesser extent corpus cardiacum extract, into decapitated individuals

That the accelerated water loss induced by decapitation occurs largely through the integument, and not through the excretory or respiratory systems, is deduced from the following evidence First, anal blocking did not reduce the rate of waterloss in decapitated individuals Second, the activity of thoracic spiracles was reduced following decapitation Third, exposure to 5% CO_2 greatly increased spiracular opening, in both normal and decapitated cockroaches, but did not abolish the more rapid water loss in the latter Finally, spiracular blocking did not significantly reduce water loss in decapitated individuals

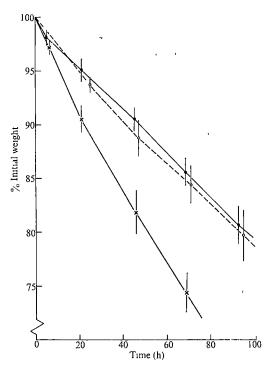
The accelerated integumentary water loss induced by


Fig 1 Effects of decapitation and severance of the neck connective on the decline in weight of individuals maintained at 54–55% r h In this, and subsequent diagrams, the symbols indicate the mean of measurements made on ten individuals, the vertical lines indicating the extent of twice the standard error of the mean ●, Normal insects, ○, neck connective severed, ×, headless insects

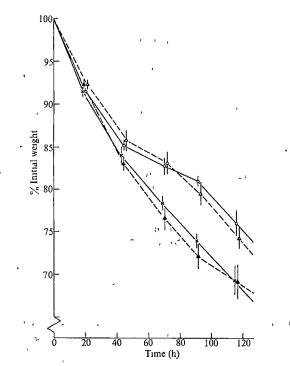
decapitation could have resulted from nonspecific effects on the permeability of the epidermis, perhaps through an increase of intercellular diffusion resulting from changes in the lateral junctional complexes of epidermal cells (see ref 2) The cation permeability of the cellular layer of the nerve sheath, however, was unaffected by decapitation the extraneuronal potentials, and absence of effects on


Fig. 2 The effects of injection of brain extract (1 brain + 50 µl saline) on the decline in weight of decapitated insects compared with that of normal and control individuals maintained at 48–50% r h ○, Normal insects, △, headless + brain-extract, ▲, headless + Ringer solution, × headless

the action potentials induced by high-potassium saline were similar to those of normal individuals[5]

It is also possible that the apparent blood-borne factor might act by changing the synthesis and deposition of epicuticular lipids The incorporation of ^{14}C-acetate into epicuticular lipids[6] following injection into the haemolymph, however, was not significantly reduced in decapitated individuals The radioactivity of the lipids washed from the body surface of normal individuals with Triton X and toluene solvent 24 h after injection of 0 5 µCi into the haemolymph was $1,539 \pm 156$ $(n=6)$ d p m compared with $1,436 \pm 260$ $(n=5)$ d p m for decapitated ones

It is, thus, difficult to avoid the conclusion that integumentary permeability may be under neuroendocrine control The apparent involvement of both the brain and the corpus cardiacum suggests a similarity with other systems in which neurosecretory material is synthesised within neuronal cell bodies in the brain and is then transported along specialised axons to the corpus cardiacum (see ref 7)

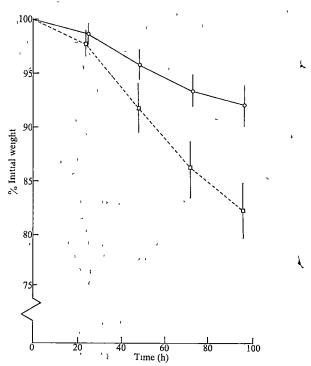
The prolonged effect of injected brain extract (Fig 2) in reducing water loss suggests that the blood-borne factor is not rapidly metabolised in decapitated individuals A rapid inactivation must, however, be assumed in normal individuals, for injection of brain extract 24 h before the application of a neck ligature produced no appreciable reduction in water loss (Fig 3) This situation seems to be analogous


Fig 3 The effect of the application of a neck ligature 24 h after the injection of brain extract (1 brain + 50 µl saline) on the decline in weight at 48–50% r h ○, Normal insects, □, brain extract injected 24 h before application of neck ligature

to that for the diuretic hormone in the tsetse fly, in which it is proposed that an inactivating factor is released into the haemolymph from the thoracic ganglion together with the hormone[8] The persistence of the effects of brain extract in decapitated insects could either mean that the inactivating factor is unstable following extraction, or that it is normally synthesised in the brain only in response to high levels of the waterproofing factor in the haemolymph

Removal of the frontal ganglion or severance of the frontal connectives increases the rate of water loss from cockroaches and it is suggested that the frontal ganglion receives an input from osmoreceptors[9] The frontal ganglion could also be involved in mediating the release of water-

proofing factor from the brain by way of the corpus cardiacum

Little is known concerning the mode of action of the postulated blood-borne factor It has been shown, however, that decapitation has little effect on the electrical resistance of the integument[10] The resistance for normal pronotal integument averaged $3,571 \pm 1,324\,\Omega\,cm^2$ as compared with $3,661 \pm 1,020\,\Omega\,cm^2$ measured in decapitated individuals The observations would accord with the idea, for example, that transpiration is increased by alterations in an oriented epicuticular lipid layer[1] which may be insufficient to affect permeability to inorganic cations and thus the flow of current across the integument

The physiological role of a neuroendocrine control of integumentary transpiration remains to be elucidated It would be an obvious advantage for insects to be maximally waterproof in dry conditions It is conceivable, however, to cite a single example, that under conditions of excessive water intake (such as might occur with a liquid or semi-liquid diet of low nitrogen content) it could be physiologically advantageous to increase the rate of integumentary transpiration Alternatively, it could be that this apparent neuroendocrine control ensures that the organisation of the epicuticular lipids is maintained so as to ensure maximal waterproofing An example of such a maintenance function could be the controlled release of the antioxidant, protocatechuic acid, which is necessary to prevent the degradation and polymerisation of epicuticular lipids[11]

Anaesthetisation of prefrontal cortex and response to noxious stimulation

REPORTS indicate that responses to pain may be modified by damage to the frontal lobes (see refs 1 and 2) Nevertheless, neither the nature of the change nor the degree to which any effect of damage is localised anatomically has been firmly established I have systematically examined the function of the prefrontal cortex in response to an aversive stimulus in the rat Small quantities of a short-acting anaesthetic, procaine hydrochloride, were injected to block directly the neural function of specific areas within the prefrontal cortex The prefrontal cortex in the rat occupies both a lateral region, the dorsal bank of the rhinal sulcus, and a medial region, the pregenual medial wall of the hemisphere[3] In the rat, the prefrontal cortex is involved in brain-stimulation reward[4] I suggest that, in addition, the prefrontal cortex acts to limit the response to painful stimulation, and that this anti-nociceptive function is localised in or near the sulcal region

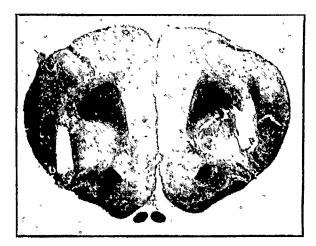
Following the bilateral injection of 1 0 μl 5% procaine hydrochloride (see legend to Fig 1), the preinjection jump threshold of 0.86 ± 0.22 mA (mean $\pm$ s d) was reduced to 0.77 ± 0.19 mA ($t=6.2$, $P<0.001$), and after bilateral injection of 2 μl, it was further reduced to 0.73 ± 0.21 mA ($t=6.9$, $P<0.001$) Every animal exhibited a reduction in jump threshold following both the 1 0 and 2 0 μl bilateral injections The


Fig 1 An example of bilateral cannula tracks with the tips in the sulcal prefrontal cortex For the cannula implantation, level-head stereotaxic coordinates[6] were used Adult male, hooded rats (300 g) were cannulated and injected as described elsewhere[4] Each rat was implanted bilaterally with stainless steel guide cannulae, fitted with an obturator The latter was removed and replaced with an injection cannula before an injection experiment Ten rats were implanted bilaterally with cannulae in the sulcal prefrontal cortex The stereotaxic coordinates of each cannula tip were 2 3 mm anterior to the bregma, 3 5 mm lateral to the sagittal sinus, and 4 0 mm beneath the dorsal surface of the brain (+2 3 3 5 4 0 mm down) Either 5% procaine hydrochloride in 0 9% saline or saline alone was injected bilaterally Responses to aversive footshock were determined using a 'flinch–jump' test[5] Each rat received six series of ten shocks per series, in which scrambled electrical shocks (0 5 s duration) were delivered at 15 s intervals to the floor of the test box The shock intensities in each series were ten consecutive values from the range 0 13 to 1 60 mA, with 60 s between each series Shocks were delivered in ascending and descending order on alternate series The rat's response to each shock was recorded as either no response, flinch (startle, including forepaw-shaking), or jump (both rear paws leave floor) The jump response alone seems to be related to specifically painful stimulation, since morphine greatly increases the jump threshold without affecting the flinch threshold[5] The flinch and jump thresholds were noted for each series, and the mean values over the six series calculated The rat was then removed, injected bilaterally with 1 0 μl 5% procaine hydrochloride, and immediately returned to the test box Six more shock series were run to determine postinjection flinch and jump thresholds After 30 min, the effects of the procaine having dissipated, the rat was reinjected with 2 0 μl 5% procaine hydrochloride, and a second series of six postinjection series were run The same procedure was repeated no sooner than 48 h afterwards, to determine the effects of the injection of 0 9% saline For statistical analysis, the threshold results obtained for the pre- and postinjection series were compared using a correlated t test (two-tailed)

flinch threshold, in contrast, remained unchanged The pre-injection flinch threshold was 0.19 ± 0.05 mA, after bilateral injection of 1 0 μl procaine hydrochloride 0.18 ± 0.03 mA, and after 2 0 μl bilaterally 0.18 ± 0.03 mA (non-significant differences) In the saline control experiments, the preinjection jump threshold of 0.86 ± 0.22 mA did not differ significantly from the threshold value 0.87 ± 0.22 mA after the injection of 2 0 μl saline bilaterally The lowered jump threshold which followed bilateral anaesthetisation of the sulcal prefrontal cortex did not result from a nonspecific reduction in response thresholds, since first, the flinch thresholds remained unchanged, and secondly, such anaesthetisation has been shown to increase self-stimulation thresholds[4] Thirdly, while the anaesthetic was effective, the general behaviour of the animals seemed to be unaffected (see also ref 4) Bilateral procaine injections seemed to be necessary since, in subsequent work, no effect of unilateral procaine injection on the jump threshold was observed An example of histology which shows that the tips of the cannulae were placed bilaterally in the sulcal region is shown in Fig 1

Additional experiments were run to determine the degree

of localisation of the effect of bilateral anaesthetisation on the jump response to footshock Four rats were implanted with bilateral guide cannulae aimed at the medial prefrontal cortex (+2 3 2 0 2 4 mm down, angled 28° towards the midline) and three rats with bilateral cannulae aimed 1 0 mm behind the effective sulcal placement The animals were tested as above Bilateral injections of 1 0–2 0 μl procaine hydrochloride, or 0 9% saline, had no effect on either the jump or the flinch thresholds in both groups of animals This series of experiments demonstrates conclusively that bilateral anaesthetisation of a region in or near the sulcal prefrontal cortex lowers the threshold of the jump response elicited by footshock The jump response, in contrast to the flinch response, seems to be elicited by painful consequences of footshock[5] A region specifically in or near the sulcal prefrontal cortex seems to be implicated, since procaine injected into either the medial prefrontal cortex or a site 1 0 mm behind the effective site had no effect on the jump threshold The conclusion that, in the intact rat, a region in or near the sulcal prefrontal cortex functions to limit the response to painful footshock, is supported by the results of these experiments Also of interest was whether the prefrontal cortex is a site of action of the potent analgesic drug, morphine Since bilateral injections of morphine sulphate (4% solution) into either the sulcal or the medial prefrontal cortex do not affect the jump threshold (S J C , unpublished), it would seem unlikely that morphine analgesia[5] involves any action within the prefrontal cortex

Pre- and postsynaptic components in effect of drugs with α adrenoceptor affinity

ACTIVATION of α adrenoceptors on noradrenergic nerve endings is thought to inhibit the release of noradrenaline by nerve impulses[1,2] The existence of a presynaptic receptor system introduces a new concept to the pharmacology of drugs with affinity for α adrenoceptors Only when the presynaptic nerve does not secrete, as for example in the absence of impulses, may one assume *a priori* that the observed postsynaptic effects of these drugs result from their interaction with postsynaptic receptors When action potentials arrive at the nerve endings, noradrenaline is released and keeps the postsynaptic receptors in a certain degree of excitation Drugs which activate α adrenoceptors may enhance this excitation by their postsynaptic effects, or reduce it by their presynaptic actions Conversely, α adrenolytic drugs may diminish the excitation by postsynaptic blockade, or enhance it by facilitation of release If the postsynaptic receptors are of the β type, the prevailing action is presynaptic, thus, drugs which activate α adrenoceptors reduce[3–5], whereas, less regularly, α adrenolytic drugs increase[6] cardiac responses to sympathetic nerve stimulation If the postsynaptic receptors are of the α type, the prevailing effect of α adrenolytic drugs is postsynaptic blockade[7], we report here that the effects of drugs which activate α adrenoceptors are diverse

The experiments were performed on rabbit main pulmonary arteries, in which postsynaptic α adrenoceptors mediate

vasoconstriction Artery strips were superfused with Krebs–Henseleit solution containing propranolol, cocaine and corticosterone to block β adrenoceptors and the neuronal and extraneuronal uptake of noradrenaline, respectively Actions on postsynaptic α adrenoceptors were studied by determining dose–response curves in the absence of nerve impulses For the separate study of presynaptic actions, arteries were preincubated with ³H-noradrenaline, and drug effects on the overflow of tritium evoked by transmural electrical stimulation were measured The mode of stimulation used selectively excites the adrenergic nerves of the arteries, the stimulation-induced overflow of tritium reflects the stimulation-induced secretion of noradrenaline from nerve terminals[8,9] To study the influence on postsynaptic cells during active neurotransmission, frequency–response curves were elicited before and after the addition of the drug

Isolated pre- and postsynaptic actions of oxymetazoline and phenylephrine are shown in Fig 1 Oxymetazoline preferentially activated presynaptic α adrenoceptors and thus inhibited release, whereas phenylephrine preferentially activated postsynaptic receptors and thus induced contraction Methoxamine behaved like phenylephrine, clonidine has been shown to behave like oxymetazoline[8] The differences in the relative potencies of these drugs may reflect structural differences in pre- and postsynaptic binding sites

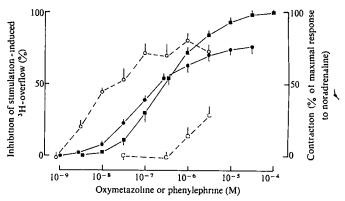
Stepwise increases in the frequency of transmural stimulation induced stepwise contraction, maximal at 16 Hz Figure 2 illustrates the influence of drugs which activate α adrenoceptors at low concentrations which, in the absence of impulse flow, caused contractions ranging between 1 0% and 3 7% of the maximal response to noradrenaline As would be predicted from their relative pre- and postsynaptic potencies, oxymetazoline and clonidine reduced, whereas phenylephrine and methoxamine enhanced neurogenic vasoconstriction The effect of α adrenoceptor-activating drugs in inhibiting noradrenaline release, declines as the frequency of stimulation is increased[3,5] Accordingly, clonidine and oxymetaxoline inhibited smooth muscle responses to stimulation at low, but not at high frequency The


Fig. 1 Pre- and postsynaptic actions of oxymetazoline (○, ●) and phenylephrine (□,■) in the rabbit pulmonary artery Left ordinate, presynaptic action (○,□) Arteries were preincubated with 1 5 × 10⁻⁸ M (—)-³H-noradrenaline for 1 h and then superfused with fresh medium containing 3 × 10⁻⁵ M cocaine, 4 × 10⁻⁵ M corticosterone and 4 × 10⁻⁶ M propranolol Each strip was stimulated five times (S₁–S₅) for 3 min with pulses of 0 3 ms duration and 150 mA current strength at 2 Hz Stimulation periods started after 126, 144, 162, 180 and 198 min of superfusion Oxymetazoline or phenylephrine were added 12 min before S₄ Phenylephrine concentrations exceeding 3 × 10⁻⁶ M could not be tested, since they accelerated basal tritium outflow In control experiments, the ratio between the overflow of tritium evoked by S₄ and that evoked by S₃ was 0 97 ± 0 03 (n = 11) The ordinate indicates percentage decreases of the ratio caused by the drugs Each point is the mean ± s e m of four to eight experiments Right ordinate, postsynaptic action (●,■) Two dose–response curves were determined on each strip, first a curve for noradrenaline, then a curve for oxymetazoline or phenylephrine Results are corrected for the increase of contractions with time[8] Values are the means ± s e m of five dose–response curves for oxymetazoline and phenylephrine

inhibition was observed with 10^{-8} — 10^{-7} M clonidine[8] and 10^{-9} — 3×10^{-9} M oxymetazoline, at higher concentrations, postsynaptic receptor activation prevailed and vasoconstriction was enhanced In contrast, phenylephrine and methoxamine uniformly enhanced vasoconstriction in response to low frequency stimulation at concentrations from 3×10^{-9} — 3×10^{-8} M and 3×10^{-8} — 3×10^{-7} M, respectively

In vivo, action potentials continuously arrive at nerve endings Our results demonstrate that in this situation a presynaptic component significantly contributes to the overall postsynaptic effect of some drugs activating α adrenoceptors, even if postsynaptic receptors are of the α type Selective pre- and postsynaptic receptor activation may also explain the diverse effects of α sympathomimetic drugs on the response of vas deferens to stimulation of its motor nerves [5,10-12] Detailed analyses of preand postsynaptic components may lead to a more complete understanding of the pharmacology of drugs that interact with α adrenoceptors

Affinity partitioning of acetylcholine receptor enriched membranes and their purification

AFFINITY chromatography, which uses a specific ligand coupled to a solid matrix to adsorb selectively a macromolecule, has been used extensively in the purification of soluble proteins[1] Although the purification of cells or cellular membrane fragments containing surface receptors has been attempted with this procedure[2-15], the approach has been less successful because of difficulties in eluting bound particulate substances from the solid matrix Recently, we described a method called affinity partitioning[16] for separating soluble proteins in aqueous polymer two-phase systems[17] by adding a polymer-ligand with a relatively high affinity for a binding site on the protein to be purified, and a solubility preference for one of the phases Since cells and cell fragments[18,19] can be partitioned and recovered from aqueous polymer two-phase systems, it seemed possible that the principle of affinity partitioning could be used in their fractionation With the absence of a solid matrix, problems of recovery would be obviated We describe here the use of polymer coupled to a ligand that binds to the nicotinic cholinergic receptor site to purify cholinergic receptor enriched membranes derived from electroplax of *Torpedo californica*

This membrane system was used to evaluate application of affinity partitioning to particulates because of the following favourable characteristics first, the membranes contain unusually high receptor densities (up to $30,000\ \mu m^{-1}$)[20,21], second, there is detailed knowledge of the ligand specificity and molecular properties of the binding site[22], third, differential and sucrose density gradient centrifugation have shown[23] that discrete membrane fragments enriched in nicotinic cholinergic

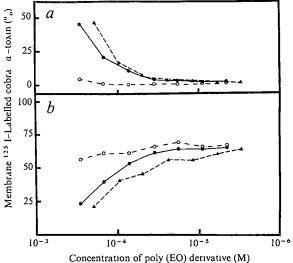
Concentration of poly (EO) derivative (M)


Fig 1 Distribution of membrane-bound ^{125}I-labelled α-toxin in presence of various concentrations of MA-poly(EO) (○), TMA-poly(EO) (●) and PTMA-poly(EO) (▲) The final phase system contained (per kg) 4 32% (w/w) Dextran T-500, 3 59% (w/w) poly(EO) 6,000, 1 25 mmol sodium phosphate, pH 7 4, 4 75 mmol NaCl Unsubstituted poly(EO) was replaced with an equal amount of poly(EO) derivative to give the indicated concentrations of terminal ligands Substitution grades of PTMA-poly(EO), MA-poly(EO) and TMA-poly(EO) were calculated from elemental analysis to be 66%, 96% and 103%, respectively, where 100% substitution grade is two terminal molecules of ligand per linear poly(EO) molecule We express the molarity of polymer-ligand as the ligand molarity, were it free in solution Sufficient iodinated toxin to occupy approximately 7 3% of the α-toxin binding sites was added to a membrane fraction purified by sucrose density gradient centrifugation[23] Phase systems containing membrane-bound ^{125}I-labelled α-toxin were mixed and placed on ice for 15 min and then centrifuged at 500g for 15 min at 5 5 °C Aliquots of top (*a*) and bottom (*b*) phases were collected and counted in a Nuclear Chicago gamma-counter

Table 1 Effect of bisquaternary methonium compounds on toxin binding and affinity partitioning

	Concentration (M) that inhibits initial rate of toxin binding by 50%	Concentration (M) that inhibits PTMA-poly(EO) effect by 50%
Decamethonium	3×10^{-8}	2×10^{-7}
Hexamethonium	1×10^{-6}	3×10^{-6}
Trimethonium	7×10^{-5}	$> 5 \times 10^{-4}$

Initial rate of ^{125}I-labelled *Naja naja siamensis* α-toxin binding was determined by a modification of the method of Schmidt and Raftery[26] Reaction mixtures contained 4×10^{-8} M acetylcholine receptor and fourfold molar excess of ^{125}I-labelled *Naja naja siamensis* α-toxin (5–10 Ci mmol^{-1}) in 10 mM phosphate, pH 7 4 The reaction rate approximated pseudo first-order kinetics During incubation in the absence of inhibitory ligand the reaction progressed to 30–40% of completion and initial rates were calculated assuming a first order approach to equilibrium The concentrations of bis-quaternary methonium compounds required to inhibit the affinity partitioning of membrane-bound ^{125}I-labelled α-toxin in the top phase was determined using a system like that in Fig 1 with 1 85 × 10^{-4} M PTMA-poly(EO)

receptors, or Na$^+$-K$^+$-stimulated adenosine triphosphatase, or membrane-bound acetylcholinesterase can be fractionated from homogenates of the electric organ of *Torpedo californica*

A standard two-phase system containing dextran and polyethylene oxide was used The polymer-ligand, α,ω-*bis*-4-trimethylammonium (phenylamino) polyethylene oxide [PTMA-poly(EO)] was synthesised from (4-aminophenyl) trimethylammonium hydrochloride iodide (Eastman) and α,ω-dibromopolyethylene oxide by a method based on that described by Johansson[24] The quaternary ligand we used has been coupled to Sepharose through a side arm and used for affinity chromatographic purification of acetylcholinesterase and detergent-solubilised receptor[25] Since this compound like most others known to react with the cholinergic receptor is charged, other cationic ligand-polymer conjugates with anticipated differences in receptor affinity, α,ω-*bis*trimethylammonium polyethylene oxide [TMA-poly(EO)] and α,ω-*bis*methylamino polyethylene oxide [MA-poly(EO)] were examined for comparative purposes At the same level of substitution, the conjugates would impart the same charge to the phase system

Initial studies were conducted with electroplax membranes partially purified by density gradient procedures[23] Cholinergic receptor concentrations in the individual phases were monitored with ^{125}I-labelled *Naja naja siamensis* α-toxin (5–10 Ci per mmol) using the assay procedure of Schmidt and Raftery[26] This assay, and a simpler monitoring procedure that consists

Table 2 Specific activity of fractions from single extractions in phase system containing PTMA-poly(EO)

	ATPase*	AChE†	Toxin binding‡
Crude pellet	62 8	35	353
Bottom phase	26 4	20	201
Top phase	2 5	7	2,499

The phase system used in this extraction contained (per kg) 4 32% (w/w) Dextran T-500, 3 59% (w/w) poly(EO) 6,000, 1 85 × 10^{-4} M PTMA-poly(EO), 24 75 mmol NaCl, 4 75 mmol sodium phosphate, pH 7 4 A particulate fraction was obtained from a homogenate of electroplax by differential centrifugation[18] This fraction, containing 15 6 mg protein was resuspended in 2 ml of 1 mM phosphate buffer, pH 7 4, and added to the phase system to give the above concentrations in 40 g of total system The mixture was placed on ice, mixed by repeatedly inverting the tube, and then added to a 60-ml syringe fitted with a valve The syringe assembly was centrifuged at 1,000 r p m for 30 min at 5 5 °C in a GLC-1 centrifuge (Sorvall) The top phase was collected directly and the bottom phase was collected through the valve The top and bottom phases were diluted with distilled water and centrifuged for 3 h at 35,000 r p m in a type 35 rotor (Beckman Instruments) Of the protein added to the phase system, 6 63 mg was recovered in bottom phase and 0 51 mg was recovered in top phase No determination was made of the constituents in the interphase
*μmol of ATP hydrolysed per h per mg protein[28]
†μmol of acetylcholine hydrolysed per min per mg protein[29]
‡pmol of ^{125}I-labelled *Naja naja siamensis* toxin bound per mg protein[26]

of addition of toxin at concentrations less than 7 5% of site saturation before phase separation, yielded similar values for the partitioning of receptor between the two phases

In a conventional aqueous polymer two-phase system (Fig 1) less than 1% of membranes containing the cholinergic receptor was found in the polyethylene-oxide-rich top phase and about 65% was in the dextran-rich bottom phase The remaining material was presumably localised to the interphase When PTMA-poly(EO) was added there was a striking increase in the concentration of the membranes containing receptor in the top phase and a commensurate reduction in the bottom phase (Fig 1) Addition of TMA-poly(EO) produced similar results although this polymer-ligand was somewhat less potent than PTMA-poly(EO) in this and other studies (Fig 1) When MA-poly(EO) was used there was only a slight effect on the partitioning of the cholinergic-receptor-containing membranes even when relatively high concentrations were used (Fig 1) Since MA-poly(EO) is a secondary amine which is about 99% charged at the pH used in these studies (7 4), the addition of a cationic polymer-ligand, which might be expected to alter the E M F between phases[27], is not responsible for the partitioning effect that we observed

To examine further whether the effect of PTMA-poly(EO) on the partitioning of membranes containing the cholinergic receptor was the result of specific binding to the cholinergic receptor site, we studied the effects of three bisquaternary methonium compounds with differing affinities for the cholinergic receptor The affinity of these compounds for the cholinergic receptor was measured from inhibition of the initial rate of binding of ^{125}I-labelled α-toxin to membrane-bound receptor (Table 1) As expected, decamethonium was more potent than hexamethonium, which in turn was more potent than trimethonium Addition of each of these compounds to the aqueous polymer two-phase system in the presence of PTMA-poly(EO) inhibited the affinity partitioning (Table 1) with an order of potency related to their affinity for a ligand-binding site on the receptor We also determined the effect of progressive saturation of the cholinergic receptor with increasing concentrations of α-toxin (unlabelled) on the affinity partitioning effect of PTMA-poly(EO) Progressive addition of increasing concentrations of α-toxin antagonised the affinity partitioning effect of PTMA-poly(EO) in direct proportion to the saturation of toxin binding sites Binding of toxin is known to compete with ligands behaving as agonists and antagonists for the nicotinic receptor[22]

Having established that affinity partitioning could be applied with partially purified membranes, we investigated whether it could be used to purify membranes containing the cholinergic receptor from a crude mixture of membranes obtained from a homogenate of electroplax When this mixture was added to a system containing 1 85 × 10^{-4} M PTMA-poly(EO), there was about a sevenfold increase in the specific activity of toxin binding in the membranes that partitioned to the top phase, as compared with the crude particulate fraction (Table 2) About 25% of the toxin binding activity was recovered in the top phase The specific activity of ATPase in the membranes of the top phase was less than 5% of that of the crude particulate fraction and the specific activity of acetylcholinesterase in the membranes of the top phase was about 20% of that of the starting extract It should be emphasised that all these activities are membrane bound since they were collected by centrifugation after the partitioning was completed Partitioning of these membranes in an identical aqueous polymer two-phase system in the absence of PTMA-poly(EO) showed that the top phase contained less than 2% of the toxin binding activity, acetylcholinesterase or ATPase added to the system

The purification achieved with a single partitioning step is comparable with that achieved by sucrose density gradient fractionation[23], since about 25% of the total protein in the membranes found in the top phase after affinity partitioning was found to be cholinergic receptor protein Experiments in progress suggest that even greater purification can be achieved

either by sequential affinity partitioning steps or by combining the sucrose gradient centrifugation purification procedure with affinity partitioning

These results suggest that a similar approach might be applied to the purification of cell membranes or even intact cells that contain sufficient concentrations of specific receptors Preparative scale purifications should be possible since large volumes of two-phase systems can be handled conveniently

Uptake of noradrenaline by an adrenergic clone of neuroblastoma cells

THERE are specialised transport systems mediating noradrenaline (NA) uptake from the extracellular fluid in various types of neurones in peripheral and central noradrenergic nerve terminals

A specific and saturable high affinity uptake for the NA precursor tyrosine has been demonstrated in the adrenergic neuroblastoma clone NIE-115 (ref 1) Another adrenergic neuroblastoma clone, M1 (ref 2) possesses a transport system for tyrosine with similar characteristics Cells of the M1 clone can synthesise ³H-NA from ³H-tyrosine, the ³H-NA formed is found not only in the cells, but also in the medium where it attains a higher specific activity than in the cell interior (J Z, unpublished) Thus a system may be operating which permits the passage of NA across the membrane Here, we present data

which demonstrate the existence of an uptake for NA itself in the adrenergic neuroblastoma clone M1

Cells of the adrenergic clone M1 isolated from C-1300 neuroblastoma were cultivated in Dulbecco's modified Eagle's MEM with foetal calf serum under an atmosphere of air-CO_2 at 37 °C Assays were performed in a phosphate-buffered saline medium (PBS) containing labelled NA (Fig 1) The effect of amphetamine, desipramine, imipramine and ouabain on NA uptake was tested in the same medium

When the initial velocities of L-³H-NA uptake by the neuroblastoma cells were plotted[3] against various amine concentrations, the presence of two components was revealed (Fig 1) One component operating at low NA concentrations has an apparent K_{m1} of 0 14 µM This value for the high affinity transport of NA is similar to that reported for the isolated heart[4] and synaptosomal preparations[5-7] Another component which corresponds to a low affinity system has an apparent K_{m2} of 2×10^{-5} M This K_{m2} value was determined by incubation in NA concentrations $(3 \times 10^{-7}–5 \times 10^{-4}$ M) higher than indicated in Fig 1 It is possible that this system is related to a non-saturable component Free diffusion, however, cannot totally account for this NA influx, in view of the data in Table 1 which indicate that the low-affinity system is partially energy dependent

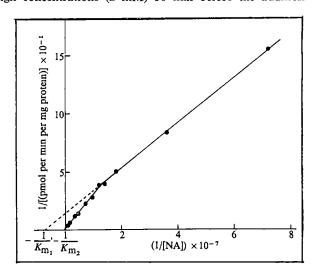
The uptake of NA was inhibited when a metabolic poison 2,4-dinitrophenol (DNP) was added to the incubation medium in high concentrations (2 mM) 30 min before the addition of


Fig. 1 Double reciprocal plot of L-³H-NA uptake into adrenergic clone M1 against NA concentrations Cells were grown to confluency (4 d) in Petri dishes in Dulbecco's modified Eagle's MEM with 10% foetal calf serum under an atmosphere of 5% CO_2 in air at 37 °C Assays were performed at 37 °C in 5 ml of phosphate buffered saline (PBS) containing 137 mM NaCl, 2 6 mM KCl, 0 7 mM $CaCl_2$, 0 5 mM $MgCl_2$, 3 2 mM Na_2HPO_4, 1 4 mM KH_2PO_4, 10 mM glucose The pH was adjusted to 7 3 (at 37 °C) by addition of NaOH The osmolarity was 305 mosmol l^{-1} This medium was not found to have any detrimental effect on cell viability as judged by Trepan blue colouration Ten minutes after replacement of the growth medium by PBS, the reaction was started by adding L-³H-NA (the Radiochemical Centre, Amersham, specific activity 7 2 Ci $mmol^{-1}$) Substrate was present in the reaction mixture at concentrations from $1 4 \times 10^{-8}$ to 10^{-6} M The length of incubation was 2 min, preliminary experiments had shown that the uptake was linear for this time period Reactions were terminated by removal of the incubation medium followed by four washes with NaCl 9‰ at 37 °C Cells were quantitatively harvested with 1 ml and one wash of 0 8 ml of distilled water Then, 0 2 ml NaOH N were added An aliquot (1 5 ml) of this solution was counted in the presence of 10 ml scintillation mixture (Monophase 40, Packard) in an Inter-technique SL-30 liquid scintillation spectrometer Protein was determined by the method of Lowry *et al* [18] using bovine serum albumin as standard Each point is the average of four determinations Velocities are expressed in 10^{-12} mol ³H-NA per min per mg protein The following kinetic constants were determined using the method of Wilkinson[19] High affinity transport apparent $K_{m1} = 0 14$ µM, apparent $V_{max1} = 0 07$ pmol per min per mg protein Low affinity transport apparent $K_{m2} = 2 10^{-5}$ M, apparent $V_{max2} = 5 4$ pmol per min per mg protein

Table 1 Effect of various drugs and Na^+ deprivation on NA uptake

	(NA) 1 4 × 10^{-8}M		(NA) 2 × 10^{-5} M	
Control	100 ± 18	(12)	100 ± 17	(4)
DNP 2 mM	73 ± 10*	(4)	69 ± 8*	(4)
4 °C	36 ± 7‡	(4)	17 ± 7‡	(4)
Sucrose	53 ± 2‡	(4)	72 ± 2*	(3)
Ouabain 10^{-4} M	58 ± 2‡	(4)	101 ± 15	(4)
Amphetamine 5 10^{-5} M	75 ± 4*	(5)	113 ± 23	(4)
Desipramine 10^{-5} M	61 ± 5†	(3)	101 ± 27	(4)
Imipramine 10^{-5} M	62 ± 6†	(4)	126 ± 30	(4)

Cells were grown and assayed as described in Fig 1 ^{3}H-NA was added after a 15-min preincubation with the drugs, except for DNP (30 min) and the reaction was stopped after 5 min Each determination was repeated as indicated Data are expressed as percentages of control uptake ± s d, determined as d p m of ^{3}H per mg protein in the dish When Na^+ was omitted, sucrose was added in the same osmolarity Control values (100%) for uptake (d p m of ^{3}H per mg protein ± s d) were 3,884 ± 706 and 1,818 ± 306 for NA concentration of 1 4 × 10^{-8} M and 2 × 10^{-5} M respectively Significance, as judged by Student's t-test is indicated as follows
$* P < 0 05$
$† P < 0 01$
$‡ P < 0 001$

labelled substrate Those conditions have been reported to inhibit NA uptake into synaptosomal preparations[8]

In addition of being energy-dependent the accumulation of NA was found to be temperature-sensitive At 4 °C, both components of the NA uptake were greatly reduced The high affinity process seemed to be dependent on the presence of Na^+, since it was greatly reduced by replacing the NaCl in the incubation medium by sucrose of the same osmolarity

In similar conditions, addition of ouabain (10^{-4} M) inhibited the high affinity uptake only The low affinity process was less markedly sodium-dependent and was found to be not ouabain-sensitive These data are in good agreement with those of Iversen[9]

Potent inhibitors of catecholamine uptake such as imipramine, desipramine[4,10,11] or amphetamine[12,13] all inhibited the uptake of NA, but only that by the high affinity process (Table 1) Amphetamine was the least effective drug The inhibition, however, was less marked than that described by Baldessarini and Vogt[7] for rat brain homogenates This relatively weak inhibition cannot be explained by the destruction of NA in the incubation medium since in separate experiments, we have observed that after 5 min of incubation, it remains at least 80% of the initial NA level Thus our observations are probably the result of a difference between the neuroblastoma cell membrane and the cell membranes studied by other authors[4,10-13]

The uptake of NA in the adrenergic clone M1 of C-1300 neuroblastoma seems to have similar properties as the neuronal uptake studied by Iversen[4,9] First, a saturable high affinity transport system was found which was partially energy dependent and temperature sensitive This uptake seems to require Na^+ and to be inhibited by ouabain, amphetamine, imipramine and desipramine Second, the presence of a saturable low affinity transport system was demonstrated This low affinity uptake system was also partially energy dependent and temperature sensitive, but was not inhibited by the drugs tested

In many respects, neuroblastoma cells grown in culture may be used as model systems for nerve cells[14-17] We have shown that this applies also for NA uptake into an adrenergic clone The similarities between NA uptake operating in the cultured cells and those shown to exist in other systems are especially noteworthy Most studies with NA uptake processes have been done with nerve ending preparations or with tissues containing adrenergic nerve terminals, whereas cultivated neuroblastoma cells are devoid of synapses When moreover nerve terminals are present, the investigation of transmitter uptake by the neuronal membrane is complicated by the presence of a second uptake into the storage granules Adrenergic neuroblastoma clones may therefore represent a useful system for the study of catecholamine transport processes across the neuronal membrane

Mode of action of an anti-inflammatory fraction from normal human plasma

A FRACTION isolated from normal human plasma[1], contains a substance of low molecular weight (< 500) which shows anti-inflammatory activity in a number of animal models, including paw oedema tests in the mouse and rat[1,2], adjuvant arthritis in the rat[3] and Arthus reactions in the rat and rabbit[4] Its activity in the carrageenin-induced paw oedema test in the rat does not involve an interference with either the release or action of chemical mediators of inflammation such as histamine, 5-hydroxytryptamine, kinins or prostaglandins[5,6] The fraction is not active in inflammatory reactions in which these mediators play the more prominent role, for example, passive cutaneous anaphylaxis and the extravasation of plasma protein elicited by intradermal challenge with the mediators[4], but shows marked and reproducible anti-inflammatory activity in situations in which the emigration of circulating leukocytes is a major factor, for example, Arthus reactions and the accumulation of polymorphonuclear and mononuclear cells into pleural and other inflammatory exudates[7] The plasma fraction causes a reduction of up to 90% in the migration of leukocytes into the exudates found in porous inert sponges implanted subdermally in the rat[7]

An important group of substances thought to induce the directed migration of leukocytes from the blood through the tissue extravascular spaces are the chemotactic factors derived from the complement system[8] Although chemotaxis is an extremely difficult phenomenon to prove by direct observation *in vivo* the circumstantial evidence for it is overwhelming[9] One example is the inhibition of migration of leukocytes into implanted sponge exudates in the rat when the circulating complement levels are depleted by treatment with purified cobra venom[10] The plasma fraction does not act by depleting serum complement levels *in vivo* since it has no effect on the circulating titre of total haemolytic complement in the rat Neither does it prevent the activation of the classical or alternate pathways of complement in fresh guinea pig serum by either antigen–antibody complexes, heat-aggregated γ-globulin or zymosan, as assessed by measuring the residual total haemolytic titre[7]

The preparations of the plasma fraction used were fraction II (ref 1) further purified by absorption on Sephadex A25 ion-exchange resin and elution with 5% (w/v) acetic acid and 0 45% (w/v) NaCl The activity associated with the final peak showing absorption at 254 nm was collected and desalted by passage through Sephadex G-25 Three separate bulk preparations were made and tested for their effects on the accumulation of total leukocytes in sponges implanted subdermally in the rat[7] The results (Table 1) show that the preparations produced a significant reduction, approximately 60%, on the migration of the leukocytes into the sponge exudate There is some variability in activity between different preparations of plasma fraction and our normal practice is to define an active fraction as one which reduces either the development of swelling in the carrageenin-induced paw oedema test[2] or the migration of polymorphonuclear leukocytes into the 5 h sponge exudate[7] in the rat by at least 50% When the plasma fraction was heated at 100 °C for 1 h with 1 5 M NH₄OH solution (inactivated plasma fraction) it failed to inhibit the migration of leukocytes into the 5 h sponge exudate

The second set of experiments used the Boyden chamber technique[11] to investigate the directed migration of rat and human leukocytes in vitro This procedure not only allows quantitative assessment of chemotaxis but also investigation of interference with either the release or the action of complement-derived chemotactic factors Polystyrene, disposable chemotactic chambers (Adaps, Dedham, Massachusetts) and Millipore filters with 3 μm pore size were used, and the methods for the assembly, incubation and counting of the cells which had penetrated the filter were as described by Goetzl and Austen[12] The upper chambers contained the leukocyte suspensions and to the lower chambers were added mixtures of serum and zymosan, which had previously been incubated for 1 h at 37 °C to ensure release of chemotactic factors Plasma fraction preparations, tested on the same day as in the sponge experiments (Table 1) were added, in amounts ranging from 0 1 to 0 005 ml, either to the serum–activator mixture, before or after incubation, or to the cell suspension in the upper chamber Random motility of the leukocytes was also studied in the chemotactic chambers by omitting the incubation of the serum with zymosan The results (Table 2) show that when the plasma fraction was added either to the cell suspension or to the serum–activator mixture after incubation there was no significant change in the chemotaxis of either the rat or human leukocytes When the plasma fraction, but not the inactivated plasma fraction, however, was added to the serum before incubation with the zymosan, a significant reduction in the directed migration of the leukocytes was observed This action of the plasma fraction on the release of the chemotactic factors is dose dependent Thus in the rat leukocyte-serum system the action increased from 10% with 0 01 ml of plasma fraction to 36% with 0 1 ml The human cell–serum system is more sensitive and an inhibition in excess of 80% occurred after the addition of 0 02 ml of the plasma fraction

The failure of the plasma fraction to significantly alter the directed migration when added to the cell suspensions in the upper chambers suggested that the plasma fraction did not act

Table 1 Effects of plasma fraction preparations on leukocyte migration into the 5 h sponge exudate in the rat

Group	Number of cells*
Control	29 1±5 9
Plasma fraction	13 0±1 7†
Inactivated plasma fraction	29 5±3 4

*Results given as mean ±s d and expressed as number of cells ×10⁴ per ml of sponge exudate[7] One sponge implanted in each rat which received an intravenous injection of 1 ml of either saline, plasma fraction or inactivated plasma fraction, five animals per group, the experiments were carried out on three separate occasions
†Significant difference (P<0 001) from results of control and inactivated plasma fraction groups

*PF, plasma fraction, IPF, inactivated plasma fraction (see Table 1) Leukocyte suspension (1 0 ml) containing 3 to 5×10⁶ cells per ml of either rat or human leukocytes in upper chamber, corresponding serum (0 9 ml), zymosan (50 μg) and either saline, PF, IPF or mixtures of these to give a final volume of 1 0 ml Results given as mean ±s d and expressed as number of cells per high power field, ten such fields were counted in each experiment and number of separate experiments given in brackets
†Significant difference (P<0 01) from results in which no plasma fraction was added to the serum–zymosan mixture before incubation, in which the plasma fraction was added to the serum–zymosan mixture after incubation, in which the plasma fraction was added to the cell suspension in the upper chamber and in which inactivated plasma fraction was used
‡Significant difference (P<0 01) from results in which no plasma fraction was added to the serum–zymosan mixture
§Reaction mixtures as for directed migration experiments except that incubation with zymosan omitted and either saline or plasma fraction added to both chambers
ND, not determined

on the leukocyte cell surface to prevent chemotactic attraction Further evidence that the plasma fraction did not affect leukocyte behaviour and function is provided by the results of the random migration experiments in the chemotactic chambers (Table 2) and from other work in which suspensions of rat and human leukocytes exposed to the plasma fraction showed no changes in the uptake of trypan blue[13], the phagocytosis of either ink or zymosan granules[14], random motility in capillary tubes[15], adherence to glass and rosette formation[16]

We conclude that the plasma fraction exerts a selective action on the release of chemotactic factors, for example, C3a and C5a (ref 17), after activation of the complement cascade by the alternate pathway in vitro This effect may be of some significance in vivo since the effective amounts of the plasma fraction used in the present work are comparable In the sponge experiments (Table 1) 1 ml of the fraction was injected intravenously and may be assumed to have been diluted in the circulation by a factor of 10 In the chemotactic chamber experiments (Table 2) amounts of the fraction were diluted from 1–10 to 1–200 with either rat or human serum in the lower chamber When complement proteins and leukocytes have entered inflammatory exudates a vicious circle is set up because leukocyte lysosomes not only contain a C5-cleaving enzyme[17] but a substance causing a non-immune activation of the complement system[18] More chemotactic fragments may be generated by the interaction of the leukocytes and extravascular complement thus amplifying the inflammatory response through positive feedback mechanisms[18] The persistence of an inflamatory reaction may be largely dependent on the secondary events mediated by leukocytes which have accumulated at the site of the inflammatory insult The anti-inflammatory activity of the plasma fraction in susceptible animal models, that is, those associated with neutrophil emigration such as carrageenin-induced paw oedema, Arthus

reactions and implanted sponges, is explicable on the basis of a selective interference with the release of complement-derived chemotactic fragments This rather specific site of action may be of wider relevance since it has been proposed[19] that a logical approach to anti-inflammatory therapy would be a blocking of any one of the many steps in the chemotactic response of the neutrophil

Electrophoretic variation in allelozymes related to function or structure?

ATTEMPTS to explain variation at enzyme loci in terms of the function of the protein molecule[1–5] have shown that enzymes characterised by a single physiological substrate are less variable than enzymes which have been shown *in vitro* to act on a number of substrates[5] and that enzymes regulating the flux through a pathway are more variable than enzymes with no regulatory function[3,4] The explanation for this is that different enzymatic forms are favoured in different environments What distinguishes this hypotheses from others concerning the maintenance of protein variation is that it is to a large extent independent of mutation rate, population size, gene flow among populations and whether or not the population is at equilibrium For these reasons it can easily be tested Johnson[4] and Gillespie and Langley[5] analysed separately data from *Drosophila*, small mammals and man Although the collection of data on small mammals and man is more or less complete, both papers, and that by Gillespie and Langley[5] in particular, ignored a number of *Drosophila* studies I have collected electrophoretic data referring to 61 species and semispecies of *Drosophila* (Fig 1) and carried out an analysis identical to that of Johnson[4], supporting the observation that enzymes with multiple substrates are more variable than enzymes with single substrates Also, enzymes with variable substrates are more polymorphic than regulatory enzymes, which in turn are more polymorphic than non-regulatory enzymes

This analysis (see Fig 1) does not take into account the distribution of variation within the classes mentioned above

Figure 2 gives this distribution for the 260 hydrolases and for the 133 esterases in particular, 23 % of the hydrolases and 21 % of the esterases are monomorphic In most of the studies cited in Fig 1, several populations were examined and all were found to be identically monomorphic at a number of loci with esterase, phosphatase and peptidase activity[6,11,16–18] When closely-related species were studied it was found that this conservatism transcends the species limits[6,22] It seems that about one-fifth of the loci specifying enzymes with hydrolytic activity constitute some of the most conservative loci studied in *Drosophila*, yet they are in the class of multiple or variable substrates

Both α glycerophosphate dehydrogenase (αGPDH) and malic dehydrogenase (MDH) are classified as non-regulatory and by implication their evolution has been guided by the same type of selection forces[4] But αGPDH is consistently poorer in variation than MDH (see Fig 1) Table 1 shows how non-regulatory enzymes change within three groups of closely related species Within the *willistoni* group only two species share the same major allele at MDH, all the others being almost fixed for different alleles No differentiation took place, however, at αGPDH This marked difference repeats itself in the other two groups and it is obvious that when looked at over periods of millions of years, MDH and αGPDH have followed different evolutionary patterns

The classification of enzyme loci according to their function evidently cannot account for the pattern of their variation, although a pattern may arise when heterogeneous data are pooled One reason may be that the assignment of a locus to a

Table 1 Number of major alleles observed within a group of closely related species of *Drosophila*

Triose phosphate isomerase	3	4*	–

* Studied in ten species
Data for the *willistoni* group from Ayala and Tracey[2,3] and Ayala *et al*[24], for the *obscura* group from Lakovaara and Saura[22], and for the *repleta* group this study

multiple substrate group is based on the *in vitro* behaviour of the enzyme, which may indicate nothing about its physiological role This remains unknown for the majority of these non-specific enzymes Contrary to their ability to utilise a wide range of substrates *in vitro*, their function *in vivo* may be quite specific *EstA* of the olive fruit fly *Dacus oleae* behaves *in vitro* like an acetylcholinesterase[25], flies heterozygous for a 'null' allele are less resistant to organophosphate insecticides, and the enzyme is present in the head and the thorax, but not in the abdomen[26] The evidence, therefore, is convincing that *EstA* is associated with the nervous rather than the digestive system of the insect If so, it is difficult to see to what kind of environmental variability this enzyme has been exposed Yet, *EstA* is one of the most polymorphic loci described so far more than fifteen alleles have been detected and in a population of *D oleae* as much as 76 % of the individuals are heterozygous[27]

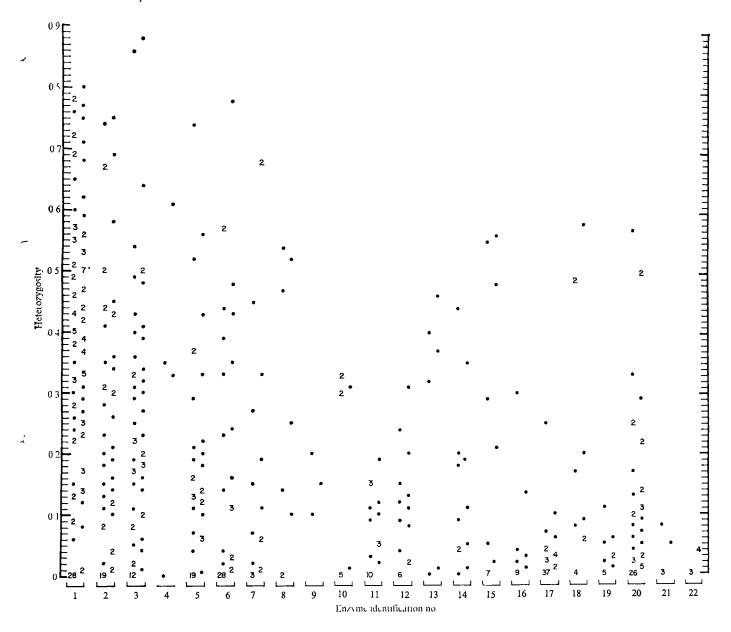
Far more variation has been observed in some esterases and far less at αGPDH than in loci of other enzymatic functions This observation can be explained by postulating that the most important single factor determining the extent of electrophoretic variation is the primary structure of the protein molecule The primary structure determines the extent directly and not through the functional properties of the enzyme and the environmental diversity to which it is exposed King[28] argued that, provided the size of the population is maintained above a


Fig 1 Estimates (635) of hererozygosity at a number of *Drosophila* loci The following species were included in the analysis *affinis²*, *aldrichi⁶*, *ananassae⁷*, *arizonensis⁶*, *athabasca²*, *bipectinata⁸*, *busckii⁹*, *equinoxialis¹⁰*, *maleikothana⁸*, *melanogaster²*, *mojavensis⁶*, *mulleri⁶*, *obscura¹¹*, *pachea¹²*, *parabipectinata⁸*, *paulistorum¹³* semispecies *A*, *AB*, *I* and *T*, *pavani¹⁴*, *persimilis¹⁵*, *pseudoobscura¹⁶*, *robusta¹⁷*, *simulans²*, *subobscura¹⁸*, *tropicalis¹⁹*, *willistoni²⁰*, and 34 species of the genus *Drosophila* in Rockwood *et al* ²¹ Identification numbers stand for 1, esterase, 2, phosphatase, 3, peptidase, 4, amylase, 5, octanol dehydrogehase, 6, alcohol dehydrogenase, 7, aldehyde oxidase, 8, adenylate kinase, 9, glyceraldehyde-3-phosphate dehydrogenase, 10, glucose-6-phosphate dehydrogenase, 11, hexokinase, 12, malic enzyme, 13, phosphoglucose isomerase, 14, phosphoglucomutase, 15, xanthine dehydrogenase, 16, aldolase, 17, αGPDH, 18, isocitric dehydrogenase, 19, fumerase, 20, malate dehydrogenase, 21, 6-phosphogluconate dehydrogenase, 22, triose phosphate isomerase Numbers in the body of the Figure indicate the number of times the corresponding value of heterozygosity has been observed at a given enzyme locus, dots indicate this value has been observed once The amount of variation at a given locus is taken to be independent of the amount of another locus of the same or other species The multiple substrate group of Gillespie and Langley⁵ includes loci from No 1 to No 7 The single substrate group includes the rest of the loci The Wilcoxon two-sample rank test performed on the heterozygosities at these loci gives u_{1-P} = −7 82 According to Johnson⁴, loci from No 1 to No 5 fall in the group variable substrate, loci from No 6 to No 15 in regulatory, and the rest in non-regulatory enzymes Regulatory against variable substrate gives u_{1-P} = −5 24, and non-regulatory against regulatory, u_{1-P} = −3 93 αGPDH against MDH gives u_{1-P} = −3 44 In all tests (corrected for ties) $P<0.001$ Loci from No 1 to No 4 constitute the class of hydrolases

certain limit, the electrophoretic variation at a protein locus is determined by the number of lysine, arginine, glutamic, and aspartic acid residues and, to a lesser extent, by the probability that a conformational change will not affect the protein function Given that this property remains basically unchanged and the composition in the four amino acids mentioned above varies little from species to species, we expected (and found¹⁶,¹⁹ ²⁴) the same amount of polymorphism at homologous loci over populations of the same and related species The differences we observe may be attributed to sampling error or

to genetic drift Indeed, the heterozygosity distribution of esterases (Fig 2), excluding the zero class, is close to normal, as would be expected if these 105 esterases were drawn from the same Universe (When the expected numbers are calculated on a 10% heterozygosity interval, a test for normality gives $\chi^2 = 4.79$, d f = 7, $0.60<P<0.70$)

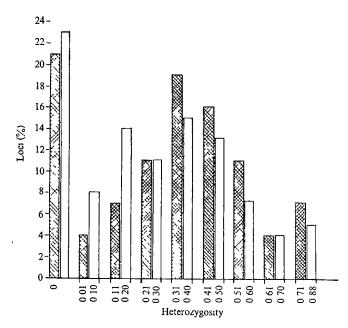
The hypothesis predicts that structurally related enzymes will show comparable amounts of variation Hydrolases represent such a group Excluding the zero class, the distribution of heterozygosities at the remaining 200 hydrolases does not


Fig. 2 Distribution of heterozygosities Open bars, hydrolases, shaded bars, esterases

deviate significantly from normal ($\chi^2 = 11 38$, d f = 7, 0 10 < P < 0 20) Hydrolases with zero heterozygosity may represent a separate class It is possible that these conservative esterases, phosphates and peptides are closer to each other in terms of evolution than they are to esterases, phosphatases and pepidases which constitute the polymorphic fraction of hydrolases Oppenoorth and van Asperen[29][30] observed that a single mutation altered an aliesterase of the house fly into an enzyme with phosphatase activity This observation demonstrates the possibility that enzymes of different function may be structurally much closer to each other than they are to enzymes with the same function, especially when this function is determined by a nonspecific substrate

This explanation of electrophoretic polymorphism is compatible with the hypothesis of neutrality[31], since it attaches no significance to the environmental variability Both function and polymorphism are determined by the primary structure of the molecule, and thus seem to be correlated, although this correlation is not a causal one The term allozymes, coined by Prakash *et al*[16] to denote the allelic forms of an enzyme locus, is not entirely proper The greek αλλος for 'other' or 'foreign' does not imply relation The proper word would be allelozymes

I thank Professor M R Wheeler for providing me with species of the *repleta* group of *Drosophila* and Professor R C Lewontin for comments This work was supported by a grant from the NRC of Canada

Biosynthesis of alkyl sulphides by an ant

ALKYL sulphides are relatively common in microorganisms and higher plants[1,2], but rare in animals In the arthropods they seem to be restricted to the African stink ant *Paltothyreus tarsatus*[3,4], where they are produced in the mandibular glands and function as releasers of digging behaviour The two sulphides produced by the ant are dimethyl disulphide and dimethyl trisulphide[5] An investigation of the biosynthesis of these compounds seemed particularly interesting for several reasons their *de novo* production in animals is unknown, they seem to be unique to *Paltothyreus* and biosynthetic studies of very few arthropod pheromones have been undertaken

Although microorganisms and plants such as onions, chives and garlic are known to produce both dimethyl disulphide and dimethyl trisulphide[1,6], the biosynthesis of these compounds has not been extensively investigated In plants dimethyl disulphide is known to be produced from methionine as a byproduct of ethylene production[7], and in microorganisms[8] and fungi[9] by oxidative deamination and demethiolation of methionine Since these biosynthetic studies suggested that it was the starting material for sulphide biosynthesis, methionine was chosen as the likely material from which *Paltothyreus* might synthesise its sulphides Insects were previously known only to utilise methionine for trans-sulphuration to cysteine by way of cystathionine pathway[10]

Paltothyreus workers fed on a diet of termites (*Macrotermes natalensis*) were injected with solutions containing L-^{35}S-methionine, DL-(1-^{14}C)-methionine and L-(methyl-^{14}C)-methionine The ants were maintained in the laboratory for 4 d after

Table 1 Incorporation of the label from methionine into *Paltothyreus* sulphides

Labelled methionine	Activity administered (d p m)	Activity in disulphide (d p m)	Activity in trisulphide (d p m)
L-(^{35}S)-	$2 5 \times 10^6$	1×10^4	$5 7 \times 10^4$
DL-(1-^{14}C)-	$2 2 \times 10^6$	0	0
L-(methyl-^{14}C)-	$2 1 \times 10^6$	$6 1 \times 10^2$	$2 4 \times 10^3$

injection They were then decapitated, their mandibular glands removed and extracted with methylene chloride This extract, containing the sulphides, was fractionated using gas chromatography and the di- and tri-sulphides individually collected by preparative gas chromatography The fractionated di- and tri-sulphides were then each placed in vials containing 15 ml of Packard Instagel scintillant and their radioactivity determined in a Beckman scintillation counter Table 1 shows that *Paltothyreus* can utilise the sulphur in methionine for the production of the sulphides In addition, the methyl groups in the sulphides seem to arise from the methyl group of the methionine since labelled ^{14}C is incorporated into the sulphides only when it is in the terminal methyl group

This work provides the first experimental evidence for the *de novo* biosynthesis of sulphides in an arthropod The dimethyl disulphide is probably produced from methionine in much the

same way (Fig. 1) as has been found in microorganisms[8,9]. In the case of the trisulphide the situation is more complex, since even if the two methyl groups and their attached sulphur atoms come from methionine, the origin of the third sulphur atom remains unknown. To determine whether the methanethiol group from methionine is incorporated directly into both the disulphide and the trisulphide, further experiments using methionine doubly labelled with ^{3}H and ^{35}S are being undertaken.

Whatever the uncertainties about the precise biosynthetic pathways utilised for sulphide production in *Paltothyreus*, it is clear that methionine can be utilised as the starting material for the biosynthesis of both exocrine products.

Subunit structure of chromatin is the same in plants and animals

ALTHOUGH plants and animals diverged from each other nearly 10^9 yr ago, the histone composition of their chromosomes is remarkably similar[1]; in particular, the arginine-rich histones III and IV of peas and cows differ by only four and two amino acids, respectively[2,3]. Such extreme evolutionary conservation of a protein sequence argues that histones are crucial to chromosome structure and/or function, and further suggests considerable similarity, at the molecular level, between the chromosomes of plants and animals. We present evidence here for such a similarity.

In animals, chromatin seems to be organised into subunit structures, involving several hundred base pairs of DNA and small numbers of each class of histones[4-5]. Important evidence for a model of this type, in which subunits are arranged as beads on a string, is that, after nuclease digestion of the chromatin, most chromosomal DNA can be isolated as pro-

tected fragments which are integral multiples of a monomeric fragment, 100–200 base pairs long[5-8]. We have done similar nuclease digestions of plant chromatin and have obtained similar results.

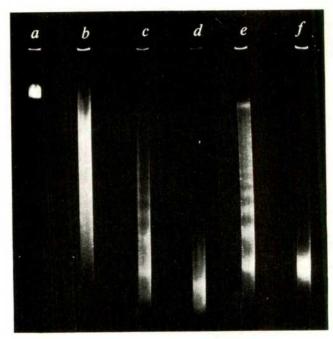
Chromatin was isolated from pea seedlings (*Pisum sativum*) by a simplification of the method of Bonner *et al.*[9], using a low ionic strength buffer previously shown to inhibit histone migration[7]. After incubation of the crude chromatin with various concentrations of micrococcal nuclease, the remaining DNA was purified and subjected to agarose gel electrophoresis as described in the legend to Fig. 1. As Fig. 1*d* shows, when pea seedling chromatin was treated exhaustively with nuclease, a discrete DNA fragment remained intact (even when free radioactive DNA or RNA added to the digestion mixture was


Fig. 1 Agarose gel electrophoresis of: λ DNA (*a*); DNA purified from crude pea chromatin after incubation with 0, 10, and 100 μg ml^{-1} of micrococcal nuclease, respectively, as described below (*b*, *c* and *d*); DNA isolated from a partial digest of mouse myeloma chromatin (*e*); peak fraction from a sucrose gradient of DNA purified from extensively digested mouse myeloma chromatin (and run as a standard in all sets of gels) (*f*). Gels were prepared from 1.4% agarose and run in a solvent of 0.04 M Tris, 10^{-3} M EDTA, pH 7.8, plus 0.1% ethidium bromide[13]. The dye, when intercalated into the DNA, fluoresces when the gel is examined under ultraviolet light. Pea seeds were germinated in the dark, and the shoots collected, washed, frozen, ground with 2 volumes of cold buffer (5×10^{-3} M sodium phosphate, 2.5×10^{-5} M CaCl$_2$, pH 7.0)[7] and blended for 60 s. The extract was filtered through eight layers of cheesecloth and centrifuged at 4000*g* for 30 min at 0–4 °C. The crude chromatin pellet was removed from the underlying starch pellet and resuspended in 1/50 to 1/100 of the original volume of buffer. Micrococcal nuclease (Worthington) was added to various concentrations and incubated at 37 °C. After 20 min, ribonuclease was added to 0.2 mg ml^{-1}, and at 30 min EDTA, sodium dodecyl sulphate and nuclease-free pronase were added to final concentrations of 10^{-3} M, 0.1% and 0.5 mg ml^{-1} respectively. The mixtures were incubated a further 30 min at 37 °C and then extracted two or three times with phenol. Phenol was removed either by ether extraction followed by bubbling with nitrogen, or by passage twice through a short column of P-2 (BioRad). The bands in the gels disappeared on incubation with DNase I, DNase II and micrococcal nuclease, but not with RNase, pronase, α-amylase or cellulase. Thermal denaturation indicated that the purified DNA was native, with a base composition close to that of pea seedling DNA. The same digestion patterns were seen with several minor variations of the above protocol; for example, using a lower ionic strength buffer (10^{-3} M Tris, 2.5×10^{-5} M CaCl$_2$, pH 8.4), extracting with a Dounce homogeniser rather than blending, or adding 1–2 mg ml^{-1} of α-amylase at the same time as the ribonuclease. Similar digestion patterns have been obtained with chromatin isolated from the shoots of black-eyed peas (*Vigna sinensis*, unpublished)

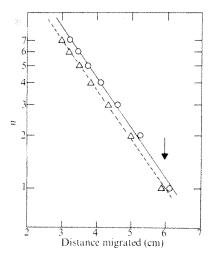
rendered greater than 95% acid soluble). Comparison of the amount of DNA in Fig. 1*d* with that of the no-enzyme control (Fig. 1*b*) indicates that more than half of the isolated DNA migrated as this protected fragment. Moreover, the size of this fragment, as estimated from the distance migrated in the gel, was close to that of a DNA fragment obtained from a digest of nuclei isolated from mouse myeloma cells (Fig. 1*f*; using a method similar to ref. 6; J.D.M. and Kimmel, C. B., unpublished). With less extensive nuclease treatment of the pea chromatin, a series of DNA bands (at least seven) was obtained (Fig. 1*c*), corresponding closely to DNA bands seen in a partial digest of either mouse nuclei (Fig. 1*e*) or calf thymus chromatin (kindly provided for comparison by B. R. Shaw and K. E. Van Holde). When the logarithm of the band number (counting back from the fastest running band) is plotted against the distance migrated in the gel (Fig. 2), the plot is linear, indicating that the length of the DNA in any particular band is an integral multiple of the length of the DNA in the monomer band. Furthermore, the data from pea, calf (not shown) and mouse digests fall on close, parallel lines, indicating similar fragment sizes. From the differences of the intercepts of least squares lines fitted to such


Fig. 2 Plot of the logarithm of the band number (n) against distance migrated in the gel: ○, pea chromatin digest; △, mouse myeloma chromatin digest. Distances were averaged from four to nine densitometer traces of film negatives of the gels (varying gel position, film exposure times and so on), and each point is the average of three parallel gels. The arrow indicates the migration position of the sucrose gradient fraction from a mouse digest used in Fig. 1*f*, above, which has been shown to be 170 ± 30 base pairs, as measured by sedimentation velocity. The lines represent the least-squares best fit of the data to the equation: $\log(n) = a \cdot (\text{distance migrated}) + b - \log(\text{size of monomer fragment})$.

data, the ratio of the length of the monomer DNA fragment in pea seedling chromatin to that in mouse chromatin can be estimated as 0.95 ± 0.2 (weighted average from 14 gels). We estimate the absolute size of the monomer DNA fragment as 170 ± 30 base pairs, based on the gel migration of a purified mouse myeloma DNA fraction (Fig. 1*f*) which had a sedimentation coefficient ($S^0_{20,w}$) of 5.5 ± 0.3 as determined by analytical band sedimentation[10,11]. This size estimate lies between those previously made on DNA fragments isolated from rat liver[6] and calf thymus chromatin[5,7]. Although we have not seen a discrete submonomer band (as has been described by Noll[6] in a digest of rat liver chromatin), as Fig. 1*c* shows, some DNA migrated ahead of the monomer band. Furthermore, after prolonged nuclease treatment (for example, Fig. 1*d*) most of the DNA migrated to a position in the gel corresponding to a size 80% of the monomer band, or about 140 base pairs (the $S^0_{20,w}$ of the DNA sample used in Fig. 1*d* was 5.0 ± 0.3, corresponding to a DNA length of 125 ± 20 base pairs).

As with similar studies on mammalian systems, the simplest model to explain our results is that a specific histone–DNA

complex protects discrete lengths of DNA from nuclease digestion; thus the fundamental architecture of chromosomes may well be the same in both plants and animals. Since, however, several of the histone classes do show differences between different organisms[1], and yet, at least at the level of this study, their combined effect on DNA is quite similar, comparative studies (potentially leading to inter-species reconstitution experiments) seem an attractive approach to the investigation of the detailed structure of the chromatin particles, and the forces involved in its maintenance. As a recent example of such a comparative study, nuclease digestion of yeast chromatin (which lacks certain classes of histones) was found to give a protected DNA fragment which was both smaller and more homogeneous than that obtained from calf thymus chromatin[12]. A number of questions are suggested. When did this subunit structure arise in evolution? What purpose does this chromatin particle serve that requires such a specific length? If it represents simply a structural means to package large amounts of DNA, why is it so unusual that it has been stringently conserved throughout the course of evolution?

Age-dependent excision repair of damaged thymine from γ-irradiated DNA by isolated nuclei from human fibroblasts

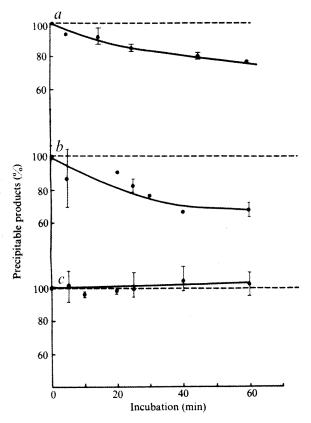
THE lifespan of diploid human fibroblasts in culture is limited[1], although there are substantial variations in lifespan with different culturing conditions and growth media[2-4]. Before death, the cells pass through a period of senescence, characterised by numerous structural changes[5]. According to the error catastrophe hypothesis, a breakdown of the fidelity of the expression of genetic information resulting in the production of faulty proteins[6-11], and the accumulation of mutations in the genome[12], may represent important mechanisms of cellular ageing. It would be predicted that the deterioration of the quality of the genome would be accelerated by deficient or error-prone DNA repair. Several steps in the excision repair of damaged DNA residues have been demonstrated in mammalian cells exposed to exogenous physical or chemical agents. In the case of ionising radiation, the removal from the DNA of thymine damaged by γ rays was observed in Chinese hamster ovary[13] and human WI–38 cells[14], and the filling of the resulting gaps, indicated by repair replication or unscheduled synthesis, has been demonstrated in numerous cell lines[15]. Recently published experiments[16] have demonstrated that the capacity of skin fibroblasts to perform ultraviolet-induced repair synthesis


Fig. 1 Excision of thymine radiation products of the t' type from γ-irradiated PM2 DNA by isolated nuclei from (a) young (passage 23), (b) medium-aged (passages 37 and 39) and (c) old cells (passages 43, 47 and 48). Diploid human lung fibroblasts WI-38 were grown in tissue culture according to the method of Hayflick and Moorhead[1]. Isolated nuclei were prepared by a modification of the procedure of Berkowitz *et al.* (ref. 21 and J. F. Remsen and P.A.C., unpublished). Cells were collected by trypsinisation into sterile screw-cap bottles (50 ml), washed twice with ice-cold Hanks' balanced salt solution, and centrifuged at 1,200 r.p.m. for 10 min. Homogenisation was then effected in

hypertonic sucrose buffer (0.32 mM sucrose, 0.3 % Triton X-100, 1 mM potassium phosphate buffer (*p*H 7.1), 1 mM Mg²⁺, 1 mM dithiothreitol) with a Dounce homogeniser, after which the suspensions were centrifuged at 1,200 r.p.m. for 10 min. The homogenisation procedure was repeated and, following centrifugation, the nuclei were washed twice in isotonic sucrose buffer (0.25 M sucrose, 1 mM potassium phosphate buffer (*p*H 7.1), 1 mM dithiothreitol, 3 mM Ca²⁺) and the nuclear suspensions centrifuged. In some experiments, nuclei were disrupted by sonication (two treatments for 10 s at the lowest setting) and the completeness of sonication checked using phase contrast microscopy. Pseudomonas phage PM2 DNA labelled with ³H-methyl-thymidine was prepared according to Franklin *et al.*[22], and purified on hydroxyapatite before each experiment. This was used as DNA substrate for the experiments using γ-irradiation because it could be prepared essentially free of strand breaks. Irradiation was carried out under non-protective conditions in aerated phosphate buffer with a ¹³⁷Cs-source; doses used (usually 15 to 25 krad) resulted in the formation of 0.3–0.6% t', as determined in the acid-precipitable material by the alkaline–acid degradation assay of Hariharan and Cerutti[23]. The DNA was passed through a small Sephadex G75 column following irradiation to remove a small amount of low molecular weight material. Although t' represents a major class of radiation products, γ-irradiated DNA contains, in addition, a variety of products derived from the other nucleic acid bases, apyrimidinic[24] and, possibly apurinic sites, as well as radiation-induced strand breaks. A second substrate containing primarily 5,6-dihydroxy-dihydrothymine and a small number of apyrimidinic sites (B. E. Dunlap and P. A. C., unpublished) was therefore prepared by the oxidation of polyd(A-T)–³H-methylthymine with OsO₄. The conditions of Beer *et al.*[25] were used and the oxidation was allowed to continue until the polymer contained 0.3–0.7% t', or 2–4.5% ring-damaged thymine[23]. The samples for the excision experiments contained (in a total volume of 150 μl) 4 × 10⁶ nuclei or sonicated nuclear equivalents, labelled (0.5–1.5 × 10⁵ c.p.m.) irradiated PM2 DNA or OsO₄-oxidised polyd(A-T) corresponding to 1–3 × 10⁻⁶ μmol t', 0.01 M phosphate buffer (*p*H 7.6), 0.09 M NaCl, 1 mM dithiothreitol, 15 U pyruvate kinase, 15 mg ml⁻¹ BSA (Fraction V), 2 mM PEP, 0.4 mM ATP, and 0.2 mM of each of the four deoxynucleoside triphosphates. Incubation with substrates was carried out for up to 60 min at 37 °C and the reactions terminated by the addition of 1.9 ml 7% trichloroacetic acid. Thymine radiation products (t') were determined using the above method of Hariharan and Cerutti[23]. The ratio of t' in the acid-precipitable material over the total acid precipitable input counts (t'/Tppt) was computed for each time point and expressed as the percentage of the corresponding value for a non-incubated control sample.

increases as a function of the lifespan of the donor species. We report that isolated nuclei or nuclear sonicates from senescent diploid human lung fibroblasts WI–38 have lost their ability to excise from DNA thymine damaged by γ rays.

We have studied the capacity of isolated nuclei and nuclear sonicates from young, medium-aged and old WI–38 cells to excise damaged thymine residues of the 5,6-dihydroxy-dihydrothymine type (t') from exogenous γ-irradiated or osmium tetroxide (OsO₄) oxidised DNA substrates. Our experimental design allows the use of non-irradiated and unlabelled nuclei. Comparison of results obtained with these two substrates allows an assessment of the effects of damage other than t', in particular, radiation-induced strand breaks, on the repair process (see legend to Fig. 1). The loss of t' from the acid-precipitable exogenous DNA substrate and the amount of undamaged thymine rendered acid-soluble were determined as a function of incubation time.

WI–38 cells of passages 14 and 29 (L. Hayflick, Stanford) were used as starting cultures for the production of cells at the three age groups investigated. Under our culturing conditions, cell death usually occurs at passages 49–52. The age in culture of the WI–38 cells from which the nuclei were prepared is reflected in the passage number (that is, the number of 1:2 subculturings) and was further characterised by the percentage of nuclei which were labelled in a 48 h pulse with ³H-methyl-thymidine according to the method of Cristofalo and Sharf[17]. These authors found a decrease with passage number in the percentage of nuclei actively synthesising DNA within a 48 h period, starting approximately at passage 30, and suggested that such data could be used for the character-

isation of the functional state of WI–38 cells. Their results and ours are in agreement. In the following, we refer to cells at passages 15–25 as 'young', to cells at passages 26–42 as 'medium aged', and to cells at passages above 42 as 'old'.

Figure 1*a* shows that young nuclei of passage 23 and medium-aged nuclei of passages 37 and 39 removed approximately one-quarter to one-third of t' from the γ-irradiated acid-precipitable PM2 DNA within 60 min of incubation at 37 °C; however, no excision of t' was accomplished by old nuclei of passages 43, 47 and 48. Only 2–6% of total thymine label was rendered acid-soluble during 60 min incubation. Excision of t' by nuclei from young and medium-aged cells remained incomplete. The percentage excision within 60 min of incubation is comparable to that accomplished by human skin fibroblasts at similar concentrations of t' (J. F. Remsen, P. V. Hariharan and P. A. C., unpublished). Analogous data (not shown) were obtained for the excision of t' from γ-irradiated PM2 DNA after incubation with nuclear sonicates. The capacity of WI–38 nuclei to excise t' from OsO₄-oxidised polyd(A-T) also depended on cell age: WI–38 nuclei obtained from young cells at passages 21 and 24 selectively excised 28% of t' within 60 min of incubation at 37° C; nuclei from medium-aged cells at passage 34 excised 22% of t'; no excision was observed with old nuclei of passage 47. The excision of t' from OsO₄-oxidised polyd(A-T) by young and medium-aged nuclei occurs with very high selectivity, the acid solubilisation of thymine label within 60 min of incubation being only 0.6–1%.

The following conclusions can be drawn from our results: Young and medium-aged nuclei up to a passage number of

approximately 42 (corresponding to a percentage labelled nuclei value of 60-70%)[17] possess the capacity for the selective excision of γ-ray damaged or OsO_4-oxidised thymine (t') from exogenous DNA. The fact that excision occurs from OsO_4-oxidised polyd(A-T) indicates that neither damage to bases other than thymine nor, in particular, radiation-induced strand breakage is required for removal of t' from DNA. The extent of polymer degradation which accompanies excision is small, particularly for OsO_4-oxidised polyd(A-T). In this case, only 1.6 undamaged nucleotides are released per ring-damaged thymine within 60 min of incubation. Old nuclei do not accomplish excision of t' either from γ-irradiated PM2 DNA or OsO_4-oxidised.polyd(A-T). The loss of the excision capacity in old nuclei and nuclear sonicates occurs within a few generations (passages 42 to 45)—at least four to five generations before cell death occurs—and seems to occur more precipitously than the loss of the capacity for DNA synthesis, as measured by the percentage labelled nuclei method of Cristofalo and Sharf[17]. The loss of repair enzymes during the preparation of nuclei from old but not from young or medium-aged cells could also explain our findings.

The observed loss of the excision repair capacity for γ-ray-induced thymine damage by nuclei from senescent WI-38 cells does not allow conclusions concerning the validity of error catastrophe hypotheses of cellular ageing[10-12]. Because the cells were found to survive for several generations after the repair deficiency had first manifested itself, however, the loss of this function does not seem to be a direct consequence of cell death. It is, on the other hand, impossible, on the basis of our data, to decide whether the observed repair deficiency is one of the causes or a consequence of senescence in cultured WI-38 cells. Painter and collaborators[18,19], found a decline in the ability of WI-38 cells to undergo ultraviolet or γ-ray-induced repair replication only in the last one or two passages before cell death occurred. Hart and Setlow[20] observed a concomitant decrease in the capacity for ultraviolet-induced unscheduled synthesis and scheduled DNA synthesis in senescent WI-38 cells. We have, however, investigated an earlier step in γ-ray excision repair than in those studies measuring unscheduled synthesis or repair replication.

Determination of recognition sites of T4 RNA ligase on the 3'-OH and 5'-P termini of polyribonucleotide chains

RNA LIGASE which was discovered by Silber *et al.*[1] in T4-infected *Escherichia coli* cells, catalyses an ATP-dependent, intramolecular joining reacion of 5'-P and 3'-OH termini of various homopolyribonucleotides[1,2]. The shortest circularising polyadenylate was shown to be $(pA)_8$, the optimal chain length for the reaction being 10–30 (ref. 2). These facts suggest that the substrate for T4 RNA ligase is a pair of suitably juxtaposed, 3'-OH and 5'-P termini, each a few single stranded residues long[2].

An intermolecular joining RNA ligase reaction can be induced by suitably juxtaposing termini of different polyribonucleotide chains. Thus a pair of $tRNA^{Phe}$ half-molecules, fragments 1–36 and 38–74, could be joined by RNA ligase at the termini of the severed anticodon loop[3]. To effect intermolecular joining reactions of non-complexed polyribonucleotide chains, however, other means must be sought to juxtapose their termini, such as increasing the polyribonucleotide concentration (O. C. Uhlenbeck, personal communication). We have therefore investigated the minimal recognition sites on the 3'-OH and 5'-P termini of RNA ligase substrates. We have tested the ability of short oligonucleotides varying in chain length and carrying only one functional terminus to participate in RNA ligase-catalysed reactions. As oligonucleotides carrying only a 3'-OH function, we generally used $(Ap)_nA$ where $n \geqslant 4$, while

Fig. 1 A, Joining of $(Ap)_nA$ with 5' ^{32}P $(pA)_7$. 5' ^{32}P-labelled oligoadenylates, $(Ap)_nAs$ and RNA ligase were prepared as before[2]. The reaction mixtures (0.01 ml) contained: 5' ^{32}P $(pA)_7$ (2,000 c.p.m. pmol^{-1}) 0.65 μM, Tris-HCl buffer pH 7.5, 50 mM; $MgCl_2$ 10 mM, dithiothreitol 1 mM, ATP 0.5 mM, $(Ap)_nA$ as indicated 2 mM, and 0.05 U of RNA ligase. The reaction mixture was incubated at 37 °C for 3 h. An aliquot of 5 μl was then mixed with 5 μl of 50% sucrose, 0.1 M Tris-borate, pH 8.3, 0.01 M EDTA, 0.01% bromophenol blue, applied to a 20% polyacrylamide 7 M urea gel slab and separated by electrophoresis as previously described[2]. *a*, $(pA)_7$; *b*, reaction mixture with no $(Ap)_nA$ added; *c*, ApA added; *d*, $(Ap)_2A$ added; *e*, $(Ap)_3A$ added; *f*, $(Ap)_4A$ added; BB, bromophenol blue R_{BB} values of $(Ap)_nAs$ were obtained by separating a mixture of $(Ap)_nA$ ($n = 4$–17) on the same gel. The bands were detected by staining with 'Stains-all' pure $(Ap)_4A$ served as a reference band. B, Joining of $(Ap)_nA$ with 5' ^{32}P $(pA)_{10}$. The reaction mixtures were essentially as described in (*A*) except that $(pA)_7$ was substituted by 1.5 μM 5' ^{32}P $(pA)_{10}$.

periodate-treated $(pA)_n$ oligonucleotides ($n = 2,3,4$) served for study of the substrate requirements at the 5'-P terminus.

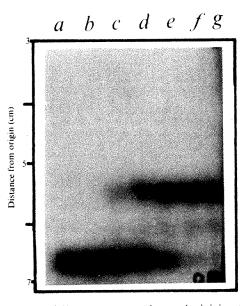
Two kinds of assay were carried out: first, linear joining of either kind of the short monofunctional oligonucleotide to one of the termini of a 5'-[32P] $(pA)_7$, and second, their competition with $(pA)_{10}$ circularisation. The shortest circularising polyadenylate was previously shown to be $(pA)_8$ (ref. 2). A hepta-adenylate will not circularise. In the presence of RNA ligase and excess of short dephosphorylated oligo As, however, $(pA)_7$ participated in a linear joining reaction. When samples of these reaction mixtures were analysed by polyacrylamide-urea gel electrophoresis, it was found that, when reacted, $(pA)_7$ was converted into a longer oligonucleotide migrating like a corresponding $(Ap)_{7+n}A$ marker (Fig. 1A). This oligonucleotide was therefore the linear joining product of $(Ap)_nA$ with $(pA)_7$. ApApA was the shortest oligonucleotide to support such a reaction while ApA had no effect. High concentrations of $(Ap)_nA$ were required to elicit linear joining (Fig. 2) at rates


Fig. 2 Effect of $(Ap)_3A$ concentration on its joining to $(pA)_7$. The reaction mixtures (0.04 ml) contained 5' [32P] $(pA)_7$ 0.5 μM, Tris HCl, pH 7.5, 50 mM; MgCl₂ 10 mM, dithiothreitol 1 mM, ATP 0.5 mM, $(Ap)_3A$ as indicated and 0.5 U of RNA ligase. The mixture was incubated at 37 °C; after 2 h 5 μl aliquots were separated by electrophoresis as described for Fig. 1A. *a*, $(pA)_7$; *b*, reaction mixture without $(Ap)_3A$; *c*, 0.075 mM $(Ap)_3A$; *d*, 0.15 mM $(Ap)_3A$; *e*, 0.3 mM $(Ap)_3A$; *f*, 0.6 mM $(Ap)_3A$; *g*, 1.2 mM $(Ap)_3A$.

comparable with those seen in the circularisation of oligoadenylates. In standard assay conditions[2], the apparent K_m of $(Ap)_3A$ (at 5.10^{-7}M $(pA)_7$) was about 8.10^{-4} M, about 1,000 times higher than the K_m of a well-circularising substrate[2] with a pair of 3'-OH and 5'-P termini.

Since short, dephosphorylated oligoadenylates were shown to serve as 3'-OH acceptor termini in an RNA ligase reaction, we expected them also to compete with the 3'-OH of a circularising oligoadenylate, such as $(pA)_{10}$, for the 5'-P terminus. As a result, linear rather than circular joining products would be formed. Figure 1B shows the analysis, by gel electrophoresis, of reaction mixtures containing RNA ligase, 5' [32P] $(pA)_{10}$ and a short dephosphorylated oligoadenylate in about 500-fold excess over $(pA)_{10}$. In the mixture containing enzyme and $(pA)_{10}$ only, complete circularisation took place as indicated by the conversion of linear $(pA)_{10}$ ($R_{BB} = 0.85$) into a faster migrating product ($R_{BB} = 0.90$), as previously described[2]. Addition of ApA had no effect, while $(Ap)_2A$, $(Ap)_3A$ and $(Ap)_4A$ induced the formation, in addition to circular $(pA)_{10}$, of two new, more slowly migrating products. Of these, the slower band comigrated with $(Ap)_{10+n}A$ marker, and probably resulted from linear joining of $(Ap)_nA$ to $(pA)_{10}$ in competition

with the circularisation reaction. The yield of the linear joining product of $(pA)_{10}$ and $(Ap)_nA$ comprised about 10% of the original labelled substrate. The slower new product resulted from the linear addition of $(Ap)_nA$ to 5' [32P] $(pA)_8$p contaminant, present in the $(pA)_{10}$ preparation (see the faster band in slot *a*, Fig. 1B). This contaminating oligoadenylate cannot circularise and is completely converted into a linear joining product in presence of $(Ap)_nAs$.

To study the requirements of RNA ligase at the 5' terminus of its substrate we tested the ability of short, 5' phosphorylated, 3' periodate oxidised, oligoadenylates ($(pA)_n^{Ox}$) in joining to 5' [32P] $(pA)_7$, and in competition with 5' [32P] $(pA)_{10}$ circularisation. Figure 3A and B shows the analysis of products of such reactions by polyacrylamide gel electrophoresis. All the $(pA)_n^{Ox}$ oligoadenylates tested, starting from a dinucleotide, participated in linear joining to $(pA)_7$ and to $(pA)_{10}$, in the latter case at the expense of circularisation. Again, relatively high concentrations of $(pA)_n^{Ox}$ were required to elicit detectable linear joining reactions.

The experiments with dephosphorylated oligoadenylates (Fig. 1A and B) indicated that the RNA ligase recognition site on the 3'-OH terminus consists of no more than a trinucleoside diphosphate (ApApA) stretch. A dinucleoside monophosphate (ApA) is not sufficient. However, a dinucleoside diphosphate cannot be ruled out as a minimal 3'-OH recognition site. Since the experiments with 5'-$(pA)_n^{Ox}$ indicated that $(pA)_2$ and possibly smaller portions of the 5'-P terminus are recognised by RNA ligase, one might expect that $(pA)_2$ would be polymerised by RNA ligase, were it recognised also as a 3'-OH terminus. Our preliminary results (unpublished) confirm this expectation.

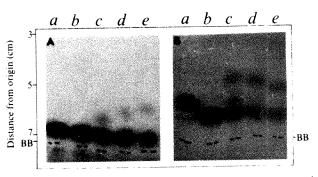
The minimal 5'-P recognition site is possibly less than a dinucleoside diphosphate (Fig. 3). It was previously found in the RNA ligase-catalysed loop closure reaction of yeast tRNA[Phe] fragments 1–36 and 38–74 (ref. 3), that no more than one single stranded nucleotide residue (emanating from a double helix) is required for recognition of the 5'-P terminus. Whether the 5'-P recognition site extends beyond the first nucleotide residue to include some portion of the adjacent residue is unknown. The possibility that T4 RNA ligase can join nicked, double stranded


Fig. 3 A, Joining of $(pA)_n^{Ox}$ to 5' [32P] $(pA)_7$. $(pA)_2$, $(pA)_3$ and $(pA)_4$ were prepared by controlled digestion of poly(A) by sheep kidney nuclease[8] followed by fractionation of the digest on a DEAE-cellulose column. To oxidise their 3' ribose these oligonucleotides were treated with sodium periodate as follows: the reaction mixture (0.025 ml) contained 10 mM oligonucleotide and 15 mM sodium periodate and was incubated for 30 min at 0 °C, at the end of which 1 μl of 0.25 M ethylene glycol was added. The solution of the periodate-treated oligonucleotide was used as such in the following experiment. The joining reaction mixture (0.02 ml) contained 4×10^{-7} M $(pA)_7$, Tris-HCl, pH 7.5, 50 mM, MgCl₂ 10 mM, dithiothreitol 1 mM, ATP 0.5 mM, $(pA)_n^{Ox}$ as indicated and 0.1 U RNA ligase. After 2 h of incubation at 37 °C, 3 μl samples were separated by electrophoresis as described in legend to Fig. 1A. 1, $(pA)_7$; 2, reaction mixture without $(pA)_n^{Ox}$; 3, 1.2 mmol of $(pA)_2^{Ox}$ added; 4, 1.2 mmol of $(pA)_3^{Ox}$ added; 5, 0.8 mmol of $(pA)_4^{Ox}$ added. B, Joining of $(pA)_n^{Ox}$ to 5' [32P] $(pA)_{10}$. The reaction mixture was similar to that in *A*, except for containing 1.8×10^{-6} M of $(pA)_{10}$ instead of $(pA)_7$. *a*, $(pA)_{10}$; *b*, reaction mixture without $(pA)_n^{Ox}$; *c*, 0.8 mM of $(pA)_4^{Ox}$ added; *d*, 1.2 mM of $(pA)_3^{Ox}$ added; *e*, 1.2 mM of $(pA)_2^{Ox}$ added.

RNA[1,4] must also be considered; a definitive answer awaits studies with carefully defined substrates.

Our results and those of Uhlenbeck (personal communication) show that T4 RNA ligase can catalyse the joining reaction between unassociated polyribonucleotide chains. In view of the high substrate concentrations required to support such reactions, we consider it unlikely that selective joining reactions of non-complexed RNA molecules are catalysed by the enzyme *in vivo*. The high affinity of RNA ligase for its substrates in the loop closure[3] and circularisation reactions, as well as the competition experiments between intra- and intermolecular joining indicate that a pair of suitably apposed 3'-OH and 5'-P termini of RNA molecules constitutes the *in vivo* substrate of RNA ligase. The requirement that the pair of termini be suitably apposed can be met when (1) they belong to different chains that are partially hybridised, as in severed loops, or (2) when proximity is mediated by a specific factor, or (3) when the termini belong to one chain capable of circularisation. A possibility that cannot be dismissed is that this T4-induced enzyme evolved as a host RNA-modifying function. Other possible participants of such a pathway could be two other early induced T4 enzymes—polynucleotide kinase[5] and the nuclease that specifically cleaves one of the isoaccepting host tRNA[Leu] species[6].

The linear joining reaction catalysed by RNA ligase offers important new synthetic possibilities. It permits joining of tri- and higher oligoribonucleotides in a stepwise manner to a 5'-P terminus of a growing chain. The following scheme is suggested for one step in such a synthesis. First, a dephosphorylated oligonucleotide is joined in an RNA ligase-catalysed reaction to a 5'-P initiator polynucleotide, the 3'-OH terminus of which is blocked. Second, the 5'-OH terminus of the product is phosphorylated by polynucleotide kinase, ready for a subsequent joining step. The synthesis may be programmed in such a way as to generate single stranded chains only; these in turn may be hybridised and subsequently joined in an RNA ligase-catalysed loop closure reaction[3].

Sequential translation of capsid and membrane protein genes of alphaviruses

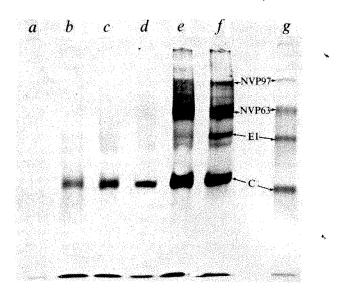
INVESTIGATIONS of the multiplication of alphaviruses such as Semliki Forest virus (SFV) or Sindbis virus have suggested that the three glycoproteins[1] (E1, E2 and E3) located in the viral envelope are initially synthesised as a large precursor polypeptide which contains the amino acid sequences of them all[2-7]. This protein, NVP97 (ref. 5), is cleaved to give E1 and another precursor polypeptide, NVP63, which is in turn cleaved to give E2 and E3 (refs 6 and 7). By analogy with the picornavirus system, it has been widely suggested that all the viral structural proteins are derived by cleavage of a common


Fig. 1 Monolayer cultures of BHK cells in glass scintillation vials (about 10[6] cells per vial) infected 5.5 h previously with SFV (20 PFU per cell) were exposed to minimal medium (Earle's salts containing 2% dialysed calf serum) to which 225 mM NaCl (ref. 14) had been added. After 40 min the hypertonic medium was replaced with isotonic minimal medium containing ^{35}S-methionine (200 Ci mmol[-1]; 10 μCi ml[-1]). Actinomycin D (1 μg ml[-1]) was present at all times after infection of the cells. As Saborio *et al.*[14] found, exposure of the cells to the salt-containing medium resulted in cessation of protein synthesis within 15 min. After restoration of isotonicity protein synthesis resumed without delay at a rate nearly equal to that before shutoff. After (*a*) 1 min, (*b*) 2 min, (*c*) 3 min, (*d*) 4 min, (*e*) 5 min or (*f*) 6 min, incorporation was stopped by freezing the cells in dry ice–methanol mixture[11] and adding 5% TCA containing 1% casamino acids. After thawing the cell sheet, washing twice with 5% TCA, and twice with ethanol–ether (1:3 v/v), it was dissolved in 2% SDS, 1% 2-mercaptoethanol, 0.1 M Tris-HCl, pH 9.0. The proteins were alkylated and analysed on 10% polyacrylamide gel slabs, which were dried and autoradiographed[8]. Proteins labelled for 2 min and chased for 12 min in similar cultures of untreated cells (*g*) are shown for comparison. Virus-specific proteins are identified using the nomenclature of Morser *et al.*[5].

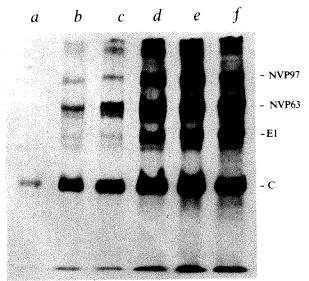
precursor and, indeed, proteins of a size sufficient to encompass the viral capsid protein, as well as the envelope proteins, have been found in infected cells treated with amino acid analogues and inhibitors of proteolytic enzymes[10,11], and in cells infected with certain classes of temperature-sensitive mutant[2,3,12,13]. Doubts have been cast on the validity of the analogy, however, by reports[8,9,16-19] that cell-free translation of SFV or Sindbis virus mRNA in several systems resulted in the production of discrete viral proteins. This situation is in marked contrast to that of translation of picornavirus RNA, in which a spectrum of polypeptides of various lengths is formed by premature termination at many points along the messenger; since no post-translational cleavage seems to take place, no polypeptides found in the mature virus or in infected cells are formed[20,21]. The possibility arose, therefore, that the alphavirus capsid protein and envelope proteins are synthesised independently.

Saborio *et al.*[14] have shown that restoring to isotonicity cultures of HeLa cells infected with polio virus, which had been treated with medium containing an elevated concentration of NaCl, induced the synchronous initiation of protein synthesis and allowed the order in which the viral proteins were synthesised to be examined. Here, I report similar experiments with SFV-infected BHK cells, which clearly demonstrate the processes of sequential synthesis and cleavage taking place during the formation of all the alphavirus structural proteins.


Autoradiographs of SDS–polyacrylamide gel slabs containing the proteins synthesised during a pulse experiment are shown in Fig. 1. By comparison with the proteins synthesised in non-synchronised cells, capsid protein is first apparent 2 min after restoring isotonicity, whereas radioactivity does not become associated with discrete envelope proteins or their

precursors until after 5–6 min, when NVP97, NVP63, and an envelope protein (whose identity is discussed below) all emerge together from the background radioactivity resulting from nascent chains and residual host protein synthesis. If the pulse of radioactivity is followed by a chase period a different picture emerges (Fig. 2). After a 1 min pulse only radioactivity which could be chased into capsid protein had been incorporated. As the length of the pulse increases there is a sequential appearance of envelope-specific material; NVP97 and NVP63 are present after a 2 min pulse and a protein migrating with the envelope proteins of the virus appears after a 4 min pulse. Large proteins of molecular weight greater than 100,000 are also apparent after a 3 min pulse and chase.

The fact that only capsid protein is labelled after a 1 min pulse and chase strongly suggests the existence of a single initiation site at the beginning of the capsid protein cistron for the translation of all the virus structural proteins. If there were two independent initiation sites for the capsid and envelope proteins, products originating from both sites would be expected to be labelled in a pulse-chase experiment, no matter how short the pulse. Other evidence, derived from work on the cell-free translation of 26S RNA, and on the kinetics with which synthesis of different viral proteins is switched off in cells treated with hypertonic medium, is also consistent only with the existence of a single initiation site for the synthesis of all the structural proteins of the virus (J. C. S. C. and S. I. T. Kennedy, unpublished).

From the time of first appearance of discrete envelope protein and precursors in the pulse experiment (Fig. 1), it seems that complete translation of the genes for the structural proteins (total molecular weight about 140,000) takes about 5 min. Assuming a constant rate of ribosome movement, the time required to translate the region corresponding to the capsid protein (molecular weight 36,500) may be estimated to be approximately 1.3 min. The appearance of capsid protein after a 2 min, but not a 1 min, pulse is in agreement with this estimate and indicates that it is cleaved from the growing peptide chain very shortly after translation of envelope-specific material begins. It is clearly not necessary that any precursor protein be completed before this cleavage occurs. The small quantities of high molecular weight proteins which can be seen after a 3 min pulse and chase may represent the precursor which has escaped the capsid protein cleavage mechanism. It is not clear whether these molecules can be processed to give viral

proteins or whether they represent errors which cannot be corrected, but in any event they are certainly not on the main pathway of synthesis of the proteins.

The next proteins to be labelled after the capsid protein in the pulse-chase experiment are the envelope precursors NVP97 and NVP63. The fact that NVP63 is labelled in the absence of radioactivity in the envelope region of the gels indicates that it is NVP63 which is translated immediately after the capsid protein. The absence of labelled envelope protein also means that NVP63 is not cleaved to give observable E2 and E3 during the short chase periods used here. This may mean that NVP63 is an intermediate with a relatively long half life, or that this cleavage is closely connected with the release of virus by budding through the cell membrane, as has been previously suggested[6,15]; if this were the case, significant quantities of E2 and E3 would not accumulate inside the cell.

Radioactivity finally appears in the envelope region of the gel only after a 4 min pulse in the pulse-chase experiment. Since NVP63 does not seem to be cleaved during the period of this experiment, the labelled envelope protein must be E1. The simultaneous appearance of NVP97, NVP63 and E1 after a 5 min labelling period in the pulse experiment indicates that the cleavage to give NVP63 and E1 takes place only after completion of their precursor (NVP97).

The sequential appearance of the proteins in the pulse-chase experiment combined with the demonstration of a single site for their synthesis indicates that the order of genes for the structural proteins of the virus is C–E2/E3–E1. It is not possible to order E2 and E3 from the present data since the cleavage to give these two products was not detected. It should be possible to arrange them in the correct order by observation of complete virions released during this type of experiment.

These results show that there is a striking parallel between the synthesis of alphavirus structural proteins and that of picornavirus proteins in that, in both cases, initiation occurs at a single site, the capsid proteins are synthesised first and they are cleaved rapidly from the nascent peptide chain. In the alphavirus system this rapid cleavage may be related to the fact that the remainder of the proteins are destined for glycosylation and incorporation into membranes. The removal of the capsid protein would thus avoid its association with membranes and allow the rapid insertion into nucleocapsid particles observed by Söderlund[22].

Fig. 2 Infected cells were treated as in Fig. 1 except that after incorporation of ³⁵S-methionine, the radioactive medium was replaced with minimal medium containing 1 mM non-radioactive methionine (pulse–chase experiment), and further incubated for 15 min after restoring isotonicity, when the cell sheets were frozen and processed as in Fig. 1. Cells were labelled for (*a*) 1 min, (*b*) 2 min, (*c*) 3 min, (*d*) 4 min, (*e*) 5 min or (*f*) 6 min after restoration of isotonicity.

Purification and ultrastructure of Aleutian disease virus of mink

ALEUTIAN disease of mink is an immune complex disease induced by viral infection. Major abnormalities include glomerulonephritis, arteritis, plasmacytosis and hypergammaglobulinaemia[1,2]. Infectious virus–antibody complexes have been found in the serum of infected mink[3], and deposits of viral antigen, antibody and complement have been demonstrated in glomerular and arterial lesions[4-6]. Detailed sudy of Aleutian disease virus (ADV) has been hampered by an inability to isolate and purify it by conventional techniques, mainly because ADV obtained from mink tissue is complexed with specific antibody[7]. The immune complexes are not sufficiently homogeneous for purification by physical or chemical properties. Applying techniques that dissociate antigen–antibody complexes to crude preparations of ADV, Cho and Ingram purified viral antigenic material[8,9]. With the electron microscope they observed virus-like particles in both immune precipitates and viral antigen from CsCl gradients. Although the immune precipitates were infectious for mink, lack of quantitative infectivity data on the CsCl gradient fractions prevented identification of these particles as ADV. We have now succeeded in purifying similar virus particles and have identified them as ADV by quantitative infectivity titration.

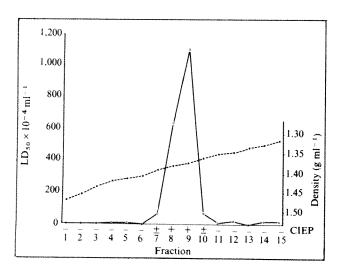
The Utah I ADV strain[4] (obtained from Dr D. Porter in fourth passage as a 10% liver suspension) was propagated and assayed in sapphire mink. Virus stocks were 10% spleen homogenates prepared from pooled spleens of mink inoculated intraperitoneally 9–10 d previously with 0.5 ml of the previous passage virus stock. Ten per cent spleen homogenates were made in phosphate-buffered saline containing 0.002 M ethylene diamine tetraacetate (PBS–EDTA). Homogenates were sonicated


Fig. 2 Electron micrographs of purified ADV pelleted from CsCl gradient fraction 9. Diameter of intact virions is 23 nm. Apparently hollow, ring structured virions are seen in upper left and lower right. Preparations were made with 2% sodium tungstosilicate as negative contrast material.
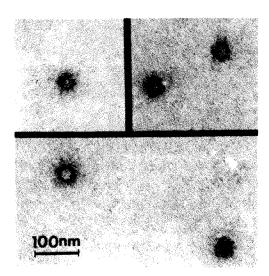

for 60 s in a Biosonik sonicator (Bronwill Scientific, Rochester), clarified by centrifugation at $500g$ for 10 min and stored in small volumes at $-70\,^{\circ}$C. We used the seventh passage of Utah I ADV which had a titre in sapphire mink of 2×10^6 LD_{50} ml^{-1} $(2 \times 10^7$ LD_{50} g^{-1} of spleen). For further purification 10-ml samples of homogenate were thawed, and debris was removed by centrifugation at $500g$ for 5 min and at $6,000g$ for 10 min. The infectious material was pelleted from the clarified suspension by ultracentrifugation at $243,000g$ for 90 min. Pellets were resuspended in 3 ml of PBS–EDTA with the aid of sonication and shaken with 7 ml of ether at room temperature for 5 min to extract lipids from tissue membrane material. The phases were separated by centrifugation at $500g$ for 5 min, and the aqueous phase was mixed with an equal volume of 0.1 M glycine-HCl buffer, pH 2.8. The mixture was incubated for 1 h at room temperature to dissociate antibody–virus immune complexes and ultracentrifuged as before to pellet the ADV and leave eluted antibodies in solution. Pellets were resuspended in PBS–EDTA by sonication, mixed with CsCl to a final density of 1.38 g ml^{-1} and ultracentrifuged for 42 h at $83,000g$ (maximum) at 4 $^{\circ}$C. Fractions were collected through a hole in the bottom of the tube, and the densities were measured by weighing 0.1-ml samples. Fractions were then dialysed against PBS, tested for viral antigen by counter immunoelectrophoresis (CIEP)[7], and stored at $-70\,^{\circ}$C. Infectivity was assayed by intraperitoneal inoculation of two to four sapphire mink with 0.5-ml volumes of serial tenfold dilutions of the dialysed fractions. Mink were tested monthly for hypergammaglobulinaemia and specific anti-ADV antibody. Those that remained clinically and serologically normal for 6 months were considered uninfected. Aleutian disease was confirmed at necropsy in all serologically positive mink.

Each mink inoculated intraperitoneally with 0.5 ml of dilutions indicated. LD_{50} calculated by Spearman–Karber method. Values plotted as $LD_{50} \times 10^{-4}$ ml^{-1} in Fig. 1.
* Number of mink affected with AD/number of mink inoculated.

A summary of results is shown in Fig. 1, and the detailed data from the infectivity titration are shown in Table 1. Although ADV infectivity was present throughout most of the CsCl gradient, a sharp peak of infectivity was concentrated at a density of 1.37–1.38, corresponding with the ADV antigen peak determined by CIEP. All fractions were ultracentrifuged at 243,000g for 90 min, and the pellets were examined in the electron microscope. Numerous 23-nm particles identical to those seen by Cho and Ingram were found in fractions 8 and 9 only (Fig. 2). Most particles were intact, but some seemed to be hollow as the negative contrast material penetrated the capsid and gave rise to a ring structure. All other fractions were negative for virus in the electron microscope, probably because of the lower ADV infectivity titres seen outside the main peak. It is interesting that the top fraction in all gradients was positive for ADV by CIEP. This could be because either ADV–antibody complexes were incompletely dissociated or non-infectious ADV antigen was found at a low density because of the absence of nucleic acid. No intact or hollow virions were seen in the electron microscope in the top fraction. A large amount of protein debris was, however, present in this region, and this could have masked recognisable virus particles. These results agree with those of Cho and Ingram as to density and morphology of their ADV antigen and provide quantitative infectivity data to indicate that the particles banded in CsCl gradients at a density of 1.37 are indeed those of ADV.

Others[10,11] have reported a buoyant density value of 1.21 for ADV. It is not clear why our value differs from this. In the conditions of centrifugation used by Yoon et al.[11] (30–60% sucrose gradient), the maximum density particle that would band at equilibrium would be 1.28 g ml^{-1}, the density of 60% (w/w) sucrose. Unless the virus particles were extremely large, centrifuging for only 2.5 h at 38,000 r.p.m. would not allow equilibrium to be attained in any case. It seems likely that velocity, rather than equilibrium, centrifugation was performed, and the location of the suspected virus material in the gradient was not an indication of the true buoyant density of the virus. Density values as low as 1.21 could also be explained by the association of lipids with the virus particle. The infectivity of ADV is not, however, affected by extraction with ether. This strongly implies an absence of lipid in the infectious particle.

The size, morphology and density of ADV reported here are consistent with the suggestion that ADV is a member of the parvovirus group (DNA-containing)[1,12]. The type of nucleic acid present in the virion has not been demonstrated. It is likely that with the availability of a simple purification technique this and other basic information on properties of ADV will be readily forthcoming.

C-type virus antigens detected by immunofluorescence in human bone tumour cultures

IN several animal species, C-type oncogenic RNA viruses (oncornaviruses) cause malignant tumours of mesodermal origin, such as leukaemia, lymphomas and different kinds of sarcoma[1]. C-type oncornaviruses have rarely been observed in human mesenchymal neoplasms using electron microscopy[2,3], but it has been claimed that molecular-biological methods can demonstrate in the tumours the presence of entities, the nucleic acids of which have sequences in common with the genomes of known mammalian oncornaviruses[4-7]. There have also been claims that C-type viruses can be detected in tissue cultures of human tumours[8-10], although it seems that a contamination with an animal virus had occurred in these cases. Recently[11] an agent with type C RNA tumour virus characteristics has been isolated from cultured human acute myelogenous leukaemia cells.

A common cytoplasmic antigen has been repeatedly observed in cultures of human sarcomas with sera from sarcoma patients or their relatives[12-15]. The cross-reactive nature of

Fig. 1 Human chondrosarcoma culture stained with a guinea pig antiserum to the major polypeptide of the SLV at dilution 1:20. For indirect immunofluorescence the microscope slides were sprayed with Teflon, while they were covered with a template, leaving eight wells open for incubation. Five of the wells were filled with different dilutions of the antiviral antiserum. One well was filled with the appropriate normal serum, and two wells with phosphate buffered saline (PBS). The slides were incubated for 30 min at 37 °C in a humid atmosphere, and washed thrice in PBS. After this, seven wells were incubated with the respective FITC-conjugate for 30 min at 37 °C; one well, previously incubated with PBS, was again incubated with the buffer. After washing and drying, the slides were embedded in Elvanol, and screened for granular cytoplasmic fluorescence with a Leitz Orthoplan microscope using Ploem illumination. A CS100 W/2 lamp was used for epi-illumination through a 40/1.0 objective (Zeiss). Narrow-band excitation and emission was performed using the following filter combination: 2 × KP 490 nm, BG 38/4, GG 455 nm, TK 495 nm (interference dividing plate) and SAL 525 nm as barrier filter. Microphotographs were taken with an Orthomat camera on Ilford HP 4 or Agfachrom 50S professional film. Tumour cell cultures originating from fresh tumour material (Dutch Bone Tumour Registry) were maintained in the Pathological Laboratory, Leiden. Control animal cell lines and cells infected with an animal oncornavirus were maintained at the Radiobiological Institute TNO, Rijswijk. To avoid contamination of the human cell lines with an animal virus, no animal cell lines were kept in the Pathological Laboratory, Leiden. For routine electron microscopy the tumour cell cultures were fixed in situ and removed from the bottle by scraping with a rubber spatula. No conspicuous sign of the presence of C-type virus was found in thin sections of these cells. Samples from many subcultures were cultured on microscope slides in Leighton tubes. When confluency was almost reached, the cells were fixed in cold acetone (−20 °C) and after washing in phosphate-buffered saline, stored in a deep freezer.

Table 1 Endpoint titration for immunofluorescence with antisera to mammalian C-type oncornavirus

Cell lines	Rat/RLV No. 45	Rat/RLV No. 76	Guinea-pig/SLV	Goat BoLV
BALB/c embryonic fibroblast (EF)	—	—	—	—
Rhesus monkey kidney	—	—	—	—
Bovine lung embryonic fibroblast (LEF)	NT	NT	—	—
Three human adult fibroblast lines	—	—	—	—
Human embryonic kidney	—	—	—	—
BALB/c EF+RLV	2,560	5,120	80	—
Woolly monkey fibrosarcoma	160	80	1,280	—
Bovine LEF+BoLV	NT	—	—	160
Several human bone tumour lines	20–160	—	40–80	—

Cultures were grown in minimal essential medium (Flow, Irving, Scotland) supplemented with glutamine, non-essential amino acids, antibiotics and 20% foetal bovine serum (Flow). The serum concentration was gradually diminished to 10% after a few days. The cultures were regularly tested for the presence of *Mycoplasma*[19]; all lines have proved to be negative so far. The isoenzyme patterns and the chromosome complements of the tumour lines have been studied. The cells proved to be human and not HeLa[20]. Antisera to RLV were prepared by hyper-immunisation of adult WAG/Rij rats with cells from a syngeneic lymphosarcoma induced by this virus[21]. The antisera were tested by immuno-diffusion and immunofluorescence for their reactivity and specificity. Only those antisera which in immunofluorescence gave a positive fluorescence in BALB/c murine embryonic fibroblasts infected with RLV at a titre of 1:2,560 or higher and no reaction at any serum dilution with uninfected cells were used for the study of human tumour cultures. The antisera were also tested for the interspecific, so-called gs-3 reactivity by immunofluorescence on cat embryonic fibroblasts infected with the feline leukaemia virus[22] or on rat embryonic fibroblasts, treated with 5-bromodeoxyuridine and dimethylsulphoxide for the induction of endogenous C-type virus[23]. All high titre anti-RLV sera were positive in both tests, giving a reaction up to an average endpoint of 1:160. A guinea-pig antiserum to the major polypeptide of the helper virus (SLV) in the woolly monkey sarcoma virus complex[24], was kindly provided by Dr R. V. Gilden (Flow, Rockville, Maryland)[25]. Its specificity was assessed by a strong reaction with a culture from a woolly monkey fibrosarcoma and negative reactions with cultures from tissues of different primate species. An antiserum to the bovine leukosis virus (BoLV) was obtained from a goat with a lymphatic leukaemia induced by neonatal inoculation with BoLV. The antiserum was kindly provided by Professor A. Ressang, Centraal DiergeneeskundigInstituut, Rotterdam. It does not react with uninfected bovine or ovine embryonic fibroblasts, but gives a significant reaction with infected cultures. Fluorescein-isothiocyanate (FITC)-conjugated antisera to the immunoglobulins of various species (Nordic N. V., Tilburg) were first tested for specificity using immunoelectrophoresis. Only those slides in which the wells incubated with normal serum, FITC-conjugate only or phosphate-buffered saline (PBS) were negative, were subjected to further study. A positive and negative control was included in every experiment. They consisted of cells infected with the virus to which an antiserum was directed and the corresponding uninfected cell line.

this antigen has been considered indicative of a virus because different C-type viruses isolated from the same species have strong cross-reactive antigenicity. The C-type oncornaviruses isolated from different mammals usually have some antigenic determinants in common[16-18]. No cross reactivity has, however, been reported between the common human sarcoma antigen and mammalian oncornaviruses. We report that, using immunofluorescence with human bone tumours, we regularly detected antigens which have determinants in common with the Rauscher murine and simian leukaemia viruses (RLV and SLV).

Table 2 Correspondence in positive fluorescence of human bone tumour cultures with anti-RLV and anti-SLV

Human bone tumour cell line	No. of passages	Rat/RLV No. 45	Guinea pig/SLV
Osteosarcoma 1	4	1:160	1:40
	5	1:80	1:40*
	30	—	
	31	—	1:80*
Giant cell tumour 1	9	—	—
4	8	1:80*	1:40*
Chondrosarcoma 1	7	1:20*	1:40*
Chondroblastoma 1	1	1:20*	1:40*
Adamantinoma 1	1	—	—

*Some cells positive.

Using indirect immunofluorescence, cultures were screened for the presence of different cytoplasmic C-type oncornaviral antigens (see legend to Fig. 1). Table 1 shows that the various antisera do not react with uninfected animal cell lines. They give a very strong reaction with cultures infected with the viruses to which the antisera are directed, but there is a significant cross reaction between RLV and SLV. The bovine leukosis virus (BoLV) did not show a cross reaction with either RLV or SLV.

Only one out of six rat antisera to RLV tested so far reacted with several human bone tumour cultures. The negative results with the other high titre antisera excludes a possible contamination with RLV. The fact that these antisera gave a good positive gs-3 reaction is an indication that the human cultures are not infected with the feline leukaemia virus or the endogenous rat virus.

The woolly monkey virus antiserum also gave a positive reaction with several human bone tumour cultures (Fig. 1). In those cases in which the results with the rat anti-RLV serum (No. 45) could be compared with those of SLV, there is a good correspondence (Table 2). As rat anti-RLV serum (number 76) reacts with a SLV-producing culture but not with any human bone tumour culture, it can be deduced that the human cell lines are also not contaminated with SLV. Tumour lines, which reacted with anti-RLV or anti-SLV serum, did not react with the goat serum that specifically reacts with the BoLV. This suggests that the cells are not contaminated with BoLV present possibly in foetal bovine serum. As this antiserum is not very strong, more studies with high titre antisera are needed.

The fluorescence with anti-RLV or anti-SLV varied per passage as shown for two tumour lines in Table 3. Most cells were positive in some passages, in others only a few cells and, in several passages no positive cells could be detected. On continued passage, however, bright fluorescence reoccurred. Our general experience is that especially early passages are highly positive. The positive fluorescence of human bone tumour cultures with patients' sera also varied per passage[13-15]. Positive fluorescence was observed in one or more passages in cultures of two osteosarcomas, four out of five giant cell tumours, one chondroblastoma, two out of four chondrosarcomas. One adamantinoma was negative during several passages.

To test further the specificity of the reaction with human tumour lines, the antisera were absorbed with RLV isolated

Table 3 Variation in positive immunofluorescence of human bone tumour cultures with anti-SLV per passage

Table 4 Absorption tests for the specificity of the immunofluorescence reaction of human bone tumour cultures with rat anti-RLV serum No. 45

Absorption procedure	Endpoint titration	
	BALB/c EF + RLV	Human bone tumour cultures
None	2,560	80
In vitro with RLV*	40	—
In vitro with MTV*	640	40
In RLV-infected BALB/c mice†	80	—
In normal BALB/c mice†	640	20

*Antiserum was mixed with an equal volume of virus in buffer (concentration 1 mg ml⁻¹) and stored overnight at 4 °C. Thereafter, the mixture was ultracentrifuged at 100,000*g* for 1 h and then tested in the immunofluorescence test. An additional control was the mixing of antiserum with an equal volume of PBS and subjecting this mixture to the same procedure.

†Antiserum (0.5 ml) was injected into 8 week old BALB/c mice or into BALB/c mice with RLV-induced erythroblastosis of the same age.

from plasma of leukaemic mice[26] or with murine mammary tumour virus isolated from tumours[27]. An *in vivo* absorption experiment was also performed. Both absorption procedures markedly reduced in the immunofluorescence assay on RLV-infected cells and completely blocked the reaction with human tumours (Table 4). The control absorptions only slightly diminished the reaction in both systems, indicating the specificity of the reaction of human tumour cells with anti-serum No. 45. In the same way absorption of the antiserum to SLV with SLV, isolated from tissue culture fluid, blocked the reaction with human tumour cultures completely, whereas absorption with the murine mammary tumour virus had only a slight effect.

The results suggest that cultures from human bone tumours harbour a viral entity, that occasionally produces antigens which have determinants in common with known animal C-type oncornaviruses. It is not likely that the observed reactions result from contamination with murine, feline, bovine viruses or SLV. A more extensive study is needed with a greater variety of antisera to purified proteins from many different animal viruses, to assess the relationship of the putative human virus to the other viruses and to detect whether it is endogenous or exogenous. Also more sensitive techniques than the immunofluorescence method we used are needed to detect viral antigens. Furthermore, tissue culture systems must be developed which lead to a more constant production of antigen and, hopefully, to the production of detectable amounts of C-type particles. Even then, the association of this virus with the causation of bone tumours remains to be established.

Mechanism of an action of an antibacterial murine lymphokine

THE inactivation and clearing of infectious agents through adaptive immune responses results from interactions between T lymphocytes, B lymphocytes and mononuclear phagocytes[1-4]. The effector cells in cell-mediated immunity (CMI) are primarily T lymphocytes and mononuclear phagocytes[1,5,6]. CMI responses appear in two stages, lymphocyte activation with subsequent production of biologically active mediators, and recruitment and activation of other cells (particularly mononuclear phagocytes) as a result of the activity of several of these mediators[1,3]. Collaboration between T lymphocytes and macrophages in bacterial infections mediated by a lymphokine that causes inhibition of the growth of organisms within the macrophage has been assayed[1,5,8]. This inhibition probably results from increased macrophage microbiocidal activity[1,5]. The subject of this report is a lymphokine that reduces the viability of bacteria. The mechanism of action of this lymphokine is impairment of the ability to divide of otherwise metabolically active bacteria.

The antibacterial activity was assayed on a diaminopimelic-acid (DAP)-dependent auxotrophic mutant of *Escherichia coli*, cultured in DAP-free supportive medium. DAP is utilised in the synthesis of the pentapeptide normally involved in cross-linking of polymeric macromolecules in cell walls and as a source of intermediates essential for lysine synthesis[9]. Incubation in DAP-free medium resulted in formation of spheroplasts and filamentous forms and gradual termination of protein synthesis. Supernatants containing lymphokine were prepared by activation of lymphocytes with a streptococcal filtrate[10] and by the lympho-

Fig. 1 Dose-dependent reduction in viable count of bacteria exposed to the purified lymphokine. The maximum ratio (control :lymphokine-treated) was approximately 2,000:1 at the highest concentration. ●, Control; ▲, lymphokine-treated.

Table 1 Incorporation of labelled metabolites into bacterial cell macromolecules and corresponding viable counts in cultures exposed to purified lymphokine and control preparations

Metabolite and isotope	Lymphokine (c.p.m.)		Control (c.p.m.)	
Incorporation in deprived cultures (3 h pulse)	(expt. 1)	(expt. 2)	(expt. 1)	(expt. 2)
^{14}C-amino acids	961 ± 17	63 ± 28	564 ± 308	1,200 ± 937
^{3}H-uridine	25,667 ± 3,700	1,081 ± 177	172,800 ± 91,700	94,600 ± 31,800
^{3}H-thymidine	3,690 ± 1,480	102 ± 30	2,180 ± 420	1,174 ± 410
Incorporation during recovery (24 h pulse)				
^{14}C-amino acids	39,430 ± 6,610	42,080 ± 9,460	54,900 ± 16,800	51,750 ± 1,970
^{3}H-uridine	200,400 ± 47,200	128,370 ± 28,960	338,700 ± 2,210	135,330 ± 32,800
^{3}H-thymidine	5,910 ± 1,290	62.0 ± 18.0	19,220 ± 2,210	4,060 ± 1,180
DAP-dependent viable count	7.8 ± 1.2 × 10^7	5.9 ± 0.8 × 10^4	5.2 ± 1.5 × 10^8	1.01 ± 0.6 × 10^8
NON-DAP-dependent viable count (Colonies on TSA without DAP)	9.1 ± 0.8 × 10^5	0	6.0 ± 0.8 × 10^4	1.40 ± 0.9 × 10^2

Bacteria were suspended at a density of 10^9 organisms ml^{-1} in DAP-free supportive medium containing lymphokine or control preparations and incubated for 10 d. At the end of this period, 0.5 ml of culture suspensions were added to 0.5 ml of medium containing 0.1 μCi of labelled tracer (Amersham), and incubated for 3 h. At the end of the incubation, culture suspensions were diluted 1:10 in supportive medium containing DAP, and 0.5 ml of this incubated with tracer as above for 24 h to assay recovery. Viable counts were performed on DAP-containing Tryptose Soy Agar (TSA) plates. Processing and determination of incorporation of label was after the method of Bartholomaeus *et al.*[12]. To optimise incorporation of ^{3}H-thymidine, 250 μg ml^{-1} deoxyadenosine was added with the isotope as an inhibitor of cytoplasmic thymidine kinase[7].

cyte phytohaemagglutanin (PHA)-coated L-cell coculture method[11]. Lymphocyte preparations (greater than 95% non-phagocytic small mononuclear cells) consisted of spleen lymphocytes prepared on Ficol–Isopaque gradients[12] mixed with equal numbers of thymus lymphocytes. Lymphokine-containing and control supernatants were concentrated on a UM 10 membrane in an Amicon Diaflo apparatus. The lymphokine was purified by Sephadex G-200 gel filtration and Pevicon block electrophoresis.

The purified lymphokine was trypsin-sensitive and gave a single band on analytical acrylamide gel electrophoresis and on immunoelectrophoresis. No cross reaction with an antiserum to foetal bovine serum could be detected. The lymphokine had a molecular weight (from Sephadex gel filtration) of 75,000 ± 15,000 and electrophoretic mobility similar to that of a fast α globulin. The lymphokine produced in lymphocyte–PHA–L-cell cocultures could not be differentiated from the lymphokine produced by stimulation of lymphocytes with streptococcal filtrates.

In cultures exposed to the lymphokine there is a reduction in viable count differing from cultures exposed to control preparations by factors up to 2,000 (Fig. 1). Exposure of wild-type *E. coli* to the lymphokine throughout a growth cycle produced an increased rate of loss of viability in stationary phase (R.L.P.F. K.J.T., and M.P.A., unpublished).

In the assay utilising the DAP-dependent mutant both lymphokine-treated and control cultures contain metabolically active organisms capable of incorporating similar amounts of labelled amino acids into protein, and uridine into RNA in recovery of metabolic activity when provided with limiting nutrient after deprivation (Table 1). The drop in viable count in lymphokine-treated cultures correlates with the almost total loss of the capacity to incorporate ^{3}H-thymidine into DNA in cultures which remain DAP-dependent (Table 1). These results are consistent with the hypothesis that the primary effect of the lymphokine is impairment of bacterial nucleic acid metabolism expressed in the inhibition of the synthesis of new DNA, and thus, loss of the ability to divide and consequent drop in viable count. In deprived cultures the effect extends to depression of RNA metabolism. This suggests that transcription as well as DNA replication may be inhibited.

The relationship between this lymphokine and the factor that inhibits the growth of microorganisms detected in the serum of immune mice after challenge with antigen[13] is of considerable interest. Investigation of the relation between these factors will give a clear indication of any involvement of lymphokines in direct antibacterial immune responses. Nonspecific production

of lymphokines in response to supernatants from streptococcal cultures would suggest that some nonspecific responses to bacteria[14] may be mediated similarly by lymphokines.

Corrigenda

In the article "Origin of fifteen cosmic dust particles intercepted by Pioneer 8 and 9" by J. W. Rhee, O. E. Berg, F. F. Richardson and S. Auer (*Nature*, **252**, 555; 1974), the second sentence should read "The two spacecraft are in direct heliocentric orbits with perihelia of 0.99 AU and 0.75 AU and aphelia of 1.09 AU and 0.99 AU, respectively."

In the article "Re-interpretation of Devensian Till stratigraphy of eastern England" by P. A. Madgett (*Nature*, **253**, 105; 1975), there was an error in Fig. 2. The abscissa should read

$$\frac{\text{Epidote}}{\text{Epidote} + \text{Zircon}} \times 100$$

and not as printed.

Erratum

In the article by J. de Leiris, L. H. Opie and W. F. Lubbe (*Nature*, **253**, 746; 1975), the title should read "Effects of free fatty acid and glucose on enzyme release in experimental myocardial infarction".

matters arising

Distance to Cygnus X-1

CHENG *et al.*[1] have recently re-examined our estimates[2,3] of the distance to Cygnus X-1. They have noted that the Cepheid V547 Cyg is at $d = 6.6$ kpc, yet has colour excess 1.1, far less than predicted by a uniform reddening extrapolation. On this basis they conclude 'the only independent distance check (on Cyg X-1) is so widely in error.' It is well known (see refs 4, 5) that the dust responsible for interstellar reddening is stratified in layers, and thus for every non-zero galactic latitude there exists a distance beyond which stars show no further colour excess regardless of modulus. In such fields one therefore expects the most distant observable stars to have colour excess no greater than that of intermediate distance objects; V547 Cyg is entirely consistent with this concept. It is also wrong to state that there exist no other independent estimates of distance, as we pointed out previously. Evidence based on spectroscopic modulus[6], linear polarisation[7], cluster membership[8] and interstellar lines[9] all indicate $d > 2$ kpc. Each of these methods has its own assumptions which may be individually questioned and evaluated; none of the methods, however, uses the same assumptions as the colour excess method we used. We find it quite convincing that five independent methods, although none individually of extreme accuracy, are all in agreement.

Cheng *et al.*[1] speculate that the "possibility" of X-ray heating of the primary makes distance estimates uncertain. The amount of heating is a directly measured quantity and has been shown to be entirely trivial[10]. They also state that an extrapolation of the reddening diagram to beyond 1 pkc is unwarranted. But if one adopts $d \leqslant 1$ kpc as they claim as a possibility, then no extrapolation is necessary, and one must then postulate that this star is situated behind interstellar matter which creates reddening per unit distance far exceeding all other of the ≈ 125 objects we measured within 50' of Cyg X-1. The alternative of circumstellar rather than interstellar reddening is excluded by the lack of infrared excess in HDE226868. Furthermore, the polarisation agreement[7] means that this excess material, implied by the authors to be in a small globule, manages in a fraction of a pc to exactly compensate for the linear polarisation otherwise provided by 2 kpc of interstellar matter.

Although we agree that Cyg X-1 is not proven to be a black hole, and other models for the system are still viable, we think that the overwhelming weight of observational evidence places this object at $d > 2$ kpc regardless of its nature.

Indirect methods for detecting γ-ray bursts from supernovae

PORTER[1] suggests the possibility of detecting γ quanta from supernova bursts with a detector located at sea level. He bases his calculations on the results of a Monte Carlo computation procedure for electromagnetic showers[2]. It follows from the tables of cascade functions[2] that the mean particle number behind the cascade curve peak decreases with depth t as $e^{-\lambda t}$, where λ is much smaller than $\lambda_{\min}$ the minimum cross section of photon absorption in the matter. This result is at variance with the assertion that the shower development at low levels is determined by absorption of photons with the greatest permeability[3]. The experimental data used by Messel and Crawford[2] produced a discrepancy for photon absorption in air compared with the calculations of Ivanenko[4], which they explained by the fact that the Compton scattering had been inaccurately included in his work. Since all essential processes are accurately included in the Monte Carlo procedure, the disagreement with the cascade curves obtained by the momentum method[5,6] was ascribed[2] to

the low accuracy of the reconstruction of the function based on a limited number of momenta

Numerical integration of the cascade theory one-dimensional equations[7,8] makes it possible to include accurately all processes and to calculate the longitudinal shower development down to

Table 1 1 MeV photon absorption coefficient

Element	$\lambda_{\min}$	λ_{calc}	λ_{MC}
Air	0.61	—	0.04 (ref. 2)
C	0.60	0.53 ± 0.01	—
Fe	0.41	0.33 ± 0.01	—
Cu	0.40	—	0.38 ± 0.02 (ref. 11)
			0.11 (ref. 2)
			0.24 ± 0.02 (ref. 4)
Pb	0.27	0.21 ± 0.01	0.25 ± 0.02 (ref. 12)
			0.27 ± 0.03 (ref. 13)

sufficiently low depths to produce a good estimate of the absorption coefficient λ. Inclusion of annihilation of positrons would result in an appreciable increase of the calculation volume because the two-equation system must be replaced by a three-equation system The contribution from annihilation was, therefore, estimated The terms, including particle redistribution resulting from annihilation, were inserted into the system of two transport equations, and the positron number was taken as 0.4 and 0.5 times the total charged-particle number in two separate runs. The calculations were carried out for an electromagnetic shower in lead where the annihilation effect is greatest. Annihilation γ quanta from stopped positrons were also included. The estimate shows that the contribution from annihilation may be neglected to an accuracy of 3–5%. This result is in line with other calculations[9,10].

A lower boundary for λ can be obtained when numerically integrating the one-dimensional equations, since the inclusion of scattering will only increase the cascade particle absorption with depth. For $E > 10$ MeV in heavy elements $E > 1$ MeV in light elements, the scattering effect on the cascade curve shape may be neglected[5,6]. We have calculated the cascade curves in lead, iron, and carbon from a primary (electron or photon) with energy E_0 in the 1–10^3 GeV range for several values of E from 316 MeV to 10 KeV. The calculated and

Monte Carlo data on the $E > 1$ MeV photon absorption coefficient λ (refs 4, 11–13; Table 1) are in agreement. The difference of the calculated and Monte Carlo λ from λ_{min} can be explained by the effects of Compton scattering and multiple Coulomb scattering.

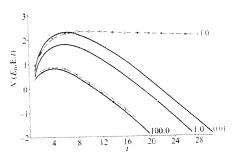
Comparison between the cascade curves for the various threshold energies has shown that the data tabulated in ref. 2


Fig. 1 The mean number of photons, $N (E_0, E, t)$ with energies exceeding E from a primary photon with $E_0 = 10$ GeV in carbon at depth t. The solid curves show the results of numerical integration, the dashed curves represent the data from ref. 2. The numerals on the curves indicate the threshold energy E in MeV.

agree with the results obtained using the numerical integration and momentum method[5,6] for $E > 10$ MeV in lead and $E > 100$ MeV in air. Figure 1 shows the typical cascade curves from Messel and Crawford's tables for air and those calculated in the present work. The results obtained cast doubt on the conclusion drawn by Porter[1] about the possibility to detect the bursts from supervonae with a mountain or sea-level detector, since the $E > 1$ MeV photon number in ref. 2 is overestimated by a factor of 10^2 at mountain level and by a factor of about 10^4 at sea level.

Solar flare X-ray polarisation

BROWN *et al.*[1] have argued that the "Intercosmos-1" and "Intercosmos-4" results of solar flare X-ray polarisation measurements are in error due to incorrect 'normalisation' procedure. The normalisation was made in order to eliminate the effect of possible differences in the sensitivity of the photon counters and it is based on the assumption that the X-ray flux is unpolarised during the decay stage of flare[2].

According to ref. 1 the Thompson scattering of intrinsically isotropic and unpolarised flare emission taking place in the lower parts of the solar atmosphere could give polarisation P up to some 30% of observed X-ray flux (the sum of primary and scattered radiation). This conclusion is based on consideration of the scattering at 90°. In fact, because of weak dependence of the Thompson cross section on the scattering angle χ the observed flux corresponds to a wide range of χ (Fig. 1). Integration over all possible χ gives a rather low value of P (ref. 3). The area of the photosphere just under the flare gives scattered flux polarised mainly in trans-

Fig. 1 Scattering of the flare X rays by the solar photosphere.

verse direction ($P < 0$), while the flux from more remote areas has a preferentially radial electric vector ($P > 0$). The resulting value of P depends on the altitude of the flare $\tau = H/R_\odot$ and on the heliocentric angle θ (Fig. 1).

Detailed calculations of the back scattered radiation in the first order scattering approximation are given in ref. 3. For the total flare X-ray flux we always have $|P| \leqslant 2\%$ (ref. 3 and see Fig. 2). Multiple scattering could alter this value by as much as a factor of two (ref. 3). It was taken into account in the computation of solar X-ray albedo using the Monte Carlo method[4], but the

Fig. 2 Polarisation P of the total X-ray flux as function of heliocentric angle θ.

statistical significance achieved was too poor to determine the polarisation.

So inclusion of Thompson scattering effects cannot substantially influence the results of normalisation in ref. 2.

In further experiments[5] the scatterer and the counters were mounted on a rotating drum. This permits continuous checking of the relative sensitivities and thus eliminates the need for normalisation. Unfortunately, we were not able to obtain absolute values of P with the polarimeter on board "Intercosmos-7" because of the failure of one of its measuring channels. The polarimeter of "Intercosmos-11" has worked well and results obtained will be published elsewhere.

Are centromeric dots kinetochores?

EIBERG[1] described a Giemsa staining technique which reveals specific paired dots in the centromere region of human chromosomes in cells treated with colcemid and hypotonic KCl. He suggested that the dots may represent organelles associated with spindle fibres. Evans and Ross[2] demonstrated similar, stained or unstained dots obtained in colcemid-treated mammalian cells by other preparatory techniques. They hypothesised that these dots "may represent the kinetochores and particularly their associated proteins".

These interpretations are unlikely for several reasons. First, the location of the unstained dots shown by Evans and Ross[2] does not coincide with that of the raised dots on unstained, shadowed chromosomes. Unstained dots adjoin chromosomes in the centromere region, whereas raised dots, like Eiberg's[1] C_d dots, lie clearly within the chromosomes. Second, there is no evidence that the centromerically located spindle microtubules are always present in colcemid-treated cells. A two hour exposure of rat kangaroo cells to 0.05 µg ml^{-1} colcemid destroys all microtubules and alters the fine structure of the kinetochores[3]. Speculation that spindle proteins concentrated in the centromere regions of chromosomes could produce centromeric dots cannot, therefore, be substantiated. Third, kinetochores are rather delicate, labile organelles and they are probably affected drastically by treatments used in the preparation of chromosomes for light microscopy. For example, no kinetochores are visible in thin sections of Chinese hamster chromosomes subjected to the aceto-orcein smear technique (L. J. Journey, personal communication). Fourth, even if kinetochores were preserved by light microscopic techniques they could hardly produce prominent raised dots, for the disk-shaped kinetochores of mammalian chromosomes are only some 100 nm thick[3,4].

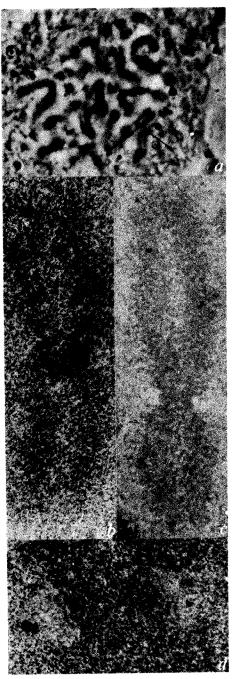
Optical and electron microscopic observations of rat kangaroo cells treated with hypotonic colcemid[5] suggest a different interpretation of centromeric dots. Paired dots are recognisable by phase contrast microscopy in the centromere region of favourably oriented chromosomes in embedded prometaphase cells (Fig. 1a). In thin sections the dots appear as patches of chromatin packed more densely than in the remainder of the chromosomes (Fig. 1b). The kinetochores which are less opaque to electrons lie adjacent to these patches. In metaphase cells the chromosomes are, overall, more condensed, but the chromatin is also more densely packed in the centromere region than in the arms (Fig. 1c). The outer layer of each kine-


Fig. 1 Chromosomes of rat kangaroo cells (line PtK$_2$) treated with hypotonic colcemid (15 min at 37 C in 0.25 µg ml^{-1} colcemid prepared by diluting an aqueous 0.5 µg ml^{-1} stock solution 1:1 with culture medium. See ref. 3 for culture conditions, fixation and embedding). *a*, Phase contrast micrograph of a prometaphase cell (× 1,625). Note the paired dots in the centromere region of favourably oriented chromosomes. Single dots are visible on laterally viewed chromosomes. *b*, Thin section of the arrowed chromosome of Fig. 1a × 11,700. Note the two patches of densely packed chromatin in the centromere region. *c*, Metaphase chromosome × 7,475. Note the dense centromeric chromatin and the adjoining electron-lucent zones. *d*, Centromere region of another metaphase chromosome × 22,425. Note the kinetochore bands at the surface of the primary constriction and the electron-lucent zones.

tochore appears as a moderately electron-opaque band lying parallel to the chromosomal surface in a distinctly electron-lucent, approximately circular zone adjacent to the centromere region (Fig. 1c and *d*).

These electron-lucent zones correlate with, and may be equivalent to, the unstained dots described by Evans and Ross[2]. This interpretation is supported by Journey's observations (personal communication) of "empty", circular zones adjacent to the centromere region of Chinese hamster chromosomes in thin sections of acetoorcein smears. The densely packed centromeric chromatin, on the other hand, may account for the dots revealed by Eiberg's[1] Giemsa staining technique and by the shadowing technique of Evans and Ross[2]. Dense structures reminiscent of centromeric dots are also seen in the centromere region in whole-mount preparations of Chinese hamster chromosomes treated with distilled water[6] and in whole mounts of HeLa chromosomes stained with phosphotungstic acid[7]. All these results can be explained by a greater resistance of the centromeric chromatin to the spreading forces to which chromosomes are subjected in a hypotonic medium. This resistance may reflect a specific DNA-protein composition of the centromeric chromatin, that in turn could account for the specific staining, as pointed out by Eiberg[1].

Logic of animal conflict

MAYNARD-SMITH and Price have shown[1] that it is not necessary to invoke group selection to explain the occurrence of 'conventional' rather than 'dangerous' tactics in animal conflict. The conditions for the evolution, under individual selection, of populations in which conventional tactics predominate are, however, more stringent than they suggest. In particular, given their pay-off matrix, the population may end up consisting mainly of individuals adopting the 'dangerous' strategies, Hawk and Bully.

Consider a population consisting almost entirely of Hawk and Bully, so that nearly all conflicts are between these. Then

Hawk is the better strategy when the opponent is Bully and Bully is better when the opponent is Hawk. Thus we have a system of frequency-dependent selection, leading to a stable mixture of Hawk and Bully. At this equilibrium, Hawk and Bully will have equal fitness on average and will therefore have frequencies: Hawk 0.575652; Bully 0.424348. In nearly all conflicts, the opponent will be Hawk or Bully, with frequencies just given, so that average pay-offs will be: Mouse 19.5000; Hawk 20.4311; Bully 20.4311; Retaliator 11.3932; Prober-Retaliator 13.6357.

Therefore, types other than Hawk and Bully are at a disadvantage and will not spread. These results will not be affected by the presence of a few individuals adopting strategy Mouse for non-genetic reasons, since Hawk and Bully are the best (equally good) strategies when the opponent is Mouse.

If, for simplicity, we regard the five strategies as reproducing asexually with fitnesses given by average weighted pay-offs, we find that the Hawk-Bully equilibrium is attained from some starting points, for example, with strategies given in the order above, (0.33, 0.33, 0.33, 0.005, 0.005) or (0.9, 0.025, 0.025, 0.025, 0.025). On the other hand, starting with all strategies of equal frequency, the ultimate population consist entirely of Retaliator. These results suggest strongly that some modification of the original model is required to explain the general occurrence of conventional strategies.

Anti-Darwinism among the molecular biologists

Ohta[1] asserted that evolutionary change at the macromolecular level was caused primarily by "mutation pressure" rather than Darwinian selection. This view, upheld by an influential school of biochemists and molecular biologists (most of them named in Ohta's bibliography), strikes some of us as regressive and potentially dangerous to our science.

One major danger is that it will dissuade biochemists from looking for functional significances in sequence differences (for example those of cytochrome *c* from different species). There is also a more general danger, that of encouraging ahistorical, statistical and mathematical thinking at the expense of the search for causal and historical explanations of the particularities of organisms.

It was a Scottish philosopher of science who wrote that "Only in the last resource, when the heavenly powers fail us, should resort be had to the demons of the underworld, chance and probability"[2]. In the case of macromolecular evolution, it does not seem to me that Ohta and those who think like him in any way have demonstrated the failure of the "heavenly powers" of Darwinian selection. Earlier, Kimura and Ohta[3] had coined the phrase "naive pan-selectionism" for the ideas of those who disagreed with them, and this phrase was taken up by Wills[4] in a paper, not cited in Ohta's bibliography, which criticised in some detail the arguments of Kimura and Ohta, and showed that the evidence was quite consistent with a selective origin for most, if not quite all, the protein differences met with in nature.

The major argument cited by the followers of Ohta and Kimura in favour of their attitude has been the alleged time-proportionality in the numbers of residues differing between species, for cytochrome *c* and other proteins. Reasons have been put forward, such as the "Red Queen hypothesis" of van Valen[13], why a loose proportionality of this sort might be expected on the basis of ordinary selectionist theory. Ohta, however, treats it as an established fact that there exists a proportionality far too accurate to be explained in this way. It needs to be pointed out that, in the graphs published to illustrate this proportionality, by Dickerson[5] for cytochrome *c*, for example, and by Wilson *et al.*[6] for haemoglobins, the apparent linearity of the relationships depends on the assignment of some very questionable ancestral ages for the taxa concerned. Thus Dickerson gives a mid-Cretaceous age (around 100 Myr) for the ancestries of the main orders of placental mammals, whereas fossil evidence[7] would place this in the very late Cretaceous or early Palaeocene, perhaps 75 Myr ago. For a common ancestry of mammals and reptiles, that is an ancestral amniote, Dickerson cites a Lower Carboniferous (around 320 Myr) age, whereas fossil evidence[7] would suggest an early Permian age of perhaps 270 Myr. For a common ancestor of Amphibia and Amniota, Dickerson's graph assigns a late Devonian age of some 350 Myr, whereas fossil evidence[7] would rather suggest the mid-Carboniferous, some 300 Myr ago. Finally, the age given by Dickerson for a common ancestor of insects and vertebrates is late Pre-

cambrian, perhaps 600 Myr old. This would be about the age of the celebrated Ediacara fauna of Australia, described by Glaessner[8] in which quite advanced annelid and possible primitive types of arthropods are represented; undoubtedly, any common ancestry of the deuterostomian line (including Vertebrata) and the molluscan-annelid one from which the insects sprang must have been very considerably older, perhaps more than 700 Myr old.

The similar graph for the haemoglobins given by Wilson *et al.*[6] assigns some even more questionable ancestral dates—for example, original separation of the cyclostome (lamprey) line from that of Gnathostomata, is placed in the Proterozoic, some 800 Myr ago, probably nearly as old as the entire metazoan line!

A further assumption of Ohta is that protein polymorphism in natural populations is non-adaptive and a result of mutation pressure. Where such polymorphism has been studied in detail for particular proteins, as pointed out by Johnson[12], the phenomena have been found to parallel closely those of polymorphism in ordinary phenotypic characters, selective control of which has been demonstrated, as pointed out by Ford[11] in another important and relevant work not mentioned in Ohta's bibliography. Selander and Kaufman[9], also not cited, draw attention to a book by Levins[10] in which the theory is developed of the long term adaptive advantages of maintaining certain critical degrees (varying with the characters and the circumstances) of heterozygosity of natural populations.

Ohta's evident pride in the mathematical sophistication of his methods of analysis prompts a scriptural gloss on his phrase "naive pan-selectionism": namely, that by adopting what he would consider as the naivety of "little children", the molecular biologists might improve their chances of entering into that "kingdom of heaven" in which the historic truths of evolution are revealed.

reviews

As a result of intensive research since the beginning of the present century, the traditional image of the Middle Ages as an epoch of sterile subservience to the authority of the Church and of Aristotle in scientific matters has been destroyed. Instead, it is now recognised as a period during which scholars became capable of wide ranging and subtle, albeit habitually inconclusive, speculation upon topics commonly supposed to be the distinctive concern of early modern science—the rotation of the Earth, for example, the atomic structure of matter, the possibility of creating a vacuum, and so on. It has emerged, moreover, that such medi-aeval speculations, although cast in a very different mould, are by no means isolated from the articulation of the new philosophy in the 17th century. On the contrary, as Edward Grant clearly illustrates in *A Scource Book in Medieval Science*, scholastic discussions exercised a patent or possible influence on such later innovators as Copernicus, Galileo and Otto von Guericke. At the other chronological extreme, Profes-sor Grant begins his anthology of mediaeval science with extracts from the late-classical encyclopaedias that preserved an inkling of ancient cul-ture in the Latin west during the Dark Ages, and proceeds thence to illustrate in considerable detail subsequent developments in logic, mathematics, physics, cosmology, chemistry, geo-graphy, biology and medicine. Although the bulk of the material is drawn from the period 1200–1500 AD to have documented approximately a millenium of, at times, intense intellectual activity

Medieval record

C. J. T. Lewis

A Source Book in Medieval Science. Edited by Edward Grant. Pp. xviii + 864. (Harvard University Press : Cam-bridge, Massachusetts, August 1974.) $32.50.

over such a wide range of subjects is obviously no mean achievement.

It is not only the sheer bulk of avail-able material that renders the con-struction of an anthology of mediaeval science so problematic a task, however. In addition, there is the difficulty of selecting topics and texts that are relevant both to the subsequent evolu-tion of early modern science and to the interests of the ordinary 'educated reader' at whom this work is partly directed, without simultaneously dis-torting the emphasis of the original speculations. Professor Grant is, of course, well aware of, and for the most part effectively reconciles, such conflicting demands.

Nevertheless, it is perhaps inevitable that he should tend towards the use of an essentially positivist criterion in making his selections. This tendency is most conspicuous in the devotion of relatively little space to alchemy and astrology, and the complete exclusion of the more exotic magical sciences. More subtly, however, the same criterion determines a concentration on the 'achievements' of mediaeval science

that I have already mentioned. Occa-sionally, this leads to a measure of dis-tortion, most obviously, for example, in the documentation of mediaeval 'kine-matics'.

On the whole, however, such mis-representation is avoided; the broader context of individual problems, the characteristic conceptual interrelation-ships and the typical methods of mediaeval science are illustrated with considerable force and economy. In-deed, a particular virtue of this source book is that the (to a modern mind) metaphysical preoccupation, and the unique gothic complexity, of much scholastic scientific discussion is clearly illustrated by the reproduction of com-plete *quaestiones* and treatises.

It is inevitable in a work of such size and scope that one should take exception to certain features and regi-ster certain omissions. Thus, although the copious annotation of individual documents renders them perfectly comprehensible, it is regrettable that the sections on physics should be pro-vided with neither a contemporary nor a modern outline of the principles of Aristotelian natural philosophy, which constituted, after all, the foundation of most scholastic physical speculation. Again, it seems a pity, considering the possible audience of this book, that further references for given topics are not more thoroughly recorded. Ulti-mately, however, it must be said that this book offers a clear and scholarly exposition of a mass of fascinating documents, and provides an unparal-leled insight into the processes and pre-occupations of mediaeval science. □

Most students find mathematical physics a difficult subject. They can follow a qualitative explanation (such as, "magnetisation lines up the dipoles"), and they can follow the steps in an algegbraic deduction, or in the solution of an equation and the evalu-ation of an integral; the physics and the mathematics are philosophically distinct activities. Difficulties arise, how-ever, at the meeting-point between these disciplines. How does one mathematise a physical problem? Why do the same equations crop up over and over again, in apparently unrelated physical con-texts?

This original undergraduate text is a largely successful attempt to answer the second of these questions. The philosophy is to apply the field equa-

tions of mathematical physics (Laplace, Poisson, wave, and diffusion) to pro-blems of increasing complexity, illus-trating the solutions obtained with examples from a very wide range of

Maths and physics

Michael Berry

Introductory Eigenphysics: An Ap-proach to the Theory of Fields. By C. A. Croxton. Pp. x + 275. (Wiley: London and New York, November 1974.) £6.95 board; £3.95 paper.

fields of physics. First, the field equa-tions are introduced. Then they are solved in rectangular, cylindrical and spherical coordinates. Finally, approxi-mate methods (perturbation, WKBJ and variational) are discussed. The origin-

ality lies in the examples chosen which are oriented towards physics rather than applied mathematics and which include lattice vibrations, Bloch waves, skin effect, aerofoil theory, vibration of a rotating star, earthquakes in the Mohorovicic layer, pseudopotentials in liquid metals, and quantum chemistry. There are many interesting exercises for the reader.

Unfortunately, the book is seriously marred by many minor errors and in-felicitudes, most of which could have been avoided by careful proof-reading. Symbols are not defined, figures are im-perfectly labelled and terms are intro-duced without explanation. This will confuse all but the best students. I do, however, warmly recommend the book to teachers. □

Agriculture and industrialisation

Agriculture and the Industrial Revolution. By E. L. Jones. Pp. xiii+233. (Blackwell: Oxford, February 1975.) £5.50.

As the title suggests, this is a book about the relationships between the development of agriculture in Britain and the process of industrialisation which we refer to as the Industrial Revolution. The work, a collection of essays published by the author during the 1960s, is divided into two main sections. A group of essays concerned mainly with agricultural change and the process of industrialisation constitutes the first part, and a further group round the theme of agriculture in the urban industrial economy comprises the second. Many of the essays are detailed studies of agricultural changes in specific locations, as, for example, are the pieces on farming in Hampshire and Herefordshire. But the author is able to bring a considerable degree of theoretical clarification to his materials. This is nowhere more clearly exemplified than in the essay entitled "Agriculture and Economic Growth in England 1650–1815: Economic Change". In this essay the author takes up vigorously the problem of explaining the essential relationships between agriculture and the Industrial Revolution. In particular he has tried to separate, for the purpose of analysis, the "longer term causes of agricultural change in the centuries before the Industrial Revolution, and agriculture's role in the Industrial Revolution through such activities as capital formation, the release of productive factors and demand expansion". The author concludes that, on balance, the agricultural sector made a valuable net contribution to economic growth during the period 1650–1815. He confirms that the typical textbook argument, for example, that labour was ejected into factory industry by the force of the parliamentary movement, needs closer scrutiny.

There is no space in a review as short as this to venture into the rich detail of the essays nor is there space even to give a brief summary of each one. It may, perhaps, serve to draw attention to the contemporary importance of this volume, if I select a passage from R. M. Hartwell's introduction and indicate the range of questions that the author treats. Did the agricultural revolution produce an industrial revolution or *vice versa*? Did more people produce more food or more food, more people? Did an agricultural surplus allow the growth of industry or did industrial change induce agricultural change? What was the relationship of the agricultural revolution to the Industrial Revolution and to the growth of population?

The use of the past tense in the forming of questions should not, however, obscure their contemporary relevance. Three quarters of the world is trying to achieve modernisation through some combination of agricultural and industrial inputs. Further, the balance chosen as a matter of policy is not infrequently frustrated by a seemingly uncontrollable population expansion. Though no one expects that in the modernisation of the Third World history will (or must) repeat itself, intellectuals and the more practically oriented alike should peruse the pages of this volume if they seek to understand the fine structure of the contemporary problem they are attempting to solve.

Michael Gibbons

Human problems

Ethical, Social and Legal Dimensions of Screening for Human Genetic Disease. Edited by Daniel Bergsma. Pp. viii+272. (Symposia Specialists: Miami, 1974. Distributed by Stratton International Medical Book Co., New York.) $13.95.

THE rise of interest in genetic screening over the last few years has probably been very largely the result of technological developments. As Tabitha Powledge says in her contribution to this work by members of the Genetics Group of the Hastings Institute of Society, Ethics and Life Sciences, "It is regrettably true that, just because we *can* do something, we very often proceed to do it, without thinking much about whether we *should*". A recurring theme throughout this book is that we should have a very clear idea of why we want to screen, quite apart from whether or not it is practical. According to Powledge, and her sentiments are echoed by other contributors, research is a rational and legitimate purpose of screening but in that case screening should not be presented as having a service or of being of direct benefit to the screened.

There are, perhaps, two important reasons for screening for genetic disease. First, if there is an effective treatment which, instituted early enough, could prevent the development of severe mental handicap, for example, in phenylketonuria. Second, so that genetic counselling and, where possible, advice on antenatal diagnosis can be given early enough to prevent the possible birth of another affected child in the family. In initiating such screening programmes it is, however, important to keep in mind the general principles of Wilson and Jungner (*Principles and Practice of Screening for Disease;* World Health Organisation: Geneva, 1968), in particular the provisos that the disorder must be an important health problem, it must be treatable (and/or preventable), the screening test must be reliable, and it must be cost-effective to screen.

In the light of these sentiments the value, and problem, of screening for unifactorial, multifactorial and chromosomal disorders are discussed. In the case of unifactorial disorders the main problem is that most are rare, and even for those that are relatively common a reliable screening test is often not yet available; for example, in fibrocystic disease. Two relatively common disorders which have been considered recently for screening are certain protease inhibitor genotypes and familial hyperbetalipoproteinaemia.

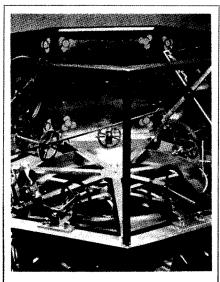
In so-called multifactorial disorders (for example, essential hypertension and diabettes mellitus) the main problem is that even if one had a reliable test for detecting preclinical cases, there is as yet little evidence to suggest that treatment at this stage would prevent the development of the disease. According to Mellman the screening of newborn populations for chromosomal abnormalities is now of doubtful justification, for apart from providing incidence figures it tells us nothing of the natural history of such disorders. The process of identifying individuals in newborn surveys and studying them from birth until social maturity is too slow to satisfy society's impatience for information on say the XYY and XXX phenotypes. Such screening would be more informative if it included school children and even samples of the adult population.

Quite apart from the scientific merit and cost-effective benefit of screening, there are the social, psychological, ethical and legal problems associated with genetic screening. Predictably, participants who volunteer for screening programmes (as in the case of Tay Sachs disease) are younger and, on average, better educated than those who do not wish to participate in such programmes. And certainly the knowledge that one is a carrier of a genetic disease may have profound effects on marriage plans and marital relationships. The legal and ethical problems of whether or not information obtained from screening programmes should be communicated to the person screened, and possibly also to his relatives if medically or genetically indicated, require the most careful consideration.

Issues raised by genetic screening are becoming increasingly important to us all. This collection of essays goes a considerable way towards making us stop to consider the implications.

A. E. H. Emery

Reflections on surfaces

Science and Technology of Surface Coating. Edited by B. N. Chapman and J. C. Anderson. Pp. xvii + 463. (Academic: London and New York, 1974.) £14.80; $41.50.


Characterisation of Solid Surfaces. Edited by P. F. Kane and G. R. Larrabee. Pp. xviii + 670. (Plenum: London and New York, 1974.) $39.00.

THESE two volumes bring out two immediate observations. First, that both the technology of producing surface coatings and the methods of microstructural analysis have undergone extremely rapid development. Second, that many of the new surface coating techniques still owe more to acute experimental observations and technical imagination than to direct application of scientific knowledge.

These thoughts are provoked particularly by the first volume on surface coatings, the editors of which deserve congratulations on producing in less than 500 pages 44 articles written by enthusiasts. These articles outline the bewilderingly large range of methods currently available for applying surface coatings to useful materials, and indicate some of their applications. It was clearly not possible or desirable in articles of this length to discuss any of the topics at all fully, but all of the articles give an outline of the physical principles involved and in most cases a useful list of references is included.

In addition to those topics that are predictably present—for example, electroplating, evaporation, chemical vapour deposition, and so on—there are other, more unexpected but worthwhile methods discussed. These include well established technologies such as brush painting, printing and spraying; the physics of such technologies being subjects less often considered in the scientific literature. Among the newer technologies, those of plasma arc and flame spraying and detonation bonding of refractory materials are described together with fascinating new ideas, such as that of 'electrical harmonic spraying' in which an electrical potential applied to liquid drops emerging from a tube can produce a collimated beam of liquid drops that are uniformly charged and have constant mass and velocity, such that they can be deflected accurately to form a deposited pattern without the need of a mask. Another idea that seems to be technically 'sweet' was the method of 'ion plating' in which adhesion between a substrate and a coating material can be improved by an increased kinetic energy of the first deposited layer. This increased energy is achieved by ionisation

of the evaporating atoms followed by electrical acceleration onto the substrate.

Two omissions, are, however, striking —'metalliding', the electrodeposition of metals with molten fluoride electrolyte was presented by abstract only; and no discussion was given of the Xerox process. The lack of a full discussion on metalliding was probably no fault of the editors, but at least a list of references might have been obtained from the missing author. The absence of Xerography is disappointing in that many of the coating methods discussed use charged material deposited onto a uniformly charged substrate, so selective deposition onto a partially charged

Modern reconstruction of Giovanni de Dondi's astronomical clock. The original was made in about 1364. From *Gears from the Greeks. The Antikythera Mechanism—A Calendar Computer From ca. 80 BC.* By Derek DeSolla Price. Pp. 70. (Neale Watson Academic: New York, 1975.) $8.50.

insulator seems a natural extension of these ideas.

The major criticism, however, must be that only a few articles discussed the *properties* of the coatings, and only one considered their structural assessment—either the title should have been 'Methods of Producing Surface Coatings', or more consideration of the properties of coatings should have been given.

Characterisation of Solid Surfaces is a very different volume in which a smaller range of topics (23) is considered in greater depth. The analytical methods described range from genuine atomic surface techniques such as Auger spectroscopy, electron spectroscopy for chemical analysis, and field ion microscopy, to techniques normally considered only for assessment of bulk microstructure such as transmission electron microscopy (TEM) and electron probe microanalysis (EPMA). The relevance of such bulk techniques is,

however, clearly justified in that the 'bulk' material studied—100 nm for TEM and 1 μm for EPMA—though large compared with a single atomic depth may be appropriate to many surface applications, such as surface coatings.

In addition, as shown by Laird in his excellent discusion of TEM, much genuine surface information can be gained by suitable specimen preparation facilities. The converse of this idea is also discussed—the analysis of bulk microstructure by use of surface analysis combined with erosion techniques so that the bulk can be revealed as a series of exposed surfaces. As a result of this interchange between bulk and surface analysis the content of this book will be of value to all interested in the microstructure of materials; not just to the rapidly growing band of surface scientists.

The techniques described all involve the illumination of surfaces with photons of various frequencies, electrons, ions or neutral atoms, followed by an examination of emitted photons, electrons, ions or atoms. The varied combinations of these techniques has given rise to a large industry both supplying and using increasingly expensive and varied equipment. It is noticeable that only in the chapter on optical microscopy was the cost of the equipment considered in respect to the value of the information obtained.

The rapidly growing arsenal of expensive equipment described indicates the importance of deciding what information is really needed in any application and which method is best for obtaining it. It often seems that scientists may become oriented to using just one technique—that in which they have detailed knowledge—ignoring others that may be more useful. The level of expertise obtainable from most of the chapters in this book should do much to indicate the advantage of other techniques, though for a detailed understanding one would have to make use of the literature cited.

Among the noticeable omissions was a discussion of low energy electron diffraction, though the editors refer to a good review. Perhaps more serious in view of the seemingly inevitable delays between writing and publication was the lack of a list of important references that might have covered the interval between writing and final printing of the volume.

A final and inevitable reflection on these two volumes is the lack of application of the analytical techniques to the evaluation of the structure of surface coatings; one can only hope that these two books will lead to some cross fertilisation between these two groups of surface scientists and technologists. **R. D. Doherty**

announcements

Awards

The Royal Geographical Society has announced the following awards: **Founders Medal** to **Sir Lawrence Kirwan** (geographical history of Nubian Nile Valley and Eastern Africa; services to exploration); **Patron's Medal** to **J. P. Kuettner** (exploration of Earth's atmosphere and oceans); **Victoria Medal** to **C. O. Sauer** (geographical research and education); **Busk Medal** to **N. N. Ambraseys** (historical seismicity and recent earthquakes in Near and Middle East); **Murchison Award** to **A. L. Mabogunje** (geography of West Africa); **Back Award** to **H. C. Brookfield** (geographical studies of Pacific region); **Peek Award** to **A. S. Goudie** (Late Pleistocene climatic phases in north-west India); **Gill Memorial** to **T. W. Freeman** (geography of Ireland); **Ness Award** to **A. Thompson** (botanical surveys in Guyana); **Cherry Kearton Medal and Award** to **Eric Ashby** (nature cinematography).

Appointment

T. G. C. Murrell has been appointed Foundation Professor of Community Medicine at the University of Adelaide.

Miscellaneous

Interstellar clouds. Professor A. Dalgarno, Professor of Astronomy at Harvard College Observatory, will give two Special University Lectures on Molecular Processes in Interstellar Clouds at University College, London (Gower Street, WC1) at 5 pm on April 23 and 25.

Geodynamics Project. The British National Committee for Geodynamics wishes to produce a comprehensive listing of papers relevant to this project, published by UK workers between January 1, 1971 and the present. Would such workers please send a bibliography of their papers to the Royal Society by April 30 (6, Carlton House Terrace, London SW1Y 5AG, UK).

Standard Telecommunications Laboratory. SRC and NERC are prepared to receive applications for the use of this facility at Harlow in Essex by university research groups for high pressure geophysical and geochemical experiments (Dr V. Essex, State House, High Holborn, London WC2, UK).

Person to Person

Oxford–Stanford. Oxford scientist requires three to four bedroom house in Stanford, California for sabbatical period, August 1, 1975–May 1, 1976. Possible exchange with modern four bedroom house in north Oxford, convenient for laboratories and all university buildings (Dr W. G. Richards, Physical Chemistry Laboratory, South Parks Road, Oxford, UK).

London flat. Canadian couple urgently require accommodation (flat rental) in London area from June, 1975–December, 1976. In return for assistance offered, willing to help with accommodation problems in Montreal, Toronto or Vancouver (Dr I. Altosaar, Department of Biochemistry, Imperial College, London SW7, UK).

London–Washington. Three bedrooms, central heating, available for exchange with accommodation in Washington, DC (within reasonable distance of National Cancer Institute). Approximate dates: August 1, 1975–July 1, 1976. Contact: M. Norman, 97 Highland Road, Bromley BR1 4AA, UK.

Boston–London. Two to three bedroom accommodation required for all or part of August in London or along the south coast, by a responsible academic family (two school children) from Boston area. Exchange arranged if interested. (Christine Armett-Kibel, 18 Devon Terrace, Newton Centre, Massachussetts 02159.)

nature

nclude that there is no justification for our assertions, that more work is needed.

The work reported in this paper was supported by the Science Research Council who paid £15,000 for a project, the title of which can only be said to bear a remote resemblance to the title of this paper. This money paid for a highly sophisticated microscope which turned out to be unnecessary, a digitiser of a type which it later transpired was possessed by many other laboratories within walking distance, a chart recorder which has been useful on a couple of occasions, a trip to America to give a ten-minute lecture at 8.20 on the first day of a conference, numerous train journeys to London to attend committee meetings the value of which the entire committee agrees privately is nil and a research assistant whose use has been minimal but whom the professor could find nobody else able to pay for.

Capital facilities were provided by the University Grants Committee and include my large office and personal laboratory which unfortunately remained empty during my sabbatical year.

I thank my research students who, initially unable to see the point of my work, are now unable to see the point of anyone else's. I appreciate their good-humoured forbearance whilst I wrote their theses for them, persuaded the examiners that this was a significant contribution to knowledge and set them up in university careers of their own despite their initial belief that they could be more productive in industry.

I thank my secretary for patiently retyping this manuscript in its entirety several times when I have discovered grammatical and punctuation errors. Her cheerfulness in re-making forty photocopies of the manuscript and dispatching them each time by air mail to my friends and enemies is acknowledged. Her skill in finding things to do during my sabbatical absence is also appreciated. Admittedly the absence was mitigated by her being able to type my book, for which I shall receive a modest royalty, and being able to look after my other private business interests for which the facilities of the department are occasionally most helpful.

I thank my wife for acting as laboratory assistant. Her initial untutored clumsiness did not deter her from continuing to try hard. She was particularly helpful as my personal assistant on my trip to America.

The computational work described in the paper was done at the University Computer Centre whose staff I thank for their courtesy in helping me debug the program and in carrying over my paper output to me every day. They may be reassured that their work was not in vain— the final results agreed perfectly with predictions based on my pocket calculator. Although the amount of printing on each page of my output may have seemed to them somewhat slight, the paper is being put to good use for crayonning in my son's nursery school.

I thank the departmental tea-lady who never forgets to acquire, during her lunch break, a large cream bun which I particularly like to have delivered to my office with my cup of tea at four o'clock.

The equipment used in the experiments reported in this paper will not, as far as I can see, be used by me again. Nevertheless, I cannot, alas, see my way to letting anyone else use it, as it has certain characteristics which might confuse other users and there is always the possibility of damage. Likewise although the data which I have amassed is by no means completely described in this paper, I do intend some day to look once again at these results. In the meantime it would be inappropriate for anyone else to attempt to set up similar experiments; I am perfectly happy to share my unworked data with anyone. But I must point out that the information on the magnetic tapes is not self-evident, so anyone wishing to share would do well to visit my laboratory—I would happily co-author any paper that emerged from such a visit.

Finally, I must say something about this idea of accountability in science which some people are talking about these days. The thought that a researcher at the frontiers of knowledge should be spending the government's money and his own and his students' time other than in an efficient and conscientious way is quite alien to me and contrary to the spirit of academic freedom. I know I give value for money in my research and I need no small-minded bureaucrat telling me how to cut costs —besides 'value for money' is mercifully indefinable in the world of pure research. Yet, for what it's worth, I am prepared to say that I have rigorously observed the government's energy conservation measures. To conserve electricity, nobody on this project has been allowed to work in the laboratory during the hours of darkness. This has, of course, somewhat affected our productivity, but it reflects my concern that at a time like this we should not waste the nation's resources.

Metal-bending child: paranormal phenomenon? (Picture: Hemel Hempstead Gazette.)

In the past 18 months the scientific community has been confronted with renewed claims that certain people possess paranormal powers, including the ability to effect physical changes in materials. Work has proceeded in several scientific laboratories in an effort to come to terms with these apparent abilities. What sort of attitude should be adopted in attempting to verify these claims? First, J. B. Hasted, D. J. Bohm, E. W. Bastin and B. O'Regan describe their approach in recent work done at Birkbeck College, University of London. Then J. G. Taylor, of King's College, London, who is the author of a forthcoming book on his study of these phenomena, reviews the philosophy of his work.

IN February 1974 we made contact with Mr Uri Geller and were able throughout the year to observe psychokinetic phenomena at four sessions, in addition to participating in sessions with children. A brief report of our observations has been prepared for circulation to those interested. Among the claims made are that plasticity of metal was paranormally produced and that part of an enscapsulated single crystal of vanadium carbide apparently vanished. It is clear both to us and to the referees used by *Nature* that this account does not amount to a rigorous loop-hole-free report on a subject historically shot through with loop-holes. Nevertheless we believe that we have some significant work in progress, and the experience we have gained may be of value to other physicists interested, like ourselves, in the interactions between mind and physical systems.

We have come to realise that in this domain the experimental situation is different in certain crucial ways from that which has been common in scientific experimentation. This is because the phenomena under investigation have to be produced from the minds of one or more of those who participate. Relationships among the participants therefore play a much more essential role than is usual in traditional scientific fields. These relationships have to be taken into account in a way that is somewhat similar to that needed in the disciplines of psychology and medicine. But, of course, this does not mean that we are committed from the outset to the belief that paranormal phenomena are genuine. Rather our minds are open to all possibilities, and our wish is simply to discuss what is the truth about these phenomena. Indeed, our experiments contain features designed to clear up a number of doubts that naturally arise in this type of work. Nevertheless, in addition to being careful in this way, we have also to be sensitive and observant, and not to react with a preconceived pattern of tough-mindedness that will interfere with our perception, and that may destroy the very possibility of the phenomena that we wish to study. With proper sensitivity and perceptivity we attempt to develop an approach that will adequately allow for the interpersonal element and yet permit us to engage in valid scientific research.

One of the first things that reveals itself as one observes is that psychokinetic phenomena cannot in general be produced unless all who participate are in a relaxed state. A state of tension, fear, hostility, on the part of any of those present generally communicates itself to the whole group. The entire process goes most easily when all those present actively want things to work well. In addition, matters seem to be greatly facilitated when the experimental arrangement is aesthetically or imaginatively appealing to the person with apparent psychokinetic powers.

We have found also that it is generally difficult to produce a predetermined set of phenomena. Although this may sometimes be done, what happens is often surprising and unexpected. We have observed that the attempt to concentrate strongly in order to obtain a desired result (the bending of a piece of metal, for example) tends to interfere with the relaxed state of mind needed to produce such phenomena. It appears that what is actually done is mainly a function of the unconscious mind, and that once the intention to do something has been firmly established, the conscious functions of the mind, in so far as they have bearing on the goal, tend to become more of a hindrance than a help. Indeed, we have sometimes found it useful at this stage to talk of or think about something not closely related to what is happening, so as to decrease the tendency to excessive conscious concentration on the intended aim of the experiment. A comparison might be made with the process of trying to go to sleep, for which is needed a firm intention, without subsequent efforts.

Many of the conditions described above are also required for fruitful research in the natural sciences. Thus, if any of those who participate in a physical experiment are tense and hostile, and do not really want the experiment to work, the chances of success are greatly diminished. Likewise, the aesthetic appeal of the experimental set-up often helps to maintain interest and enthusiasm, whereas an attitude that consistently tends to damp these latter is evidently detrimental to the whole enterprise. In the study of psychokinetic phenomena, such conditions are clearly much more important than in the natural sciences, because the person who produces these phenomena is not an instrument or a machine. Any attempt to treat him as such will almost certainly lead to failure. Rather, as indicated earlier, he must be considered to be one of the group, actively cooperating in the experiment, and not a 'subject' whose behaviour is to be observed 'from the outside' in as cold and impersonal manner as possible.

The following analogy may help to give a more orderly overall description of the phenomena in the field. Consider a person whose hand has been paralysed as a result of destruction of nervous tissue. If this person is to regain the use of his hand, he must somehow

activate new nervous pathways. How he is to do this, he does not know. All he can do, with all his energy, is to feel out the possibilities of movement and to observe with great attention and alertness what movements actually take place. He cannot describe or even think about just what it is that he does in getting his hand to move. Moreover, he cannot at first produce controlled movements, which bring about consciously intended results. Rather it is clear that the contact between brain and hand is brought about almost entirely by unconscious functions of the mind, which tend to be erratic and fortuitous. Of course, if he works with sustained interest and energy, he will generally find that his movements do begin to come closer to what he intends. But it is also clear that if he is surrounded by people who are not open to the possibility that he can move his hand or who bring about a state of psychological tension through hostility, then he will be less likely to be able to sustain the interest and energy needed for learning how to move his hand.

Those who work with such a person (for example, the physiotherapist) must evidently not be committed to resisting the notion that the hand can eventually move. For the thoughts in the paralysed person's mind, and those in the minds of his colleagues, are both important factors in bringing about success. The necessary open-ness to the possibility of an ultimate result must be maintained in the minds of all concerned, while at the same time there is a healthy capacity to be tentative and free of definitive conclusions in statements about what particular results may have been achieved at a certain stage. And so reliable inferences can be made in physiotherapy, though by methods that are rather different from those used traditionally in the natural sciences.

The analogy between this field and that of psychokinetic research is fairly clear. The main difference is this: we can account for and to some extent explain the connection between the brain and the hand in the case of the paralysed person (through the nerves which link them) but we have no way either to account for or to explain the connection between the brain and the object that is moved, bent and so on, in terms of what is now known to science. If, however, we suppose that there is some at present unknown force, energy or mode of connection, then we may also suppose that psychokinetic power may function in a way that is essentially similar to the power to move the hand. Thus, one might suggest that perhaps there is an unconscious 'feeling out' of the connection. In many cases there is a visible 'feedback' that enables a person to

recognise that he has done something, and that permits him to try to go further along the same (indescribable and undefinable) lines. But there may other forms of 'feedback'. Thus, if a piece of metal can respond to the brain in an unknown way, the brain may similarly respond to the metal. By being sensitively aware of this response, the person concerned might be able to tell when something had actually happened, even though the object in question was not sensually perceptible to him.

It is important, at this point, not to insist on having a potential theoretical explanation before one will seriously consider observing the phenomena themselves. Thus, when magnetic and electrostatic effects were first observed, it was impossible to account for them in terms of the known forces, which were considered to arise only when bodies were in mechanical contact. Evidently, this did not prevent the effects from being observed. The main aim of such observation is to give rise to an orderly account of the phenomena, which is first qualitative and

then quantitative—for example, first the qualitative observation that like charges repel, unlike charges attract, and then the quantitative observation that the force is inversely proportional to the square of the distance. On the basis of such an account, current field-theoretical explanations of electromagnetic phenomena were later developed. We propose a similar approach to psychokinetic phenomena, and in our work thus far we have tried to carry it out.

In such research an attitude of mutual trust and confidence is needed; we should not treat the person with psychokinetic powers as an 'object' to be observed with suspicion. Rather, as indicated earlier, we have to look on him as one who is working with us. Consider how difficult it would be to do a physical experiment, if each person were constantly watching his col-

leagues to be sure that they did not trick him. How, then, are we to avoid the possibility of being tricked? It should be possible to design experimental arrangements which are beyond any reasonable possibility of trickery, and which magicians will generally acknowledge to be so. In the first stages of our work we did in fact present Mr Geller with several such arrangements, but these proved to be aesthetically unappealing to him. From our early failures, we learned that Mr Geller worked best when presented with many possible objects, all together on a metal surface; at least one of these objects might appeal to him sufficiently to stimulate his energies. In a later session, we had such a set-up, which included two small plastic capsules, each containing a thin disk of vanadium carbide single crystal. A clearly observable change in the disk within one of the capsules was brought about when Mr Geller held his hands near them.

In discussions with magicians we have learned that the best conditions for a conjuring trick arise when the happening significantly precedes the observation. In the above instance we believe that the conditions were such that the failure to observe and record the precise moment of change is of no importance, because there is no known way of producing this effect within the closed capsule and no possibility of substitution. For this reason we conclude that this was something that no magician could have done.

Nevertheless, we realise that conditions such as we have described here are just those in which a conjuring trick may easily be carried out. We understand also that we are not conjuring experts, so that if there should be an intention to deceive, we may be as readily fooled as any person. Moreover, there has been a great deal of public criticism, in which the possibility of such tricks has been strongly suggested. For this reason it has often been proposed that a skilled magician should be present, to help to see to it that there will be no possibility of deception.

It is in the nature of the case, however, that no such assurance can actually be given. For a skilled magician is able to exploit each new situation as it arises in a different and generally unpredictable way. The corpus of tricks is not fixed, but rather continually changes and evolves. A particular magician could therefore say at most that he knew of no tricks that could have brought about a given set of observed phenomena. Of course, if several magicians of recognised proficiency were to conclude that what was done on a certain occasion did not in-

volve any tricks, this could help create a presumption in favour of the notion that the phenomena are genuine. In principle, we would welcome help of this kind in decreasing the possibility of deception. It has been our observation, however, that magicians are often hostile to the whole purpose of this sort of investigation, so that they tend to bring about an atmosphere of tension in which little or nothing can be done. Indeed, even if some magicians were found who were not disposed in this way, it does not follow that their testimony will convince those who are hostile, since the latter can always suppose that new tricks were involved, beyond the capacity of those particular magicians to see through them. Because of all this, it seems unlikely that significant progress toward clearing up this particular question could be made by actually having magicians present at the sessions, though we have found it useful to have their help in a consultative capacity. We have learned in such consultations not to withdraw our scrutiny from the identified specimen, from the first moment when it reaches the hand of the subject until the bend occurs. We are familiar with the use of the human hair in producing small movements, with the use of mercuric salts in alcohol to corrode metals, and with the weakening in metals produced by continued bending to and fro. We recognise that there is a genuine difficulty in obtaining an adequate answer to criticisms concerning the possibility of tricks, and that a certain healthy scepticism or doubt on the part of the reader may be appropriate at this point. Indeed, it would be inappropriate if the scientific community did not at first react in such a way. We believe, however, that our approach can adequately meet this situation.

It is essential that in at least some experiments, conditions must be controlled in such a way that the possibility of deception is insignificant. Metal bending and cleavage experiments are particularly suitable for this approach. Encapsulated specimens can play an important part, although up to the present we have only been able to achieve success with one such specimen.

We feel that if similar sessions continue to be held, instances of this kind might accumulate, so that there will be no room for reasonable doubt that some new process is involved here, which cannot be accounted for or explained in terms of the laws of physics at present known. Indeed, we already feel that we have made sufficient progress toward this point to warrant further investigations along these lines. We hope to carry out more tests and to report on them when results are available. ☐

It is not easy to discern a sharp boundary at which scientists must stop and turn into magicians . . .

THE crucial question that any scientist has to ask himself if he wishes seriously to investigate the paranormal (spoon-bending, telepathy, clairvoyance and the like) is how to do so scientifically. There are those who claim the very elusiveness which paranormal events have in their nature precludes any such approach. But there are also persons like myself who feel that these strange phenomena are relevant to their world view and so deserve careful study. Do we necessarily have to doff the garb of scientist when satisfying our curiosity about such events?

We can say at the outset of attempting to answer this question that if the response were "yes", science would be circumscribed in a very peculiar way. No elusive phenomenon would be allowed as a suitable object of scientific enquiry; on this score quarks, for example, would be beyond the scientific pale. To avoid such absurdity we must realise that there is a continuum of levels of elusiveness. It is not easy to discern a sharp boundary at which scientists must stop and turn into magicians.

There is one feature, however, which should be present in any phenomenon to be investigated scientifically. That is repeatability, allowing the possibility of many investigators observing the event at different times. Not only does this allow the 'consensibility' to be practised which is so crucial to scientific investigation but above all it permits the phenomenon concerned to be probed ever more deeply. Only then can the event begin to be seen in terms of current understanding. Thus the two processes of validation and model building can be carried out, possibly hand in hand or almost simultaneously.

At this point the notion of repeatability for paranormal phenomena must be clarified, since it seems to mean different things to different people. It is being used here in the following sense. Suppose that an event, such as a child causing a spoon to bend, has occurred a number of times in a given environment. The bending may not happen every time the child is tested, possibly because some crucial factor in the surroundings has changed from one test to the next without anyone realising. Yet provided that in a non-zero fraction of the test situations spoon bending (or whatever it is) has occurred and enough tests have been made to feel confident that the phenomenon will continue at about the same rate then the para-

normal event will be termed repeatable.

One of the main difficulties in applying this criterion is in the specification of the precise environment in which the event will recur. There can well be psychological pressures put on the subject by the presence of particular objects or persons, and the most suitable environment has to be found by laborious trial and error. But these problems need not make one despair of obtaining repeatability. In particular subjects should not be expected to cause a paranormal event every time they are asked to, and in any surroundings. It is like expecting a particle accelerator to produce its beam of particles whatever level of vacuum there is in the accelerating tube or whatever potential is applied. The design of such a machine is so precise that it can only function under very special conditions. We are in the position of dealing with even more complicated machinery in human beings and account must be taken of that when investigating the paranormal.

In order to be able to investigate a phenomenon further, it is necessary that it can occur under suitably modified conditions. If spoon bending were only ever possible when the subject could not be directly observed during the bending process then, even if it were repeatable, a number of explanations for it, including the obvious one, would be possible. In general it is clear that conditions must be able to be chosen so that simple explanations of paranormal phenomena, especially trickery, are ruled out.

We come, then, to the clash between the eventual rigour of science and the laxity apparently needed to produce paranormal phenomena. Seances need to be held in the dark since the light of day seems to prevent anything strange occurring. This is not true of spoon bending or distant viewing, for which there is some level of repeatability in daylight. There are other phenomena, such as dowsing, which can also bear further investigation of a sort which allows various explanations to be tested.

It is this feature of allowing critical testing which is a *sine qua non* of a phenomenon for its investigation to be regarded as scientific. The range of tests used will naturally be at the discretion of the investigator, but it is in the event itself that this 'testability' resides. Not that further enquiry need prove easy, since it will involve modifying the environment in some way that may prevent the phenomenon from recurring. If any such change is too inimical to the event then clearly it is not possible to test it at all; the event will have to be regarded as a curiosity, but one which at present cannot usefully be studied scientifically.

As new tests are tried with a subject,

the phenomenon may initially disappear but then return at a later stage after several attempts. The investigator clearly requires patience in such a situation, but this must be exercised since otherwise the phenomenon remains too poorly investigated. It may be necessary to do this gradually, but somehow or other the phenomenon must be delimited precisely enough that it can be validated and that conjecture as to its possible explanation can begin. In particular, tests must be introduced which show with utmost rigour that fraud can be excluded as the cause of the events. Provided these tests are conclusive, then the phenomenon can be probed further.

An example of this is spoon bending, which has been observed by many investigators during the past two years. Some of the accounts are valuable, though not conclusive by the above criteria. Only by careful measurement of various physical parameters during the bending process, especially the pressure applied, can the phenomenon be classified as paranormal. The measurement process itself would best be done automatically, as has been arranged in some preliminary tests with positive results. Measurement of various parameters such as temperature and radiation levels of various sorts have also been attempted. In all of these attempts care has had to be taken to relax the subject as much as possible, yet always to avoid simultaneously relaxing scientific rigour.

The problem of preventing stress by the presence of the sceptical observer seems to be handled best by using as much automatic measuring apparatus as is feasible. The investigator can then devote more of his attention to the psychology of the subject than would be the case if he had to divide his time between trying to keep the subject relaxed and observing precisely what was occurring. Film or video tape have not proved as useful here as one would like, since they only provide a single view of the event. And they cannot monitor crucial variables such as pressure or magnetic field strength.

Finally we come to the sceptic in whose presence the phenomena may not occur or who has not been able to observe the events and considers them too strange ever to be possible. Such a critical attitude plays an important role in science, though over-reaction can take place if the sceptic is too emotionally involved in the event to preserve his objectivity. Even this serves the purpose of ensuring that standards of scientific rigour are preserved. But advance in the paranormal field will be held up by too sceptical an attitude. The question to be settled is what sort of evidence would be accepted by the sceptic? The answer to this clearly

depends on the particular sceptic involved, but certain general features of such an attitude can be discerned.

The most extreme sceptic is one who will never budge from his sceptical attitude, whatever is presented to him about the paranormal. Such an obdurate attitude can only be attacked by senility and death, so we turn to the slightly less sceptical. He requires to observe the phenomenon at first hand, since it seems for him such an impossible occurrence. Yet, even when he has observed it, he may claim that fraud had occurred. He must be asked to observe in situations with all possible rigour applied. Time and patience will be needed by him to obtain results; only if he can be influenced to expend them may he be able to observe under conditions which will convince him.

It has been assumed here that it would be possible to obtain conditions for observing paranormal events under which fraud is impossible. Some claim that this is not so, but this is clearly false. It is always possible to choose conditions in which trickery can be completely excluded. A piece of metal to which a pressure sensor is attached cannot be bent surreptitiously unless the sensor is inoperative. If the method of bending were non-mechanical, such as by the application of chemicals or by the use of a laser beam, careful chemical analysis or temperature measurements would indicate this. An object caused to be distorted without contact cannot have become so by normal means.

It is not possible at present for all such sceptics to be able to observe careful tests performed on the too few subjects with apparent paranormal powers. Nor does it seem that even a fraction of them will ever be able to do so. To counter such a weight of scepticism, it is necessary to consider its source in more detail. At the root of scientific scepticism of the paranormal is the fact that the events being investigated are in contradiction with present scientific understanding. At least, it is claimed that this is a fact for all paranormal events, but there are differences between different sorts of phenomena.

Firstly there are strange events which seem to be scientifically impossible, on the face of it, but which might possibly have a scientific explanation in the future provided that the present lack of knowledge in the relevant area is acknowledged. A case in point is, again, spoon bending, for which an electromagnetic explanation has recently been suggested. To test this properly requires considerable research into the interaction of especially low frequency electromagnetic radiation with various materials up to the point of their fracture. Only very recently has a new

feature of the latter been discovered in support of the hypothesis, in that transient electric and magnetic fields have been measured in association with tensile fracture of various metals. A similar hypothesis can be put forward for telepathy and distant viewing. Recent results from the group at the Stanford Research Institute (Targ and Puthoff) indicate an upper limit to bit-rate transfer which would again implicate very low frequency radiation. Since low frequency electromagnetic radiation has been shown to have effect on psychological parameters of animals, such an electromagnetic hypothesis might just be considered.

Other physical phenomena are more difficult to understand in such terms. Thus, if objects can truly be caused to disappear from closed containers then the energy required to dissolve chemical bonds is so enormous that no feasible physical explanation can be given in present terms. The phenomena of this type are not as well attested as those of spoon bending and distant viewing, so there is still a possibility that 'travelling' objects are not totally disappearing in one place and reappearing in another. If they are, however, then clearly a contradiction has occurred with current scientific understanding of the forces of nature and the principles they satisfy, especially that of conservation of energy.

Similar difficulties arise with other paranormal events such as precognition. That is also hard to put into the usual causal framework, which uses retarded potentials as solutions of the field equations for all the forces. The advanced potential solutions have been attempted in the past, though it would be strange if such advanced effects only arose when human beings were present. Naturally enough it is also necessary to consider the part which consciousness plays in these phenomena. A consistent picture of the mind as constructed from material building blocks is far more feasible than a tachyon-like picture which at present has currency (especially because of the complete lack of evidence for the existence of tachyons).

In conclusion, it would seem that paranormal events can be investigated scientifically provided the investigator uses his patience and ingenuity to the full, both with his subjects and with his colleagues. He must aim for the highest level of scientific rigour in his tests, though be prepared to spend a great deal of time before a subject can cause a paranormal event to occur in scientifically satisfactory conditions. Furthermore the investigator must attempt to make feasible models of the events. If all goes well, he will make enough progress to build his own machine to achieve the effect. □

international news

WHEN Congress put a stop to development of an American supersonic airliner five years ago, looming large in its decision was a controversial theory put forward by Harold Johnston of the University of California, Berkeley. Johnston argued that the aircraft would emit pollutants into the stratosphere which would partially destroy the ozone layer, the ultimate consequence of which would be a large increase in the amount of harsh ultraviolet radiation reaching the Earth's surface and a corresponding increase in the incidence of skin cancer in the Northern Hemisphere. The theory has been under strong attack ever since it was first put forward, but last week Johnston was vindicated by an unusually blunt report published by a committee of the National Academy of Sciences.

The report stated that operation of 300 to 400 of the Boeing supersonic aircraft then under consideration would "in all probability" have caused a 20% increase in skin cancer in the United States—that translates to about 80,000 extra cases a year. To emphasise the point, the report added that "a few additional people would probably have died each year and a few hundred people would probably have contracted skin cancer each year, for each formerly

NAS report spells trouble for Concorde

by Colin Norman, Washington

projected US SST put into service".

Those conclusions are of more than academic interest, for they almost certainly spell more political trouble for the financially beleaguered Concorde supersonic aircraft in the United States. The immediate effect of the report is likely to be to strengthen moves to deny Concorde landing rights at American airports.

The committee's chief conclusion is that a fleet of 100 Concordes or Soviet TU-144s, operating in the stratosphere for about 5 hours a day, would cause a reduction of 0.7% in the ozone layer. The resulting increase in ultraviolet radiation reaching the Earth would be about 1.4%, and that would be expected to lead to an increase in the incidence of skin cancer in the United States of about 1.4%, or 6,000 extra cases a year.

Concorde is expected to pose less of

a hazard than the scrapped Boeing SST because it will fly at lower altitudes and emit smaller amounts of the oxides of nitrogen—the chief pollutant responsible for depleting the ozone layer. But the problem is not limited solely to supersonic aircraft, the committee notes, because wide-bodied jets also fly in the lower stratosphere and inject oxides of nitrogen into it. If the subsonic fleet grows in size, and if the aircraft are designed to fly higher, as has been predicted, then it would pose just as serious a threat to health as a large fleet of Concordes.

Those effects can at least be mitigated by some costly engine modifications, however, and the committee therefore suggests that international regulations should be drafted to ensure that cleaner engines are used on aircraft flying in the stratosphere in future years. As a rough estimate, committee members suggested at a press conference last week that it would cost about $100 million for research and development on engine redesign, and that it would take between 10 and 15 years to equip aircraft with the cleaner engines.

The committee's conclusions are essentially the same as those reached by a three-year study conducted by the Department of Transportation which

SUPERSONIC airliners are not the only potential violators of the ozone layer. In fact, in view of the dismal economic outlook for Concorde and the enormous costs of operating the aircraft, the SST fleet is unlikely to become large enough to represent much of a threat to human health for many years, in which case there is probably sufficient time to develop cleaner engines to guard against potential hazards. Of more immediate concern is the possibility that propellants used in aerosol spray cans—chlorofluoromethanes, which are more commonly referred to by their trade name, Freons—may already be depleting the ozone layer at an alarming rate, and there has recently been a flurry of activity in the United States to try to assess the dimensions of that hazard.

In February, the federal government announced that it has established a top-level scientific committee to examine the potential dangers from aerosol sprays, and that it hopes to have a report by mid-June. Last month, the National Academy of

Sciences also announced that it has established a committee to look into the problem, and named Dr H. S. Gutowsky, Director of the School of Chemical Sciences, University of Illinois at Urbana, as its chairman. The study is expected to be completed within a year. The academy decided to establish the committee after an *ad hoc* panel, which met under the chairmanship of Donald M. Hunten of Kitt Peak Observatory, had suggested that there is an urgent need to determine the possible danger from aerosol propellants. After that panel had made its recommendations, Hunten suggested at a press conference that, in his opinion, the injection of Freons into the atmosphere should be halted as rapidly as possible and that a moratorium on their use should be maintained until the potential dangers have been assessed.

According to some estimates, Freons may already have been responsible for depleting the ozone layer by about 1% and, if their use continues unchecked, the depletion may

increase to about 5% by the 1990s.

Another concern that has recently been expressed is that extensive operation of the space shuttle will pose a threat to the ozone layer because it will inject hydrogen chloride into the stratosphere. NASA is now studying the basis for that concern.

Finally, NASA announced last week that it will use the Copernicus Orbiting Astronomical Observatory to monitor the amount of chlorine in the stratosphere. Freons are thought to pose a threat to the ozone layer because ultraviolet radiation may break them down in the upper atmosphere, to release chlorine, which then breaks down ozone molecules. Thus, by measuring chlorine in the stratosphere over long periods of time, it should be possible to determine the extent of the threat to the ozone layer. This will be done by comparing the ultraviolet radiation from a bright star which is absorbed at the wavelength characteristic of chlorine, first when the star is high in the sky and again when it is on the horizon.

was published earlier this year. Called the Climatic Impact Assessment Project (CIAP), that study resulted in an estimate that a fleet of 100 Concordes flying in the stratosphere for 4.4 hours a day would deplete the ozone layer by about 0.4%. The two estimates are well within the uncertainty range of the calculations, and Dr Henry M. Booker, the chairman of the academy committee, suggested in a statement last week that both of them indicate that "strict measures might be needed to protect the environment from the effects of future large-scale flight operations in the stratosphere".

Yet another report on the environmental effects of supersonic aircraft is expected to be published soon by the British Meteorological Office's Committee on the Meteorological Effects of Stratospheric Aircraft (COMESA). According to pre-publication snippets provided recently by Dr R. J. Murgatroyd, COMESA's chairman, the report will conclude that 1,000 Concordes would be expected to reduce the ozone layer by about 3%.

Much has been made of the fact that all those studies predict that the effects of Concorde on the ozone layer will be much smaller than natural fluctuations—concentration of stratospheric ozone can vary by as much as 25% from day to day, for example. But the academy committee notes that aircraft flying in the stratosphere will cause a systematic reduction in ozone concentration, superimposed on the daily fluctuations.

"Remember that skin cancer is an integrated effect (of exposure to ultraviolet radiation) over a long period of time", Booker said last week, and he noted that average exposure to ultraviolet radiation seems to be the chief factor which causes the incidence of skin cancer to vary with latitude.

Because the ozone layer is much thinner at the equator than it is at the North Pole, the amount of ultraviolet radiation reaching the Earth's surface at low latitudes is much greater than at high latitudes; sure enough, geographic variations in the incidence of skin cancer are closely correlated with geographic variations in ultraviolet flux.

The upshot of those conclusions is that if either the supersonic fleet or the fleet of high-flying subsonic aircraft is increased in size, or if a new generation of supersonic airliners, designed to fly at greater altitudes, is brought into service, potentially serious health hazards may result. The academy committee therefore suggests that regulations should be drafted post-haste to ensure that cleaner engines are developed and installed. It suggests that the best forum for drafting such regulations is the International Civil Aviation Organisation, and the World Meteoro-

IN exceptionally blunt language, a high level advisory committee last month expressed concern about the ordering of priorities within the much-publicised cancer research programme in the United States. In particular, the committee indicated its "astonishment" at the low priority accorded to studies on environmental carcinogenesis, and it took a swipe at the massive amounts of money that have been poured into research on possible human cancer viruses.

The committee, a special subcommittee of the National Cancer Advisory Board, said in a report delivered to the board last month that although there is "widespread recognition of the importance of environmental c h e m i c a l carcinogenesis", the National Cancer Institute (NCI) seems to have given such studies a low priority in terms of expenditures. Less than 10% of the cancer budget is spent on research into the environmental causes of cancer, the committee estimates.

Those concerns are the latest in a long line of grumbles from biomedical scientists about the content and direction of the so-called war on cancer. The grumbles have mostly been concerned with the fact that the cancer programme has been soaking up funds at the expense of other areas of biomedical research, and that it has adopted a highly targeted approach which has emphasised applied rather than basic research. But in this case, the committee is arguing that an area of research dealing directly with cancer control and prevention is being relatively neglected.

The report, which resulted from two days of meetings by the subcommittee under the chairmanship of Philippe Shubik, Director of the Eppley Institute for Research in Cancer, University of Nebraska, lists a number of recommendations for increasing the research effort on environmental carcinogens. The preamble to the report describes the committee's concerns in graphic language.

"There was an obvious sense of general astonishment throughout the meetings that the National Cancer Programme does not appear to have accorded an adequate priority nor sense of urgency to the field of environmental carcinogenesis, particularly when this concerns chemical carcinogens", the committee states. Later in the report, the committee suggests that "epidemiology thus far seems to suggest that a viral etiology for most human cancers is an unlikely eventuality; in view of this, the distribution of the budget of the NCI in the area of etiology with its emphasis on viral oncology should perhaps be reconsidered; perhaps the time is ripe for a reordering of priorities or at least for an in depth examination of this basic conclusion".

But the committee recommends that "the NCI should foster the development and validation of new and innovative bioassay techniques" for detecting and identifying potential carcinogens in the environment. In particular, the committee suggests that more special centres for research on environmental carcinogenesis should be established in the United States.

logical Organisation.

Although no threat is likely to be posed to the ozone layer by the handful of Concordes now scheduled to enter service, the academy's report is likely to strengthen opposition to any operation of the aircraft in the United States. It should be noted that the report has been published at a crucial moment, for public hearings open on April 14 on a request by British Airways and Air France for permission to land Concorde at John F. Kennedy Airport in New York and Dulles International Airport in Virginia, for a small number of proving flights later this year.

Last month, the Federal Aviation Administration (FAA) tentatively recommended that such permission should be granted, but a final decision will not be made for several weeks. In an environmental impact statement on the request for landing rights, the FAA noted that Concorde's engines emit substantially greater levels of some pollutants—particularly carbon monoxide—

and create more noise than any other passenger aircraft, but it suggested that "the environmental consequence of the limited volume of Concorde operations requested are not so severe as to compel a refusal (of the request)". Opponents, of course, did not agree.

Meanwhile, a bill has been introduced into the House of Representatives by Lester Wolff, a New York Congressman, which would prevent Concorde from landing anywhere in the United States unless it meets the federal noise and pollution standards which apply to subsonic aircraft. A few days before the FAA announced its tentative recommendation to grant the request for landing rights for Concorde, the Environmental Protection Agency proposed noise standards for supersonic aircraft which would be less stringent than those for subsonic aircraft. Hearings will be held on Wolff's bill in July by the Public Works Committee and, if passed, it would effectively deny Concorde access to the United States. □

Seminar contacts under pressure

from Vera Rich, London

THE increasing pressure on the remaining members of the Voronel Sunday seminars now seems to be spreading to their contacts throughout the Soviet Union. In Tbilisi, pressure is being exerted on the Goldshtein brothers, Isai (35) and Grigorii (42), both cyberneticists and both "refusniks" since 1971, when their applications to emigrate to Israel were rejected on the grounds of "security".

After they were refused their visas, the brothers were both dismissed from their posts at the Institute of Cybernetics of the Georgian Academy of Sciences. It is reported that the director of the institute admitted in a private conversation after their dismissal that neither brother had ever been connected with secret work but that he, the director, was "afraid".

The Goldshtein brothers have maintained close contacts with the members of the Moscow seminar, especially with Aleksandr Lunts and Viktor Brailovskii, who, since Voronel's departure for Israel, have been the leading organisers. The Goldshteins had planned to visit Lunts and Brailovskii at Passover, but were prevented from doing so by the authorities. After this attempt, they were taken to their local KGB offices, questioned about their activities and warned that their files would be handed over on April 7 to the State Prosecutor in preparation for a trial. It was also intimated that the

The Goldshteins: Isai (left). Elizaveta Bykova and Grigorii

charges against them would be linked with four other trials now being prepared in the USSR. Since Lunts and Brailovskii have already been threatened with legal proceedings, it is feared that they will be involved in these other trials.

The charge against the Goldshtein brothers falls within the category of an unpublished edict of the Presidium of the Supreme Soviet of 1972. It is alleged that since they were refused permission to go to Israel, they have been slandering the USSR, and that their activities threaten the security of the USSR—a charge which carries a maximum sentence of seven years in a strict regime labour camp.

So far, no charge has been preferred

against Elizaveta Bykova Goldshtein, the wife of Isai and, like him, a physicist. Since, however, she is the author of a survey of the problems and backgrounds of refusniks and the means used to intimidate them, which has recently reached the West through *samizdat* channels, it seems not unlikely that she too could share the fate of her husband and brother-in-law.

In the week that physicist Evgenii Levich, who was associated with the Voronel seminar, was finally allowed to emigrate to Israel together with his brother, Aleksandr (an engineer), it seems ironic that two other brothers, also associated with the seminar group, should attract the renewed attentions of the KGB. ☐

"A major climatic change would force economic and social adjustments on a worldwide scale . . . it is not primarily the advance of a major ice sheet over our farms and cities that we must fear . . . rather, it is persistent changes of the temperature and rainfall in areas committed to agricultural use, changes in the frost content of Canadian and Siberian soils, and changes of ocean temperature in areas of high nutrient production . . . Our vulnerability to climatic change is seen to be all the more serious when we recognise that our present climate is in fact highly abnormal".

These sentiments will already be familiar to readers of *Nature*; now they come with the official blessing of the US National Academy of Sciences in a report, "Understanding Climatic Change—A program for action" prepared as part of the US contribution to the Global Atmospheric Research Program (GARP). There is little in the report that will be new to the serious student of climatic change, although a lengthy appendix surveying past

climates does pull together in one handy review a wealth of scattered information; but the Panel on Climatic Variation which has produced the report makes some far-reaching recommendations about the nature of future research:

● The immediate adoption and development of a coherent National Climatic Research Program to include

● A Climatic Data Analysis Program with the development of new climatic data-analysis facilities and

● A Climatic Index Monitoring Program to acquire the needed data with

● A Climatic Modelling and Applications Program to accelerate research on climatic variation.

The Panel sees these American efforts as best taking place within an international framework, and suggests that the period prior to 1980 "be used to develop additional scientific and technical manpower through the establishment and support of fellowships in appropriate areas of climatic research", and that the period 1980–2000 should be designated the "International

Climatic Decades" during which data should be gathered extensively on an internationally collaborative basis and regional climatic studies of anomalies of special interest carried out.

Apart from the rather leisurely time-scale mapped out (in view of the present world food situation and the changes in climate that have occurred in the past 25 years) the report is likely to be welcomed by all of those climatologists whose lonely warnings about the importance of climatic change are now provided with the seal of scientific respectability. The cost of the massive effort needed (massive by scientific standards, but small compared with, say, the development of a nuclear missile system) must make it doubtful whether a really effective programme will take place. That is in the hands of the politicians; but politicians outside the USA should also take note of this NAS report. They may decline to take appropriate action, but they cannot say any longer that they do not have the necessary information on which to base a course of action. *John Gribbin*

The NPT and the IAEA

SIR,—Your editorial on "The unloved treaty" (March 13, 1975) shows how important it is to exercise the utmost care in reaching conclusions about political as well as scientific matters The gist of the article is that the foundations of the Non-Proliferation Treaty (NPT) "show signs of crumbling" and that it has failed "to catch on"

It is strange to read this at a time when all the non-nuclear-weapon countries of the EEC are at the point of completing the process of ratification of the treaty, when the Government of Japan is reported to be putting the treaty to the Diet in April for discussion and ratification and indeed when many countries are seriously concerned to prevent further nuclear proliferation and to increase the effectiveness of IAEA safeguards During the past year we have witnessed several steps taken by the main supplier countries in this direction, such as an agreement on a list of nuclear equipment and materials which will "trigger" the application of safeguards requirements for safeguards on specialised technological information and an increased interest in safeguards in countries that have previously been somewhat indifferent

The editorial's comments on the peaceful uses of nuclear explosions are, I believe, equally inaccurate Article V of the NPT specifies that the potential benefits of peaceful applications of nuclear explosions be made available to non-nuclear-weapon states party to the treaty "under appropriate international observation and through appropriate international procedures " And further, "n o n - nuclear-weapon states party to the treaty shall be able to obtain such benefits, pursuant to a special international agreement or agreements, through an appropriate international body with adequate representation of non-nuclear-w e a p o n states"

When you ask "so where is the international body?" you overlook that the IAEA, with 106 member states, would clearly seem to meet the requirements set out in NPT and that there is no need to establish a new international organisation In 1968, the United Nations Conference of non-nuclear-weapon states recommended that the agency initiates studies on its possible functions in the field of peaceful nuclear explosions (PNE), and the agency's suitability in this respect has

been specifically recognised by its own General Conference and by the United Nations' General Assembly

Some of the major steps taken by the IAEA with respect to the responsibilities outlined in Article V are

● In 1972, guidelines for "The international observation of PNE under the provisions of NPT and analogous provisions in other international agreements" were developed and approved by the agency's Board of Governors

● In 1974, an advisory group developed "Procedures for the Agency to Use in Responding to Requests for PNE-Related Services" These procedures have also been approved by the Board of Governors

● The Agency has convened a series of technical meetings which reviewed the "state-of-the-art" These meetings were convened in 1970, 1971, 1972 and in January 1975

● Potential PNE Supplier States were approached in December 1974 concerning their participation in elaborating the basic conditions to be incorporated into the special agreements referred to in Article V of NPT

● A separate "Unit for Peaceful Nuclear Explosions Services" was established within the IAEA Secretariat in January 1975

Far from resisting "the accumulation of yet more duties for a secretariat already fully extended", the IAEA has taken active steps to meet its obligations as the appropriate international body mentioned in Article V of the NPT The point that is entirely missed in your editorial is that despite the extensive exchange of information that the IAEA has promoted over several years on this subject (incidentally we do not put out "fairly enthusiastic publicity" but merely publicise the statements of national experts), the equally extensive preparatory work that the IAEA has done on the legal and administrative aspects, not a single formal request for a PNE has yet been received by us We have had a few enquiries from member states, and we have arranged some preliminary investigations, but in no case has a serious project emerged

Finally, your conclusion that someone should have the courage at the NPT Review Conference to suggest that "the treaty be scrapped and new approaches tried" is most difficult to take seriously The NPT and the related Test Ban Treaty are the two major achievements of post-war arms

control negotiations What is needed is to pursue efforts to control the spread of nuclear weapons and to strengthen and supplement NPT by additional non-proliferation nuclear arms control and disarmament measures

Yours faithfully,

SIGVARD EKLUND

International Atomic Energy Agency, Vienna

Cabora Bassa hazards

SIR,—The Cabora Bassa Dam, the second barrage across the Zambezi, closed on December 5, 1974 The 171-metres high dam, situated on the Cabora Bassa rapids (the natural boundary between the Middle and Lower Zambezi), will hold back a 250 km long lake, with a mean breadth of 11 km and a maximum capacity of $6\ 23 \times 10^{10}$ cubic metres at a retention level of 336 m AMSL It will inundate 2,739 square km with a mean depth of 25 2 m (maximum depth 157 m) Five south bank turbines at present nearing completion each have a power capacity of 430 MW Four more turbines planned for a future north bank station will bring the eventual power capacity to 3,870 MW

Pre-impoundment surveys of the status of the Zambezi and some of its major tributaries in relation to the dam, began in April 1973 and included physico-chemical characteristics of the rivers (A Hall, I Valente and J da Costa Martins), phytoplankton (J C Oliveira), fish (R Morais), zooplankton and benthos (the author) The objective has been to provide basic data from which to monitor future changes in the valley ecosystem, occurring directly or indirectly as a result of the dam The work has also produced the first information on the Zambezi since Kariba was closed in 1958, and has shown the effect of the combined influence of the Kariba and Kafue dams on the river in Moçambique

In January 1974, a small team studied the probable future impact of the dam on the valley, including such problems as aquatic macrophyte infestation (expected to include *Salvinia molesta* D S Mitchell, *Pistia stratiotes* L and *Eichhornia crassipes* Mart), fisheries development, lake management, the creation of national parks and reserves and the impact of the dam on agriculture, industrial development and existing game reserves and fisheries in the Lower Zambezi Valley During the study, the valley planning authority

engineers, Gabinete do Plano do Zambezi (GPZ) in Tete revealed that they intended to fill the lake to capacity during a period of four months, allowing less than 60 cubic metres of water to discharge daily to the gorge below the dam In normal years, the average flow through the gorge is of the order of 2,000–3,000 cubic metres per second

Recommendations made by the team to the GPZ and the then Portuguese and Moçambique governments included allowance of a minimum discharge from the dam during the filling phase of 400–500 cubic metres per second with the lake taking between one to two years to reach maximum capacity, thus reducing the expected detrimental effects associated with prolonged water reduction in the Lower Zambezi The gorge below the dam, approximately 25 km long (river depth between 30–40 m), has no source of water other than the dam Four major rivers enter the Zambezi between the gorge and the coast, 560 km downstream, namely the Luia, Revuboé, Mazoe (Luenha) and Shire, the Shire draining Lake Malawi to the north Unpublished data supplied by the GPZ shows that these rivers add little by way of volume (though the Shire considerably alters the chemistry of the Zambezi below their confluence) and then only during the latter part of the wet season (mid-January to late March)

Accompanying a press announcement of closure (Noticias de Moçambique, 28 11 74) was the comment that the dam would be completely closed until such time as the water level reached 306 2 m AMSL (approximately three weeks after closure according to the report), after which time water would be discharged into the gorge The lake would then fill at a slower rate The minimum discharge recommendations were ignored The engineers anticipated that little or no noticeable difference in river level would occur during this early filling phase due to the expected onset of the rains This statement contradicts the river flow data supplied by the GPZ and gives no consideration to the possible long-term ecological consequences of such action To compound the problem, local rains did not begin until two to three weeks after closure Within seven days of closure, the river at Tete (approximately 120 km downstream from Cabora Bassa) was reported to have dropped to dry season levels By February 8 this year, levels had dropped sufficiently to prevent operation of water supply intakes for Tete, and no discharge from the dam had taken place up to this date At the same time, large numbers of spawning fish were stranded in the lower river and slaughtered in large numbers by local Africans

This apparent disregard of recom-mendations made with long-term con-siderations in mind bodes ill for future co-operation between ecologist and engineer and could have important long-term repercussions for the agricul-ture (mainly sugar cane), fisheries and game reserves of the Lower Zambezi Valley and its floodplains Important decisions, such as the timing of artificial floods and the controlled fluctuation of water level in order to facilitate de-velopment of hydrophytes, essential for fisheries development in the new lake, must be taken in the near future A dialogue between ecologist and engineer is essential if a balanced use of the resource is to be made

African finds

Sir,—In his article on the Leakeys' work at East Rudolf (*Nature*, February 20, 1975) Bernard Wood writes, of the Taung discovery in 1924 "It was for-tunate that the remains of a fossil monkey had been recognised at the same quarry only a few months pre-viously " In fact, fossil baboons were found at Taung as early as 1920 On 19th May 1920, a paper on seven or eight fossil baboons from Taung was read in Cape Town before the Royal Society of South Africa by S H Haughton, subsequently Director of the Geological Survey of the Union of South Africa, and still later, Honorary Director of the Bernard Price Institute for Palaeontological Research at the University of the Witwatersrand Haughton's paper of 1920 was not pub-lished in full, though he made his notes available to R A Dart, R Broom and J H S Gear An abstract of Haugh-ton's communication was published in 1925 To accommodate the small baboon skulls from Taung, he had pro-posed to create a new species, *Papio antiquus* However, as his paper was not published and as no type was desig-nated, the name *P antiquus* was both a *nomen dubium* and a *nomen non rite publicatum* Gear recognised that the sample of cercopithecoids from Taung included two different species to which he gave the names, *P africanus* and *P izodi*

Presumably, the "fossil monkey" re-ferred to by Wood was a baboon cranium which, in 1924, one of Dart's students, Josephine Salmons, recovered from the home of E G Izod, a direc-tor of the Northern Lime Company This find led Dart to request R B Young, then professor of geology at the Witwatersrand University and about to survey the Taung area, to speak to the Timeworks manager in the hope of obtaining more specimens

The recovery of the Taung australo-pithecine skull, said by Wood to have been discovered by accident, actually occurred as follows Mr M de Bruyn, a miner at Taung, had been interested for many years in collecting fossilized bones A week before Professor Young's visit, in October 1924, de Bruyn had blasted out a number of fossils These included the brain cast of a baboon and, embedded in another fragment of breccia, a second, larger endocast, among the other rock frag-ments part of a lower jaw was exposed The manager, A E Spiers, and de Bruyn showed the collection to Young, who selected certain pieces which Spiers railed to Dart It was the sec-ond, larger endocast which turned out to be that of *Australopithecus* Another piece of rock made a perfect join with the former and from it Dart extracted the face (There is no evid-ence whatever to support Bernard Wood's statement that "The child's skull was in fact identified by Pro-fessor Young" indeed this would have been virtually impossible since most of the skull was totally embedded in the matrix Only a part of the endocast was showing on the surface of one piece and the back of the lower jaw on another piece Identification was out of the question until Dart had extracted the specimen from its matrix in time for Christmas, 1924)

The article also stated that Taung was situated "in what was then Bechuanaland" This common mistake arose because Taung was situated in the northernmost part of the Cape Province, an area formerly known as 'British Bechuanaland' (and totally dis-tinct from 'Bechuanaland') But this area was in 1924 an integral part of the Union of South Africa, entirely sepa-rate from the Bechuanaland Protec-torate which is today the Republic of Botswana This old name of the nor-thern Cape Province led several scien-tists and textbook writers erroneously to place Taung in 'Bechuanaland' or even 'Botswana'

Wood's statement that ' work has been resumed recently at three of these sites' (in the Transvaal) is mis-leading, since Brain resumed excava-tion at Swartkrans in 1965, while Tobias and Hughes began excavating at Sterkfontein in 1966 Work has con-tinued ever since, in the case of Sterk-fontein without any interruption for 48 weeks a year for over eight years Hence, although the article admirably reflects recent work in East Africa, it does scant justice to the palaeo-anthro-pological researches in the Transvaal over the past decade

news and views

MOSSBAUER spectroscopy has never achieved the universality of application experienced by many other spectroscopic methods, and will probably never do so This is not due to any intrinsic difficulty in the technique itself, but rather because the number of different elements which can be studied without special facilities is small, and also because the information obtained from the spectra, although frequently crucial to the elucidation of a structure, can rarely be fully interpreted in the absence of other data about the compound concerned But the technique possesses a number of valuable attributes which may be exploited where other analytical methods would fail, and this allows its use in systems which would otherwise pose considerable analytical problems

The basis of Mossbauer spectroscopy is the recoilless emission and resonant absorption of gamma rays of suitable energy The line width of this resonant process is so narrow that the effect can only be demonstrated where the emitting and absorbing atoms are isotopically similar, spectra normally being generated by the Doppler modulation of source or absorber to allow absorption measurements over a small range of photon energies

First observed by Rudolf L Mossbauer in 1957, the effect was rapidly found to have possibilities for the study of changes in the electronic environment of the atoms whose spectrum was measured, because the atoms' environment influenced the nuclear energy levels between which the resonant gamma ray transitions occurred This influence was twofold, and allowed structural information regarding the atomic environment to be obtained

First, any difference between the s-electron density as experienced by the emitting and absorbing nuclei will cause a displacement of the absorption line known as the 'isomer shift' This allows the comparison of s-electron densities in different compounds and thus gives, among other things, information about oxidation states Second, any electron distribution which is not spherically symmetrical may give rise to a 'quadrupole splitting' in which the single absorption line becomes a doublet centering on the original position The separation of the doublet is proportional to the field asymmetry, and provides information on the geometry of the atom's immediate environment In addition, the presence of an internal or external magnetic field may lift the nuclear spin degeneracy and be exhibited as a multi-line spectrum

The letter from Hedges in this issue of *Nature* (page 501) exemplifies the situation where Mossbauer spectro-

spectroscopy
in
archaeology

from Nigel J Seeley

---

scopy has been used to gain information which would not readily be obtained by other methods Archaeological materials and works of art present many difficulties to the analyst They are frequently complex and unknown mixtures, and in many cases sampling cannot be allowed Provided that the sample geometry is suitable, wholly non-destructive analysis is possible, but unless surface scattering spectra are to be obtained it is generally more convenient to take a sample unless the object is thin, as in the case of a painting

Also, because the Mossbauer spectrum obtained is that of one specific atomic species, the presence of impurities containing other elements, even when present as a major constituent, will not complicate the spectrum, although their attenuation of the gamma rays may be inconvenient This means that the spectrum obtained will be only that of the atomic species being studied, and if that element is present in two or more compounds or environments in the sample a simple and resolvable additive spectrum will be obtained

The elements most suited to Mossbauer studies on archaeological material are iron and tin, although nickel, zinc and gold might be useful in certain circumstances

Iron is not only a particularly convenient element for study, but its very wide occurrence in raw materials results in its presence in a diversity of artefacts Iron impurities in ceramics were first investigated by Cousins and Dharmawardena (*Nature*, **223**, 732, 1969) for typing purposes, and at the recent Symposium on Archaeometry and Archaeological Prospection at Oxford (19–22 March, 1975) Longworth and Warren presented data relating to the black slip on certain samples of Etruscan pottery Here the problem is to identify an iron compound present, with other minerals, in particles too small for conventional X-ray diffraction, but presenting no difficulty regarding the Mossbauer spectrum Though it is not possible to arrive at an identification of an unknown compound from the Mossbauer spectrum alone, comparison with spectra of known likely compounds can readily be used to characterise such materials Glasses and glazes are another class of substance which, having no long-range ordering, are unsuitable for X-ray diffraction, but yield valuable information about the environment of iron atoms present in the network or as microcrystalline impurities

Mossbauer spectroscopy has also been used by Keisch (*Archaeometry*, **15**, 79, 1973) to identify iron-containing pigments on paintings where its non-destructive nature and ability to 'ignore' compounds not containing iron were used to the full Quantitative analysis using Mossbauer spectroscopy is more difficult, at the lattice dynamics of different compounds cause the absorbing atom to vary in its efficiency, but with suitable calibration a degree of quantification can be achieved

There is therefore a number of situations where Mossbauer spectroscopy provides information on archaeological and art materials which is otherwise difficult to obtain, and much useful work remains to be done on glazes and colouring materials Ancient alloys have been little studied from this point of view, and it is likely that such materials as tin bronzes would repay investigation

Nuclear incompressibility

from P E Hodgson

MANY different measurements of the sizes of atomic nuclei have shown that their volumes are closely proportional to the number of nucleons they contain It is thus a very good approximation to assume that the nuclear radius is proportional to $A^{1/3}$, and indeed the relation $R = 1\,25\,A^{1/3} \times 10^{-1/3}$ cm is widely used This result may also be expressed by saying that nuclear matter is incompressible, so that the addition of more nucleons to a nucleus does not increase its density but only its size

But nuclear matter is not infinitely incompressible, and several lines of evidence enable us to estimate its compressibility None of these is very direct, so there is still considerable uncertainty in the values obtained.

In classical physics, incompressibility is measured by the energy needed to reduce the volume (or the density) by a definite amount Since at equilibrium the rate of change of energy with density is zero it is usual to define the incompressibility K by the second differential evaluated at equilibrium radius R

$$K = R^2\, d^2\varepsilon/dr^2$$

evaluated at $r = R = r_0 A^{1/3}$, where ε is the binding energy per nucleon

Using the semi-empirical mass formula and neglecting derivatives of symmetry terms gives

$$K = K_M + K_S A^{-1/3} + 6e^2 Z^2/5 r_0 A^{4/3}$$

where K_M is the nuclear matter incompressibility and K_S the nuclear surface incompressibility This shows that the nuclear incompressibility is a function of A

The incompressibility of nuclei can be estimated indirectly in two ways, one depending on our knowledge of the effective nucleon–nucleon forces and the other on the identification of compression oscillations

One of the most widely used nuclear theories derives from the Hartree self-consistent field theory for atoms In this theory each electron is treated as moving in the field of the nucleus and of all the other electrons. If a reasonable estimate of this field is made, it can be used in the Schrodinger equation to calculate the wave functions of the electrons, and hence to give a more accurate estimate of their field at any point. This calculation is continued until it converges, so that the field coming from the solution of the Schrodinger equation is the same as the field used to solve the equation

Such calculations have been made for nuclei, with appropriate modifications to take account of the absence of a central particle, and the equations are usually solved by electronic computers The complete calculation from the nucleon–nucleon interaction is very complicated, so simpler methods have been developed using effective interactions One of the most successful of these is the Skyrme interaction, and Vautherin and Brink (*Phys Rev*, **C5**, 626, 1972) have used it to calculate a wide range of nuclear properties from the nuclear Hartree equations The charge and matter distributions of a range of nuclei, together with the energies of their single-particle states are given very well, so it is perhaps reasonable to accept the values of other nuclear properties derived from the same interaction, even though they cannot be verified independently

Among these properties is the nuclear incompressibility, and the calculations of Vautherin and Brink gave values of 370 and 342 MeV for the nuclear matter incompressibility calculated from two of their most successful interactions Earlier nuclear matter calculations by Brueckner and Gammel (*Phys Rev*, **109**, 1023, 1958) starting from a phenomenological form of the nucleon–nucleon interaction gave $K = 187$, 167 and 172 MeV for three different interactions, while Campi and Sprung (*Nuclear Physics*, **A194**, 401, 1972) found $K_M = 190$, 213 and 295 for three more forces Statistical calculations by Stocker (*Nuclear Physics*, **A166**, 205, 1971) gave $K = 180$, 230, 195 for three different forces

Pandharipande (*Phys Lett*, **31B**, 635, 1970) has calculated incompressibilities for a range of nuclei using the constrained Thomas–Fermi method and finds values ranging from $K = 123$ MeV for ^{40}Ca and 176 MeV for ^{120}Sn to 190 MeV for ^{208}Pb These values are given by the above expression if $K_M = 266$ MeV and $K_S = -496$ MeV

These calculations with nuclear forces carefully adjusted to fit certain nuclear properties give values of the nuclear matter incompressibility that vary in the range 150–400 MeV This indicates that the incompressibility depends on aspects of the nucleon–nucleon interaction that do not strongly affect the more easily measurable properties of nuclei, so it is difficult to know the reliability of the results obtained

Another approach to the problem of determining the nuclear incompressibility makes use of a particular kind of nuclear oscillation called a 'breathing oscillation' The more familiar types of nuclear vibrations are shape vibrations, like those of a liquid drop or a jelly, and these can take place in an incompressible medium But if the medium is compressible, however slightly, it can oscillate simply by changing its size, while remaining all the time spherical It would look as if it were breathing and hence the name 'breathing mode' for these oscillations

The higher the incompressibility, the higher the energy of the excited nuclear state corresponding to such an oscillation Using a hydrodynamical model (Walecka, *Phys Rev*, **126**, 653, 1962) the energy is given in terms of the incompressibility by

$$E \approx (\hbar^2\, K/m\, r_{R\,MS}^2)^{1/2} \approx 6\,9\,K^{1/2}\,A^{-1/3}$$

(Pandharipande, *Phys Lett*, **31B**, 635, 1970)

It is not easy to identify such states in nuclei They have a monopole vibrational character and so have spin and parity 0^+ and strengths that exhaust a large fraction of the EO sum rule Such states should be readily excited by reactions like inelastic electron scattering One such state was reported by Pittham and colleagues (*Phys Rev Lett*, **33**, 849, 1974) at 8 9 MeV in Pb, but this corresponds to a rather low incompressibility of $K \approx 90$ MeV, so this identification remains uncertain (*Nature*, **253**, 92, 1975)

In oxygen detailed calculations by Sharp and Zamick (*Nuclear Physics*, **A223**, 333, 1974) gave about 28 5 MeV as the energy of the breathing mode state, but it is not yet possible to identify this with an actual state The difficulty of finding the breathing mode states thus prevents them being used to determine the incompressibility at the present time, but the development of more specific ways of exciting these states may eventually make this possible

Breakdown of superfluidity

from a Correspondent

WHAT determines the maximum velocity with which superfluid helium will flow without friction? Can we understand the dissipative processes that occur at supercritical velocities? These are fundamental questions that low-temperature physicists have been asking ever since Landau published his classic theory of the mechanism of superfluidity (*Fiz Zh*, **5**, 71, 1941 and **11**, 91, 1947) A recent paper by Phillips and McClintock (*Phys Rev Lett*, **33**, 1468, 1974), describing observations of the drag on an ion moving at high speed through helium, shows that we still do not have complete answers

The liquid phase of the common isotope of helium, ^{4}He, becomes a superfluid when it is cooled below a temperature of about 2 K The superfluid transition is associated with a form of 'Bose condensation' in the liquid, in which an appreciable fraction of the atoms accumulate in one particular single-particle quantum state (so that all the condensed atoms have, for example, exactly the same momentum) At a finite temperature the superfluid phase behaves like a mixture of two fluids a 'normal' component, behaving

A hundred years ago

IN connection with the recent meeting of the French learned societies, Mr G J Symons writes from Paris as follows —"M Michel threw out a suggestion which appears to me likely to, or at any rate possibly may, be the means of averting the principal source of danger in crossing the Atlantic I refer, of course, to icebergs in foggy weather and the total wrecks which occur from running on to them It is well known that the proximity of icebergs is indicated by a diminution in the temperature of the sea M Michel's proposal is very simple it is merely that Transatlantic steamers should carry a submerged electric thermometer, which might easily be arranged to ring a bell in any part of the vessel on the occurrence of whatever change of temperature might be decided upon "

from *Nature*, 11, 476, April 15, 1875

like an ordinary viscous liquid and composed of thermal excitations in the liquid, and a 'superfluid' component, formed from the background liquid and closely associated with the atoms in the Bose condensate

Suppose that superfluid helium is suddenly set into fairly slow motion along a tube The thermal excitations rapidly come into equilibrium with the tube, and this is observed as a viscous slowing up of the normal component But the velocity of the superfluid component does not change This velocity is identified with the velocity of the condensate, any change in this velocity would imply a change in the velocity of all the atoms in the condensate simultaneously, and this process is believed to occur with negligible probability The superfluid component is therefore observed to flow without friction

Similar considerations apply to the motion of an object through superfluid helium At low speeds it suffers a drag from only the normal fluid Its effect on the condensate is to produce only an adiabatic deformation of the condensate wave friction, corresponding to frictionless potential flow of the superfluid component past the object At very low temperatures, when there is practically no normal fluid, the object suffers negligible total drag

This absence of drag is expected to apply only at sufficiently low velocities As was pointed out, in effect, by Landau, it is energetically favourable for an object that is moving at a velo-

city exceeding a certain ('Landau') critical velocity to create a 'roton', which is one of the possible thermal excitations in the liquid In 1970 E H Takken published a theory of the rate at which rotons can be produced in this way (*Phys Rev*, **A1**, 1220), and showed that an extremely large drag should set in above the Landau critical velocity

In practice the Landau critical velocity for the creation of rotons is hardly ever observed, since another process, the creation of quantised superfluid vortices, usually sets in at a lower velocity The creation of these vortices raises many interesting questions, which have not all been answered, but that is another story The one situation where rotons do seem to be created was discovered by Rayfield (*Phys Rev Lett*, **16**, 934, 1966, *Phys Rev*, **168**, 222, 1968), who showed that negative ions in helium at a high pressure can be accelerated to a limiting velocity that seems to be equal to the critical velocity for roton creation (about 50 m s^{-1})

It is the drag on a moving negative ion at high pressures that has been investigated in detail by Phillips and McClintock They have extended the earlier measurements by Rayfield and others, and they have measured the velocity with which the ions move in a very high electric field They find that the drag on an ion moving at a velocity greater than the roton critical velocity is much less than was predicted by Takken, and they also find some unexpected features in the way in which vortex creation competes with roton creation in the drag process It seems clear that Takken's theory is inadequate, and that we have another example of the fact that even after over thirty years of theoretical effort our understanding of critical velocities in superfluid helium is still far from complete

Lunar duststorms

from David W Hughes

ONE piece of apparatus left on the lunar surface by the Apollo 17 astronauts was a three-axis microparticle detector This was designed to study the cosmic dust environment at the lunar surface to determine the nature and extent of luna ejecta produced by meteorite impacts at other spots on the Moon, to measure possible increases in flux produced by Earth focusing and to look for possible interstellar particles Berg, Richardson, Rhee and Auer (Goddard Space Flight Center, Greenbelt, Maryland) present preliminary results from this experiment in their recent letter to *Geophysical Research Letters* (**1**, 289, 1974) The sensors are

on three sides of a cube, one looking up, the other two looking along the lunar surface, pointing 25° north of east and 25° south of west respectively The cube stands on four legs and is about 20 cm above the level of the lunar soil The mass threshold is typically 10^{-13}g The apparatus is on for 76% of the time, being switched off at the height of lunar day 1,117 particles have been so far recorded during 203 days of observation

One fascinating result from the analysis is that the particle event rate increases when the terminator (the day–night dividing line) passes over the apparatus This increase starts some 40 h before sunrise and ends about 30 h after, the event rate typically increasing by a factor of 100 over the 'non-terminator' rate The sunset effect is less consistent in time of appearance, duration and quality but is definitely present Berg *et al* rule out the direct effect of solar electromagnetic radiation as a cause because the event rate goes up long before the Sun illuminates the lunar region under consideration Particles emanating directly from the Sun can also be discounted because the phenomenon always ends when the Sun is still rising in the sky Rigorous thermal testing of the apparatus prior to launch also rules out temperature effects The authors conclude that they are observing lunar surface particles, moving westward at sunrise and eastward at sunset, just as if a duststorm was sweeping across the lunar surface This storm is along the terminator line, the dust particle moving always in the direction away from the Sun

This could be a perfect example of electrostatic particle levitation and subsequent horizontal soil transport It has been shown that solar ultraviolet radiation will raise the surface of the Moon to a potential of 20 to 40 volts and will give rise to a layer of high-electron density and electric field intensity that extends several centimetres above the lunar surface This field is of the order of 60 V m^{-1} and can easily support small positively charged dust particles Moving them bodily from place to place is another problem which requires some circumstance such as deviation of the potential of dust grains from the median value, this leading to the build-up of repulsive and attractive forces

Dust movement could also be due to variations in the electrical surface charge with position on the lunar surface This idea was first put forward by Criswell (*Geochim Cosmochim Acta*, **3**, 2671, 1972) who suggested that large differences in the electrical surface charge could build up across light–dark boundaries due to the highly resistive nature of the lunar surface If this is the cause of the duststorms the

horizontal variability of the electrical field as a function of solar zenith angle (or distance perpendicular to the terminator) could be inferred from the time variability of impact events obtain from the data of Berg et al The electrical charge of the lunar surface, positive in the Sun and negative out of the Sun, is confirmed by the transport direction of the positively charged dust particles

Confirmation of dust churning in the terminator zone has been obtained from Surveyor spacecraft observations of lunar horizon glow Surveyors 5, 6 and 7 clearly detected a line of light along the lunar western horizon immediately following sunset These observations have been discussed by Rennilson (California Institute of Technology, Pasadena) and Criswell (Lunar Science Institute, Houston) in a recent paper in *The Moon* (10, 121, 1974)

They suggest that the horizon glow is sunlight which has been forward scattered by dust grains ($\sim 10\,\mu m$ in diameter, mass $\sim 10^{-9}$g, ~ 50 grains cm^{-2}) present in a tenuous cloud formed temporarily (duration about 3 h) just above the sharp sunlight–shadow boundary in the terminator zone The grains are thought to be levitated by an electrostatic field of greater than 500 V cm^{-3} across the boundary Rennilson and Criswell also find that the electrostatic dust motion totally dominates the churning produced by micrometeoritic impact The scale height of the glow is between 20 and 30 cm which is of the same order as the height of the micrometeoroid detector at the Apollo 17 site

Rennilson and Criswell comment on the fact that no obvious patterns had been seen by astronauts in the lunar soil, patterns which one would expect to result from the surface dust motion required to produce horizon glow But as horizon glow regions constitute only a small fraction of the lunar surface and tend to occur on slopes (regions avoided by astronauts) this is not too surprising Interestingly the Taurus Littrow region of the Apollo 17 dust experiment is surrounded by mountainous terrain which is ideal for horizon glow production The difference between the duration of horizon glow (3 h) and the micrometeoroid dust storm (70 h) could be entirely due to the different particle sizes responsible, the 10^{-13}g micrometeoroids remaining in the lunar atmosphere much longer than the 10^{-9}g particles responsible for light scattering

It will be most interesting to see if the more detailed analysis of the Apollo 17 site micrometeoroid data reveals storm duration to be particle size dependent When the dust storm had died down the sensor fluxes were found to be notably similar to those

measured in deep space ($\sim 4 \times 10^{-4}$ particles m^{-2} s^{-1} (2π sr)$^{-1}$ This indicates that there is very little normal lunar ejecta with speeds in excess of 0 8 km s^{-1}, the threshold speed of the detectors But the speed of the lunar dust storm particles must exceed this value to have been detected at all, so a certain percentage of them should have speeds in excess of the lunar escape velocity of 2 4 km s^{-1} and should subsequently leave the Moon to join the Solar System dust cloud

Function for *E. coli* penicillin-binding protein

from H R Perkins

NEARLY thirty years ago Duguid proposed that penicillin caused the death of growing bacteria by interfering with the synthesis of their wall components, although at that time the composition and structure of the walls were unknown Since then, as more detailed information about the constitution of bacterial walls has accumulated, progressively more sophisticated explanations of the mode of action of penicillin have become possible

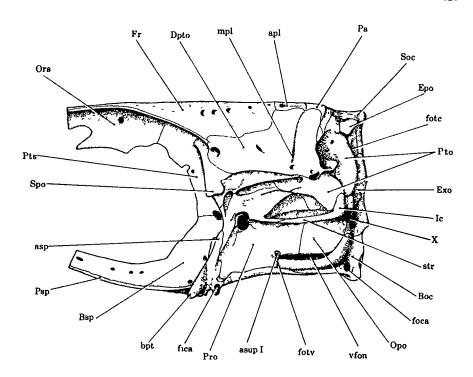
The walls of all penicillin-sensitive organisms contain a structural component called peptidoglycan, which consists of glycan chains of alternating residues of N-acetylglucosamine and its 3-O-D-lactyl ether, N-acetylmuramic acid, to the carboxyl groups of which are joined short peptide chains consisting of alternating L- and D-amino acids An essential feature is that some of these amino acids are trifunctional (for example L-lysine, meso-diaminopimelic acid, or D-glutamic acid) and in the final peptidoglycan, which forms a retaining network round the cell, these amino acids are involved in cross-linking the peptide side chains of one strand of glycan to those of another By 1965 the final cross-linking step of peptidoglycan synthesis had been pinpointed as the target of penicillin action Various cell-free transpeptidation systems are now known to be sensitive to penicillin, and indeed purified soluble *Streptomyces* transpeptidases are inactivated by taking up just one molecule of penicillin or cephalosporin per protein molecule

The amidinopenicillanic acid derivative (FL 1060) described by Lund and Tybring in 1972 acts differently from the β-lactam antibiotics previously known In the first place it is much more active on Gram negative than on Gram positive bacteria, which is the reverse of the situation observed with most penicillins and cephalosporins

Growth of *Escherichia coli*, for instance, is inhibited by 0 02 μg ml^{-1}, and the organism does not respond to this low concentration by developing filamentous forms or 'rabbit's ear' outgrowths that lead to spheroplast production as in the classical response to penicillin On the contrary, the shape of *E coli* treated with FL 1060 is characteristically ovoid, and after a period of time lysis ensues without prior spheroplast formation The second major difference is that even high concentrations of this antibiotic have no inhibitory action on peptidoglycan transpeptidation It seems, therefore, that there must be another point of intervention for FL 1060 apart from peptidoglycan cross-linking, although the change of shape and lack of cell division in *E coli* suggest some connection with cell wall metabolism

The walls of Gram negative bacteria differ from those of Gram positive species in having a much thinner peptidoglycan layer and outside that an outer membrane, which contains lipoprotein and lipopolysaccharide As Braun has shown, a proportion of one particular species of lipoprotein molecule is covalently attached to the peptidoglycan by a peptide linkage Since this linkage is formed after the initial synthesis of peptidoglycan, it may well also involve a transpeptidation reaction that is sensitive to FL 1060, as Park and Burman already speculated

The work of Spratt and Pardee (this issue of *Nature*, page 516) throws new light on the mode of action of amidinopenicillanic acid, and perhaps at the same time on a hitherto unspecified process in cell growth and division They find that in *E coli* all the six binding proteins for radioactively labelled penicillin are in the cytoplasmic membrane Pretreatment of cells with FL 1060 at 5 μg ml^{-1} results in complete blocking of subsequent binding of ^{14}C-benzylpenicillin to only one of the six distinguishable binding proteins and even below the minimum concentration inhibitory for bacterial growth there is considerable competition for binding sites Of a range of penicillins and cephalosporins studied, only the penicillin nucleus 6-aminopenicillanic acid produces the ovoid cells characteristic of the action of FL 1060 and this substance also prevents binding of labelled penicillin to the same specific membrane protein, though to a lesser extent it also decreases binding to some of the other bands

The apparent molecular weight of the specific binding protein is 66,000, and it accounts for only 0 5% of the total binding of ^{14}C-benzylpenicillin Spratt and Pardee reasonably propose that this protein is the target by which the amidinopenicillanic acid affects the


shape of *E coli*, and that it is an enzyme involved in the terminal stages of peptidoglycan metabolism, which "may be specific to Gram negative organisms

There have been many studies of the binding of penicillin to bacterial membranes In bacilli certain carboxypeptidases have been shown to be responsible for some of the observed binding, but many protein species are affected, just as in the absorption of benzylpenicillin by *E coli* The site of emergence of potential spheroplasts from *E coli* under the influence of benzylpenicillin was used by Donachie and Begg in their studies on cell growth, and the relationship of 'penicillinsensitive' sites to the growing bacterium was established It will be interesting to see where, in fact, FL 1060 is absorbed to cells, but presumably this will have to await the availability of the tritiated antibiotic The intriguing similarity of 6-aminopenicillanic acid action suggests that perhaps the binding site requires a positively charged group on the β-lactam molecule, unless, of course, the amidinopenicillanic acid is specifically taken up by the enzyme and then hydrolysed to 6-aminopenicillanic acid The fact that the membrane protein specific for the binding of amidinopenicillanic acid also takes up penicillin implies that the majority of β-lactam antibiotics will probably inhibit its cellular function too, presumably that specific action is masked by the more far-reaching effects on peptidoglycan transpeptidases that these substances also exert In any event, the specific action of FL 1060 should add to the already impressive list of antibiotics that have furthered our understanding of cellular processes

Teleost ancestry, or naming of parts

from B G Gardiner

COMPARATIVE biology is concerned with evolutionary theory and the history of life It is within the second domain that Colin Patterson's monumental paper " The braincase of pholidophorid and leptolepid fishes, with a review of the actinopterygian b r a i n case" (*Phil Trans R Soc*, **269**, 305, 1975) falls In the past hundred years there have been many great comparative works on fishes, notably those of Allis, Jarvik, Nielsen, Stensio and Woodward The use of Hennig's theoretical (phylogenetic) framework however has allowed Patterson to reach more clearly defined objectives than envisaged by his predecessors, while in carrying through the necessary rigorous com-

Patterson's restoration of the neurocranium and attached dermal bones of *Pholidophorus bechi* (from *Phil Tran R Soc*, **269**, 1975)

parative work he has achieved a breadth of study which sets a new standard for the future

Palaeontologists in the past have frequently set out to answer different questions about the history of life In particular they have searched for ancestors and have tried to reconstruct series of ancestor–descendant relationships (for example Chondrostean-Holostean–Teleost) Patterson rejects this approach as unprofitable since it has led to a fruitless search for confirmation of hypotheses Instead his paper shows the great value of the Hennigian framework, which approaches phylogeny through a direct comparison of present-day forms, looking for collateral descendants with a common ancestor (which remains hypothetical) In this way the investigator can formulate testable hypotheses in response to precisely stated problems

Patterson's paper provides the first comprehensive account of the Mesozoic pholidophorid and leptolepid fishes, which are of outstanding interest because they stand in the same relation to living teleosts as do their contemporaries the late Triassic and Jurassic m a m m a l s and 'quasimammals', to living mammals The morphological series he describes illuminates many problems of actinopterygian evolution and ancestry As well as clearing up the history of the cranial fissure and the ossification pattern of the actinopterygian braincase and snout, Patterson confirms the homology between the spiracular groove of primitive actinopterygians (the group

which includes most present-day bony fishes) and the 'prespiracular groove' of rhipidistians (an entirely fossil group) In so doing he rejects the hypothesis that the intercranial joint of rhipidistians and coelacanths is a primitive one related to those between vertebrae and confirms the view of T H Huxley in his Croonian lecture of 1858 in which he said, "It is no more true that the adult skull is a modified vertebral column, than it would be to affirm that the vertebral column is a modified skull"

Patterson has been meticulous in naming of parts, that is in tracing homologous structures throughout his series of fishes and naming them accordingly But, like Huxley, he has realised that the possession of common structures alone does not necessarily lend support to the evolutionary hypothesis unless such structures can be deemed to be 'shared specialisations' of unique origin—found nowhere except in the species under consideration It is in this context that Patterson has analysed the ossification of the braincase and the closure of the cranial fissure with the concomitant displacement of the pterotic by the epioccipital and the loss of the opisthotic and the endochondral portion of the intercalar. The phylogenetic homologies he has demonstrated show the dangers of the topographic approach, which assumes that a bone in a particular position in a series must always be the same bone

Although there are no practical limits to comparative studies, and further development may be confidently predicted, it is fair to conclude that in

a hundred years time Patterson's work will stand much as it does now, a milestone in comparative palaeontology

Palaeontologists keenly anticipate parts 2 and 3 of this work, which Patterson promises on the palate, lower jaws, gills, shoulder girdles and remaining dermal bones

Icelandic layer 3 identified?

from Peter J Smith

THE upwelling of magma to form new lithosphere at oceanic ridges is easy to envisage in general terms, but lack of access prevents any direct investigation of the detailed processes involved In the study of constructive plate margins, the existence of subaerial conditions such as those of Iceland is therefore invaluable, even though by definition such environments are not entirely typical of oceanic ridge zones Indeed, insofar as it may also lie above a rising mantle plume, Iceland itself may be even more atypical than it was considered to be in the days when only a single magma source was envisaged But be that as it may, the few land masses astride ridges offer a unique opportunity of studying an important plate tectonic feature using more traditional geological techniques

G P L Walker began his extensive field studies in Iceland long before any of these ideas were conceived, let alone widely accepted, and over the years he has been able to throw much valuable light on the island's remarkable characteristics But that much still remains to be learned is well illustrated by his latest report (*J Geol Soc*, 131, 143, 1975) in which he draws attention to the significance of a striking geological feature which has until now been largely ignored—the remarkable swarm of inclined basic intrusive sheets which cuts the Tertiary and early Quaternary volcanic pile along the south-east coast

The swarm is impressive by any standards, being exposed over a zone of about 1,700 km² Over a third of that area the sheets comprise more than 10% of the total rock, and over their 100 km² of greatest concentration they account for more than 80% of the total In all, there are tens of thousands of individual sheets with typical thicknesses of 0 2–2 0 m, chilled margins and thickness-related grain size (the thinnest sheets are basaltic, the thickest gabbroic) They increase rapidly in number down the dip, taking the concentration from less than 1% of the total rock at the top to more than 50% within a drop of only a few hundred metres Moreover, the dip angle is itself

Oceanic polarity test fails

from Peter J Smith

IN view of the critical roles of magnetic anomalies and the geomagnetic polarity-time scale as evidence for seafloor spreading, it would be desirable to measure the magnetic polarities of as many oceanic rocks as possible Unfortunately, most of the igneous rocks recovered so far from the ocean floor have been unoriented dredge samples In some cases the tops of pillow lavas may be recognised, and this limited orientation is sufficient to allow polarity to be determined by conventional palaeomagnetic methods But for the majority of samples for which this procedure is not possible, Irving (*Can J Earth Sci*, 5, 1319, 1968) devised a method of determining polarity which involved comparison of the coercive force spectrum of a rock's natural remanent magnetisation with that of an artificially induced anhysteretic moment

As applied by Irving to five Cainozoic basalt samples of known orientation, the method seemed to work And in a similar test, Brooke *et al* (*Can J Earth Sci*, 7, 1515, 1970) obtained a success rate of 11 out of 12 But in a thorough study by Mohajer-Ashjai (*Can J Earth Sci*, 12, 62, 1975) on 20 lavas from Oregon and Mull, agreement between known and predicted polarities has been obtained in only 10 cases Not surprisingly, Mohajer-Ashjai concludes that the Irving technique is not reliable enough Although it is not completely worthless (since the probability of getting a 50% agreement purely by chance is less than 0 054) it seems that unoriented dredge samples will be of little use as a source of magnetic information about the oceanic crust

closely related to the concentration of sheets, being less than 10° where sheets are scarce or absent but increasing to 35°–50° where they are most abundant Lastly, and significantly, the direction in which the sheets dip is downwards towards the spreading axis—the same direction as the less steeply dipping country rocks

How did this remarkable swarm originate? The answer, Walker argues, is by a very simple mechanism involving density contrasts between the Icelandic crust and the uprising magma As basaltic magma rises, its density changes because of the onset of vesiculation caused by the exsolution of dissolved

gases Generally, this change (decrease) will take place at depths less than 1 km, but different batches of magma with different volatile or phenocryst contents and different chemical compositions will begin to decrease in density at slightly different levels within this range

The presence of these variations raises the possibility that under certain circumstances different batches of magma may behave in quite different ways as they move up through the crust For example, the variations could be critical if the density–depth profiles for the magma were close to that for the solid crust, which seems to be the case in the upper 4 km Below a depth of about 4 km, the density of all the magma is undoubtedly lower than that of the crust, and so the magma will rise in that region In the upper 4 km, however, where the magmatic and crustal density profiles are comparable, two possibilities arise If the density of the magma never anywhere rises above that of the crust, the magma will continue its ascent until it reaches the surface and eruption results On the other hand, if the magma density does rise above the crustal density at some point, the vertical progress of the magma will be there arrested

Walker's proposal is that some of the magma does one thing and some does the other In particular, the magma that reaches a level at which its density equals that of the surrounding crust then ceases to rise and, instead, moves away laterally along an equi-density surface as an intrusive sheet An obvious difficulty with this view is that in practice the solidified intrusive sheets are not actually horizontal but are inclined away from the spreading centre with an inclination that decreases up the dip However, there are several factors which could account for equi-density surfaces of variable slope, including a non-even distribution of dykes across the width of the active zone, temperature variations in the country rock and an infilling of the voids in the country rock by zeolites in certain areas All three could contribute to density variations in the crust, although the dyke distribution is thought to be the most important In addition, however, as the magma sheet rises up-slope its density will decrease, especially if vesicles begin to form, and so it may actually cross equi-density surfaces and move towards crustal rocks of lower density

According to Walker, therefore, the existence of the swarm of inclined basic intrusive sheets may be explained in terms of processes at the spreading axis, albeit modified by the particular crustal environment through which the axis passes But if that is the case, why are such sheets limited to this particular

part of Iceland? Perhaps they are not In Walker's view, the sheets are only exposed in this part of Iceland because the erosion here has been particularly severe He proposes that the sheet swarm actually "constitutes a widespread and integral part of the structure of Iceland and is not merely a local phenomenon" Elsewhere it is not seen because it lies below sea level

He then goes on to identify this widespread swarm with crustal layer 3 Of the four main crustal layers identified seismically beneath Iceland, layers 0, 1 and 2 have been interpreted reasonably as basalt lavas and associated rocks But the nature of layer 3, which has an average thickness of 6 km and begins at an average depth of 3 5–4 0 km, is still unknown Certainly a layer 3 of basic intrusive material should have the right P wave velocity (6 35 km s^{-1}) The next step should therefore be to test Walker's hypothesis by measuring seismic velocities within the sheet swarm in south-east Iceland It is unfortunate that all previous seismic profiles were run outside the swarm or in parts of it where the concentration of sheets is very low

Group selection

from Robert M May

MANY animals seem to exhibit altruistic behaviour, whereby individuals sacrifice their own interests for the good of the group The 'warning cries' uttered by some birds are an example the individual puts his own life at greater risk for the benefit of his fellows Many other apparent examples are to be found in the patterns of behaviour with which animals regulate their population density

But natural selection acts on individuals, not groups It has been argued that 'group selection' (the evolution of traits which are advantageous at the group level, but disadvantageous at the individual level) cannot take place within the classical Darwinian framework

In many cases, closer study reveals that seemingly altruistic behaviour directly benefits the individual as well as his group, thus removing any paradox In other cases, group selection can be seen to derive from kin selection the altruist's actions are of direct advantage to his relatives, and therefore his gene type is favoured by his action, even if his own life is not As W D Hamilton has pointed out, social insects probably exhibit extreme examples of kin selection In the Hymenoptera, females are more closely related to their sisters than to their daughters, and so from a genetic point of view they do better to care for a sister than

to devote an equal amount of care to their own offspring

There remain, however, examples of apparent group selection which cannot be evaded by the above arguments Maynard Smith, Levins, Boorman and Levitt and others have tried to construct mathematical models which exhibit the phenomenon These models envisage a population distributed over many islands or other such environmental patches, with occasional migration between patches They seek to show that when a 'selfish gene' appears it will (by classical individual selection) take over the local population, but that the consequent disadvantage to this group as a whole may cause its extinction before the selfish gene can spread to the other populations All these models require the most delicate tuning if the desired effect is to be exhibited, and none of them constitutes a truly plausible explanation for group selection

Recently, two different models have been proposed, both of which exhibit group selection in a robust fashion

The first of these was suggested by May, and has independently been elaborated at monograph length by Gilpin (*Group Selection in Predator–Prey Communities*, Princeton University Press, 1975) These models take advantage of specifically nonlinear aspects of predator–prey or plant–herbivore interactions, which can produce stable oscillatory patterns in population density Small advantages to the selfish individual can now be nonlinearly magnified into disastrously large amplitudes of population oscillation for his group The result is that group selection can be rapid and powerful, although selfish genes continue to appear by mutation, the groups in which they appear are quickly extinguished before they spread

A simpler and more compelling mechanism has been pointed out by Wilson (*Proc natn Acad Sci U S A*, 72, 143–146, 1975) As in essentially all these models, first suppose the total population is constituted of several isolated groups Periodically these populations are mixed together and then redispersed (One may think of the annual episodes of winged dispersal among so many insects) The population contains two genotypes altruists, *a*, and selfish non-altruists, *b* Wilson notes that it can be that in each group the altruists suffer higher mortality than the non-altruists, but that nevertheless the overall proportion of altruists in the population can increase from generation to generation

This statistical paradox is familiar in other areas, for example medical biometrics, and is best illustrated with a numerical example To fix ideas, let *a* be birds which give warning cries,

thereby decreasing the average mortality in their group at the expense of increasing their own mortality rate relative to the selfish *b* Suppose we have two patches the first containing 25*a* and 75*b*, the second 75*a* and 25*b* Initially *a* therefore constitutes 50% of the population The birds in the first patch suffer higher mortality by virtue of the smaller complement of altruists, just before the next dispersal phase there are, say, 30 individuals, 6*a* and 24*b* The second group does better, coming down to, say, 70 individuals, 50*a* and 20*b* Note that in both groups the fraction of altruists, *a*, has decreased (from 25% to 20% in the first, and from 75% to 71% in the second), but that the altruistic genotype has increased in the population as a whole (from 50% to 56%)

Wilson's model has the quality of *a posteriori* obviousness which characterises so much of the best in science It illustrates group selection, pure and simple

Emplacement of intrusions

from G M Brown

THE geological evolution of the British Isles is a long and complex story but one period is particularly well understood, due to a prodigious amount of scientific investigation since the 1920s Relatively recently in geological time, about 60 million years ago in the early Tertiary, active volcanoes erupted in what is now north-west Britain Vast outpourings of basaltic lava were succeeded by the emplacement of a very complex array of igneous bodies in the form of dykes, cone sheets, ring dykes and other intrusive masses The rock types are variable but include, predominantly, the products of medium to slow crystallisation of basaltic and granitic magmas The intrusive complexes are believed to represent generally the eroded cores of central-type volcanoes that developed, as in Iceland, on and within the plateaux of the earlier flood lavas Remnants of the flood lavas are preserved particularly well in Antrim but also in the Scottish Inner Hebrides The later, central volcanic complexes constitute the bulk of many of the Hebridean islands such as Arran, Rhum, Mull and Skye, as well as Ardnamurchan (mainland Scotland) and the Mournes and Carlingford mountain regions in northern Ireland

The volcanic regions have been mapped in ever-increasing detail, including geophysical measurement, by British geologists, and a host of laboratory studies has been conducted on the phase petrology, mineralogy and

geochemistry aimed at understanding the genesis of the rock suites Yet the mechanism of emplacement of the intrusive complexes has remained a major problem Walker (*J Geol Soc Lond*, **131**, 121, 1975) has now provided a first, really new and comprehensive explanation since the earlier hypotheses of Bailey, Richey, Harker and associates (chiefly 1904–1936) Those hypotheses were based chiefly on the concept that some intrusions were facilitated by pressures exerted upwards by underlying magma bodies while others were formed during the release of such pressures and the downward collapse of crustal blocks The mechanisms were quantified by reference to Anderson's classic work (1936) on the dynamics of formation of cone-sheets (upward pressure), ring dykes and cauldron subsidences (downward collapse) Since then, refinement of Anderson's hypothesis rather than an alternative hypothesis has been the characteristic of modern, sparse work on the problem

Walker's paper, in his own words, " presents no new geological facts but sifts some of the great volume of existing data " The data are drawn from the meticulous observations and superb geological maps produced by the earlier Geological Survey staff referred to From that, and his own observations in Iceland, he proposes radically that the main control of emplacement mechanics was the uprise of granitic diapirs in the region, early in the history of each Tertiary intrusive centre The Goatfell granite body in northern Arran is quoted as a good example 'of such a diapir, but other examples are described Granitic liquid would have a low magma density of about 2 3, and an analysis is made of the relationships between hydrostatic (magma) pressures and lithostatic (load) pressures in the vicinity of such diapirs The construction of isopiestic (equal pressure) surfaces, after the manner of Bradley (1965), results in models that are convincing when related to the forms of intrusions in the volcanic centres, and to the early-published evidence for early doming and annular folding at most centres

Basaltic magmas, associated with the main volcanic outpourings would, according to Walker, generate granitic (acid) magmas below the surface to the point at which a large body of granitic magma develops, rises as a diapir, and grows during ascent (100–1,000 Km³) Basaltic magma would be channelled into a magma trap at its base and develop into a cylindrical prism of basic intrusives as the diapir rises The granitic body would release effusive magmas when it reached the surface, and thus diminish in size, while the basic rocks would rise in its wake

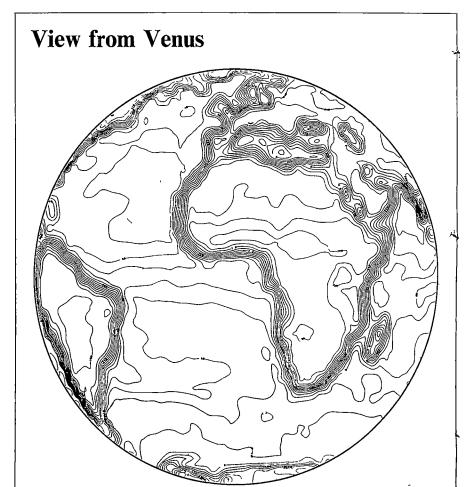
View from Venus


Image corresponding to 0 h The contour interval is 10 K with every other contour labelled From Webster, Chang, Darby and Finkelstein, *Icarus*, **24**, 144, 1975

RADIO observations of the planets are all very well, but they would be better still if we had a benchmark against which to judge them Webster *et al* have now provided such a benchmark by using Nimbus 5 observations at 19 35 GHz to produce a "degraded and smoothed" simulation of what the Earth would look like to a radio astronomer on Venus armed with an instrument with a resolving power of 1″ The clear boundary between land and sea would, it seems, make it possible to determine very accurately the rate of rotation of the Earth, and also show up large permanent features (see figure) On this evidence and that obtained from radio studies of Mars and Venus, the Earth is undoubtedly the most interesting of the inner planets

Other batches of magma would be diverted to zones outside the diapiric zones, where excess hydrostatic pressures existed (the model explains cone-sheet formation in this way) Late subsidence of the cylinder of basic intrusives below the diapir could provide for outward dipping structures such as ring-dyke and bell-jar (curved flange) intrusives

The hypothesis is difficult to fault on the basis of a vast and otherwise embarrassing array of good quality, earlier field observational data It is welcome because Anderson's model has long been found wanting, especially in regard to the role of his postulated ring-dyke mechanics The need, now, is for a more rigorous consideration of

Walker's model, especially from a possible refinement of the density data and a more detailed analysis of pressure relations and diapiric movement applied to mobile granitic magmas Certain assertions in the paper, peripheral to the main argument but nevertheless relevant, are not immediately acceptable Walker refers to the Rhum ultrabasic rocks as representing ultrabasic magma (not necessarily so), and does not face up to the sequence of events in central Skye (granitic complexes later, rather than earlier than the Cuillins layered basic intrusives) He postulates a development of igneous layering parallel to the inclined floors of gabbro intrusions of "confluent cone-sheet type" whereas such layering, if con-

trolled by gravitational crystal settling, as he accepts it, is independent of a pre-existing floor slope Some pertinent, recent publications on the Ardnamurchan cone sheets and the Skye hybrid (marscoite) bodies are not referred to Early tidying-up is a natural requisite for an hypothesis that will need severe testing

The mechanics of emplacement is a local problem, whereas the genesis of the British Tertiary magmas relates to universal problems Work over the past decade or so has concentrated on the latter, and yet the origin of the granitic magmas remains in dispute Most petrological, experimental and isotopic studies favour an origin by remelting of the crustal rocks (anatexis) rather than by crystal fractionation of the basaltic magmas Walker's model leaves little doubt that only crustal remelting is acceptable, yet surprisingly he does not refer to that clue or to magma genesis in general His granitic diapirs are shown as developing before the underlying cylinder of basic intrusives has crystallised, which would be impossible if they were late fractions of a solidifying basic intrusive, quite apart from the fact that only a very small volume of granite is produced by the latter process Proponents of the fractionation hypothesis will not approve of Walker's granitic diapirs, which makes it all the more important that his hypothesis be explored to the full, and consideration be given to the several broader petrogenetic implications

Silicon wafers without sawing

from Andrew Holmes-Siedle

ONE annoying deficiency in semiconductor device technology today is the limitation in size of the single-crystal ingots of semiconductors (such as silicon) which can be grown Nearly all mass-produced ingots are grown by slow pulling from the melt (the Czochralski method) The best ingots that can be produced in this way are about two inches in diameter and six inches long Thus, in silicon device factories, devices are formed on thin wafers cut from such ingots in a direction perpendicular to the long axis, like slices of sausage Neither the size nor shape are conducive to good yield of devices in large production runs of transistors, integrated circuits or other 'small-signal devices'

For the simpler solar cell diode, area is the dominant factor Indeed, a square foot would be a good area for a single cell, such an area just cannot be obtained at the moment, even by the expensive method of cutting ingots along the long axis, as in sawing a

plank Instead, an array of little cells has to be wired together, which greatly increases the cost and lowers the reliability of solar panels

For these reasons, crystal growers have for a long time been exploring ways of making silicon crystals of larger area which might eliminate wasteful and arduous sawing and polishing One technique which has recently raised hopes could be regarded as two-dimensional pulling of crystals Crystallisation proceeds along a thin film of molten silicon lying in a mould The method can be turned into a flow process if the film can be generated continuously A ribbon, of theoretically unlimited length could then be produced Tyco Laboratories, of Boston, have been exploring this process, termed edge-defined film-fed growth (EFG) As yet, few of the ribbons produced are single-crystal, most consist of large polycrystals which themselves contain imperfections in the form of dense tangles of dislocations Nevertheless, there is often a dominance of one crystal orientation at the surface It is thus possible that, under the right conditions, one might be able to promote totally single-crystal growth in a layer of silicon deposited on to the ribbon by one of the known epitaxial growth techniques

Now one epitaxial growth technique is already widely used to improve the properties of integrated circuits formed on ingot-grown silicon wafers This is the so-called chemical vapour deposition method The layers grown are several micrometres thick and are of excellent single-crystal quality The advantage of this deposition method is that only flowing gases are involved and the method, again a flow process, can probably be scaled up to cover large areas

Thus, the process for making large, though imperfect silicon wafers in one step can possibly be married to this already widespread epitaxial growth technique to form a production method which yields large ribbons of crystalline silicon (it should be noted here that, for most active semiconductor devices, all of the electronic functions occur in a layer a few micrometres thick at one surface only)

Henry Kressel and co-workers at RCA Laboratories are the first to report this marriage In *Applied Physics Letters* (25, 197, 1974) they note the happy result that, when the epitaxial growth from the vapour is carried out on ribbons of p-type silicon, made by Tyco Laboratories using the EFG technique, the defects in the original wafer are not strongly propagated into the newly forming crystalline lattice This is shown clearly in X-ray topographs but more to the point is the finding that p–n diodes

with good minority-carrier lifetime, good breakdown voltages and low leakage currents can be made by putting down first p-type and then n-type layers on to this silicon ribbon Although the ribbon used by the investigators were only 1 3 cm wide, there is no basic bar to scaling this up by an order of magnitude Ribbbon lengths of 2 metres, and widths of 2 5 cm have been reported unofficially

For the integrated-circuit and transistor manufacturer, the availability of such ribbons could give the era of single-crystal devices a new lease of life, maintaining the price-competitiveness of this form against the rapidly developing and currently less expensive thin-film device fabrication methods

For the solar array designers, the prospect of cheaper, more reliable solar panels is improved if the ribbon method succeeds Indeed, it is probably no coincidence that the work at RCA took place under the supervision of Paul Rappaport, one of the pioneers of the silicon photovoltaic device and co-author of a recent survey for the National Academy of Sciences on the terrestrial use of solar converters The latest news over the agency wires is that, despite some remaining problems with crystallinity, preparations are being made to make ribbon silicon on a factory scale

Chromosomal proteins and control of transcription

from a Correspondent

> The Florida Colloquium on Molecular Biology "Chromosomal Proteins and Their Role in the Regulation of Gene Expression" was held at the University of Florida in Gainesville on March 13 and 14

ALTHOUGH there have been many reports correlating changes in non-histone chromatin proteins with alterations in gene expression, there has to date been little direct evidence linking the two processes Encouraging however were reports from two laboratories of direct demonstrations that nonhistone chromatin proteins mediate control of transcription of the histone and globin genes G S Stein (University of Florida, Gainesville) has synthesised a DNA complementary to histone mRNAs and used it to establish that the transcription of histone genes from chromatin is restricted to the S phase of the cell cycle Chromatin re-

construction experiments showed that the nonhistone proteins of S phase chromatin are responsible for regulating the transcription of histone mRNA sequences R S Gilmour and J Paul (Beatson Institute for Cancer Research, Glasgow) have provided evidence using reconstruction experiments that in chromatin of mouse foetal liver cells and DMSO-stimulated Friend cells nonhistone proteins render globin genes transcribable In both the histone and globin transcription studies the potential interference of endogenous RNA was ruled out There has been some concern about both chromatin reconstitution and the use of bacterial polymerases for chromatin transcription, but the histone and globin systems at least seem amenable to these approaches

Several laboratories are engaged in isolating and characterising defined nonhistone chromatin protein fractions and exploring their functions H Busch (Baylor College of Medicine, Houston) has been isolating chromatin and nucleolar proteins by differential salt extraction and fractionating them on a preparative scale by two-dimensional polyacrylamide gel electrophoresis His group has purified and is at present sequencing a protein whose appearance is correlated with nucleolar activation

Another technique which has been much used for fractionation of chromatin proteins is DNA affinity chromatography V Allfrey (Rockefeller University, New York) described new methods for the fractionation of nuclear nonhistone proteins which utilised DNA of various average C_0t values covalently attached to solid supports such as amino-ethyl sepharose, Sephadex G25 and Sephadex G200 This method yields reproducible fractions some of which interact preferentially with 'moderately reiterated' sequences while others bind to unique DNA sequences Some of the DNA binding proteins exhibit a high and selective affinity for cyclic AMP or cyclic GMP G Patel (University of Georgia, Athens) described a class of proteins which do not exhibit species-specific binding but rather display a preference for AT-rich and single-stranded DNA T Y Wang (State University of New York, Buffalo) reported the isolation of two nonhistone protein fractions from *Ehrlich ascites* tumour chromatin, one which activates and the other which suppresses transcription of DNA *in vitro* The action of each of these protein fractions requires the homologous RNA polymerase II and homologous DNA The inhibitory protein, which is electrophoretically homogeneous, blocks RNA synthesis at initiation prior to formation of the first phosphodiester bond

There seemed to be a general consensus that DNA binding fractions are enriched in phosphoproteins Though DNA affinity chromatography appears to be an effective method for fractionation of chromatin proteins, caution must be exercised in concluding that *in vitro* binding reflects biological activity

T C Spelsberg (Mayo Clinic, Rochester) discussed the specificity of the binding of progesterone–receptor to hen oviduct nuclei and chromatin Although multiple levels of binding were observed in all tissues examined, the highest affinity binding was only detected in chromatin from target tissues The removal of one nonhistone protein fraction 'AP3' resulted in loss of high affinity binding

For some time phosphorylation of chromatin proteins has been correlated with the activation of transcription in a variety of biological systems Consistent with these observations, studies by R Platz and L S Hnilica (University of Texas, Houston) indicated that during sea urchin development the rate and specificity of nonhistone protein phosphorylation reflects the process of differentiation

L J Kleinsmith (University of Michigan, Ann Arbor) described the properties of two principal nuclear components of the chromatin protein phosphorylation mechanism Twelve kinase activities were identified, several being cyclic AMP-dependent and others refractory to or even inhibited by cyclic nucleotides Nuclear phosphatase activity was also described Dr Kleinsmith, with G Stein and J Stein, has also found that enzymatic dephosphorylation of nonhistone chromatin proteins from S phase HeLa cells resulted in a reduction in chromatin template activity and in the transcription of histone mRNA sequences The latter studies provide evidence for a functional relationship between phosphorylation of nonhistone chromatin proteins and RNA transcription

● Histones were not entirely overlooked at the colloquium R Chalkley (University of Iowa) addressed the problem of deposition of preexisting and newly synthesised histones on replicating DNA He showed that in contrast to DNA, which is replicated in a semiconservative fashion, histones are randomly distributed between the preexisting and newly replicated DNA strands

T Langan (University of Colorado, Denver) presented evidence that there are two types of F_1 histone phosphorylation, which can be distinguished on the basis of the specific amino acid residue phosphorylated and the requirement for cyclic AMP Phosphorylation of serine 37 takes place in non-

proliferating cells following hormonal or cyclic AMP stimulation Phosphorylation of amino acid residues other than serine 37 is strongly correlated with the rate of cell growth and is unaffected by cyclic nucleotides Distinct enzymes which catalyse the two types of F_1 phosphorylation reactions have been isolated P Byvoet (University of Florida, Gainesville) discussed the enigmatic phenomenon of histone methylation and its possible role in the maintenance of chromatin structure He showed that agents which are capable of intercalating into the DNA double helix increased the extent of histone methylation

● The last portion of the colloquium was concerned with the arrangement of proteins on DNA in chromatin B Sollner-Webb and G Felsenfeld (NIH, Bethesda) have examined the structure of chromatin, both purified and within nuclei, by digestion with *staphylococcus* nuclease The kinetics of nuclease digestion are consistent with the "beads on a string" arrangement of chromatin Sollner-Webb and Felsenfeld also presented evidence which suggests that the organisation of proteins in the neighbourhood of globin genes differs between reticulocyte chromatin, which actively transcribes globin mRNA, and erythrocyte chromatin where globin transcription is largely repressed In reticulocyte chromatin a distinct segment of the globin gene is not accessible to poly-D-lysine binding, presumably because it is covered by chromatin proteins In erythrocyte chromatin the entire globin sequences seem to be present in both poly-D-lysine accessible and inaccessible regions J Gottesfeld and J Bonner (California Institute of Technology, Pasadena) described a method for isolating a template-active chromatin fraction by digestion with DNase II The DNA of this fraction contained a subset of the total genetic sequences which is partially tissue-specific The template-active fraction has a decreased histone content, totally lacks histone I, and is enriched in nonhistone protein Limit digests of total chromatin with DNase II revealed nucleoprotein bodies equivalent to those described by Sollner-Webb and Felsenfeld But limit digests of the template-active fraction did not yield these nucleohistone particles

Mantle deformation beneath the South African and Siberian platforms

G. D. Borley

Department of Geology, Imperial College, London, UK

Xenoliths of mantle lherzolite from kimberlite pipes in Africa and Siberian Yakutia have undergone deformation and thermal excitation of some of their constituent minerals Their deformation states support the view that the mantle deforms systematically by creep processes resulting from shearing stress initiated, perhaps, during plate movement

XENOLITHS thought to represent material from the deeper parts of the upper mantle are brought to the surface in kimberlite magmas The most frequently occurring xenoliths are of lherzolite (olivine + ortho and clinopyroxene ± pyrope garnet), harzburgite (olivine + ortho-pyroxene ± pyrope garnet), eclogite (garnet + soda–alumina rich clinopyroxene), and pyroxenite Less frequent, or rare, xenoliths are the kyanite and corundum eclogites, and grospydites which contain a garnet rich in calcium, plus pyroxene and kyanite[1-6]

Lherzolite xenoliths from the kimberlite pipes in Africa provide evidence of deformation of the Earth's mantle[7-15], they fall into broadly-defined textural categories

Granular xenoliths of medium to coarse grain-size (1–5 mm), with weak microscopic fabrics, in which olivine and pyroxene show various strain effects, including undulose extinction, microfractures, kink and deformation bands and lamellae, slip-planes, and subgrain development, contain normal calcic-

diopsides that seemingly re-equilibrated at temperatures between 900 and 1,100 °C and at depths between 100 and 150 km (refs 7–10)

Xenoliths with variable microscopic fabric patterns containing porphyroclasts seem to have suffered increasingly intense shearing stresses through progressive deformation proceeding through a combination of creep (especially in olivine) and subgrain development The diopsides in these lherzolites become increasingly subcalcic with deformation and seem to have re-equilibrated at temperatures between 1,100 °C and 1,400 °C at depths between 150 km and 190 km (refs 7–10) The most intensely deformed of these lherzolites grade into types with a distinctively striped foliation, and they contain sparsely distributed relic porphyroclasts of partly granulated pyroxene with porphyroclasts of undeformed pyrope garnet

I have examined deformed lherzolites from African kimberlites contained in the Imperial College collection, similar lherzolites in the collection of A Nicholas (Nantes University), and xenoliths from the Siberian Yakutia kimberlite pipes, in the collection of N Sobolev

These comparative studies of deformed lherzolites indicate that similar types of lherzolite from the deeper parts of the upper mantle in widely separated regions have had similar deformation histories Compositional data on the minerals from these lherzolites also indicate that their thermal states may be comparable

Petrography of deformed lherzolites

I will describe two lherzolites which are considered to be typical of the deformed varieties one from the Jagersfontein (South Africa) kimberlite, and one from the Udachnaya kimberlite pipe in Siberian Yakutia

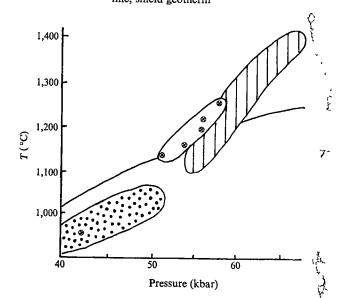
In the lherzolite from Jagersfontein porphyroclasts of enstatite and diopside have been drawn out into lozenge and spindle shaped, partly granulated relicts and, together with undeformed porphyroclasts of pyrope garnet, they are set in a granoblastic-polygonal[15-18] matrix of olivine grains 100 µm or larger in size Small relict porphyroclasts of pyroxene merge outwards into irregularly shaped sub-grains with diffuse boundaries and finally (particularly in enstatite), into outer zones of polygonal grains many of which have triple-point junctions, these grains are of the order of 25 µm or less in size Narrow zones of fine-grained enstatite run from the apices of the granulated relict porphyroclasts into the olivine matrix, which they cut sharply These zones of crystals, which resemble stripes, give the most deformed lherzolites the foliation that typifies hand specimens, they seem to have been produced by a late, intensive, shearing during which stresses have been taken up by pyroxene rather than by the already deformed olivine The lherzolite Ud.5 (Yd 5 in Table 1) comes from the Udachnaya pipe which is located in the Daldyn–Alakit region of Siberian Yakutia north of the Arctic Circle and near the edge of the Siberian platform[6] About 70 thin sections of some 40 lherzolite xenoliths from the Udachnaya pipe were examined About 75 % of these were deformed, the rest had coarse-grained, undeformed textures[7-10,15]

Ud 5 is typical of the deformed varieties and shows an early stage in the development of the striped foliation It contains a few relict olivine porphyroclasts, together with elongate or lozenge-shaped porphyroclasts of partly granulated enstatite and diopside, and undeformed pyrope garnet These porphyroclasts are set in an olivine matrix that has a granoblastic-polygonal texture and an average grain size between 70 and 100 µm

The larger subgrains in the partly granulated enstatite have diffuse boundaries and merge into the relict porphyroclast, the small (25–30 µm), polygonal, grains are furthest away from the relict grain Some zones of matrix olivine are separated from each other by the stripes, and some of the matrix olivine grains have flattened tops as though they were sheared off, or the grains changed shape by diffusion of material away from points of stress[19] Both the Jagersfontein and the Udachnaya lherzolite xenoliths have textures transitional to the most intensely deformed lherzolites described from African kimberlite pipes[11,13]

Thermal history and origin

The pyroxenes in deformed or sheared lherzolites from African kimberlites have re-equilibrated at high temperatures and pressures[7-10], the greater the degree of deformation the higher the temperature and pressure Since many of the Udachnaya lherzolites show comparable degrees and types of deformation it is clearly important to determine whether their pyroxenes also re-equilibrated under high P/T conditions

The temperature of re-equilibration of diopside that coexists with enstatite can be determined if the diopside contains low molecular proportions of ferrosilite and jadeite In these circumstances re-equilibration temperatures can be obtained by applying the experimentally determined temperatures for compositions on the diopside–enstatite solvus at a pressure of 30 kbar to the Ca/(Ca+Mg) ratios of the natural minerals[9,10,16] Using this method for several diopsides from the Udachnaya lherzolites (analyses in ref 6, selected examples in Table 1) gives re-equilibration temperatures between 1,130 and 1,250 °C for minerals from the deformed xenoliths, and a low temperature of 950 °C for diopside (Yd 111 in Table 1) from a granular


one These temperatures compare with those obtained for diopsides from deformed and undeformed African lherzolite xenoliths[7-10]

To estimate pressures of re-equilibration, and therefore depths of origin of the lherzolites, it is necessary to know or Al_2O_3 content of the enstatite that coexists with the diopside and pyrope garnet Then, the experimental data on the solubility of Al_2O_3 in enstatite at different temperatures and pressures can be used[17], after adjustment has been made to allow for Al_2O_3 combined with Na_2O in the jadeite molecule. Unfortunately data are not yet available on the pressures at which the solubility of Al_2O_3 in enstatite falls below 1 %

A few analyses of coexisting diopside–enstatite pairs from the Udachnaya garnet-bearing lherzolites are available (Table 1), and they show that a major problem in applying the experimental data on Al_2O_3 solubility in enstatite at different pressures is that the Udachnaya enstatites contain <1 % Al_2O_3 These amounts are reduced still further if allowance is made for Al_2O_3 combined with Na_2O in jadeite But it seems reasonable to assume that the pressures at which the Udachnaya enstatites re-equilibrated were probably not less than those defined at various temperatures by the 1 % Al_2O_3 isopleth in the experimental system[17], and the latter has been used in conjunction with the re-equilibration temperatures from the coexisting diopsides to provide rough approximations of the pressures This gives re-equilibration pressures of 50–59 kbar (or depths of origin between approximately 165 and 180 km) for the deformed lherzolites, and 42 kbar (depth of origin approximately 130 km) for the granular variety Again, these figures compare with those for the African lherzolite xenoliths

In Fig 1 the data for the pyroxenes from Udachnaya lherzolites have been plotted in a way similar to that used for the African lherzolite xenoliths[7-10] Accepting that compositional problems make the plots of the Udachnaya data slightly less accurate than those for the African material, two important features are still apparent First, the data for the Udachnaya lherzolite xenoliths plot close to or in similar fields to the data for the African xenoliths Second, the re-equilibration temperatures of diopsides from the deformed lherzolite xenoliths of both Udachnaya and African kimberlite pipes rise sharply with increasing pressure and both the trends are oblique to that for the shield geotherm In effect, diopsides from both sets of deformed lherzolite xenoliths are thermally excited and their re-equilibration temperatures apparently lie along a geotherm referred to as 'perturbed'[9]

Fig. 1 Udachnaya pyroxene data Stippled, diopsides from 'granular' lherzolites (Africa)[9], hatched, diopsides from 'sheared' lherzolites (Africa)[9], Udachnaya diopsides[6], solid line, shield geotherm

Further implications

Accepting that the observed deformation of the thermally excited lherzolites took place in the mantle it is possible, from ? petrographic and chemical data, to make some general observations on the state of lherzolite assemblages below a depth of 150 km in the mantle below the African and Siberian platforms

First, deformation of the lherzolites seems to be systematic, increases with depth of origin of the kimberlite magmas to at least 190 km and apparently proceeds through a combination of creep and subgrain formation The deformation is accompanied by thermal excitation of the pyroxenes that coexist with pyrope garnet and olivine in these assemblages Minor compositional differences in constituent minerals and therefore in the bulk lherzolite assemblages, for example like those that exist between the minerals of the Siberian Yakutia and African xenoliths[6-10], do not significantly affect the general correlation between thermal and deformation states in lherzolites at depth (Fig 1)

Second, the constituent minerals in the lherzolites deform in a systematic fashion[11,12,15] and in a particular order Olivine deforms more easily, and at an earlier stage, than enstatite, which seems to deform a little more readily than diopside Pyrope garnet usually remains undeformed to depths of at least 190 km, though slight granulation of the mineral has been observed in one or two highly deformed lherzolites

Third, there seem to be limits to the grain sizes attained by individual minerals during deformation For example in early stages of deformation of the lherzolites, matrix olivine grains may be of the order of 300 μm or a little less[11], but in later stages, when enstatite and diopside have commenced granulation, matrix olivine grains may be of the order of 50–100 μm Olivine grains smaller than 40 μm are infrequent in xenoliths I have examined Enstatite forms small (25–35 μm) grains, during early stages of its deformation, but in the most deformed lherzolites enstatite grains as small as 10 μm have been observed[11,15] Enstatite, or diopside, grains smaller than this do not seem to have been described

Fourth, there is no evidence of lherzolites in which diopside has re-equilibrated at temperatures higher than 1,450 °C (refs 9 and 10 and Fig 1), although this may in part be a function of unavailability of material from depths much greater than 200 km I note, however, that the T/P gradient for deformed lherzolites in Fig 1 is much steeper than that of the shield geotherm, and it may be that further stress at depths > 200 km could increase temperatures to the point where small volumes of partial melt were produced in the lherzolites, rather than further deformation and mineral re-equilibration

A major problem in geology at the moment is to account for the correlation between deformation states of lherzolite xenoliths from depths 150–190 km and the fact that P/T re-equilibration data for their pyroxenes plot along a 'perturbed' geotherm (Fig 1) It has been suggested that this perturbation of the geotherm took place during plate movement when Gondwanaland fragmented during the Mesozoic, the resulting shearing stresses causing deformation and frictional heating in the lherzolite assemblages at depth[9] A difficulty in totally accepting this view at the moment is that xenolith-bearing kimberlites from Africa and Siberia range in age from pre-Cambrian to post-Cretaceous and we do not know if deformation is restricted to lherzolite xenoliths that give Mesozoic dates The age of the Udachnaya kimberlite pipe in Yakutia is unfortunately uncertain with K/A determinations on phlogopite and olivine giving dates ranging from upper Palaeozoic to late Jurassic respectively[21] But it is clear that only a general, and major, event (or series of such events) could have produced comparable textures and thermal states in lherzolites from widely separated regions in the Earth's mantle It may be, as some geologists now believe, that plate movement has been operative since the Precambrian and that deformed lherzolites provide a record of the way the mantle has reacted to stress over a long period of time

I thank the Royal Society for a travel grant, the Royal Society and the Academy of Sciences of the USSR for arranging a visit to Siberia and Professor V Sobolev and Dr N Sobolev for help

The chemistry of sea salt aerosol and its measurement

M. P. Paterson & R. S. Scorer

Air Pollution Research Group, Mathematics Department, Imperial College, London SW7, UK

The chemistry of precipitation (rain and snow) has been extensively monitored since the 1950s, with the analysis performed for nine ions in solution It has been suggested that this monitoring should be extended to include the analysis for heavy metals The examination of results which we report here indicate that routine measurement of one of the most common ions, sodium, has been of too low a quality to prove the most significant current theory about its behaviour in the atmosphere

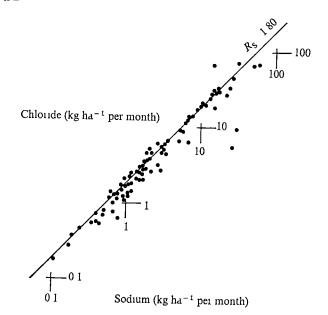
OF the nine ions which are measured[1]—SO_4^{2-}, Cl^-, NO_3^-, NH_4^+, K^+, Mg^{2+}, Ca^{2+} and H^+—only sodium and chloride are closely related in atmospheric occurrence in that the major source of both is the sea They occur in seawater in a Cl-Na ratio of 1 80 by weight, which is signified by R_s in this paper If there were no other sources, and no separation of the two ions in samples of sea salt aerosol, their weight ratio would always be R_s, whatever the degree of dilution Other land sources of chloride[2,3] and sodium[4] have been suggested but not proven to be of any significance in precipitation chemistry The most substantial and widely


Fig. 1 Monthly amounts of chloride and sodium in precipitation at three coastal stations of the European Air Chemistry Network in southern Sweden and Norway, 23, 38 and 53, for the period 1960–62 The observed values of the Cl–Na weight ratio fall close to the ratio in seawater, 1 80, which is signified by R_s Deviations from R_s are distributed similarly among months with large and small amounts of salt in precipitation

accepted, if controversial, theory about sea salt in the atmosphere is the Cauer hypothesis[5] which states that the sea salt chloride and sodium are separated by chemical or photochemical action in the air and that, from pure sea salt origins, the ratio of chloride to sodium in precipitation, signified by R, can range below and above R_s Early measurements in Sweden[6] seemed to bear out this theory but a re-examination of the data has suggested that the principal support for the theory, the large deficit of chloride in precipitation near the coast, resulted from incorrect chemical analysis[7]

Discrepancies in monitoring data

An examination of monitoring data has shown discrepancies across national boundaries in Europe, similar to discrepancies in the calcium–magnesium ratio which have been reported elsewhere[8] In the UK there is a discrepancy between results obtained by different laboratories The dominance of sea salt as a source allows us to identify one laboratory as being most probably correct A characteristic of the results from the other laboratory is found in data from monitoring networks in other parts of the world, suggesting that their results should be critically re-examined Figure 1 shows the monthly amounts of sodium and chloride at several coastal stations in Norway and Sweden over a period of 3 yr Deviations from R_s are equally distributed among months where the amounts of salt were large and small In considering the distribution of the deviations from R_s we will disregard the absolute amounts of salt and treat only the value of R We will consider the distribution in time of deviations and determine whether the observed distribution could arise from geochemical phenomena or from laboratory factors

Where deviations from R_s result from phenomena which modify the sea salt while it is suspended as an aerosol, the same phenomena should affect samples at adjacent stations in the same month A phenomenon which causes a high value of R at European Air Chemistry Network (EACN) stations 23, 38 and 53 in southern Norway and Sweden should also produce high values at stations 69, 70 and 71 in Denmark Whether it would also affect station 54 in northern Norway is a matter for conjecture A laboratory cause for a set of high values could be

either the dispatch of a contaminated set of bottles to the stations or a deviation in the analysis for either sodium or chloride when a month's samples have been returned If it is a rare event it is unlikely to coincide with a similar event another laboratory We have selected the period 1959–63 f analysis because, for the first half of that time the Danish samples were analysed in Copenhagen with samples from 12 other Danish stations The Norwegian and Swedish samples were analysed in Stockholm The Danish analysis was discontinued in May 1961 After August 1961 the samples from Danish stations 69, 70 and 71 were analysed in Stockholm together with the samples from about 30 Norwegian and Swedish stations We can thus compare, for the same set of stations, the degree of coincidence of high or low values of R when analysed at either one or two laboratories

Table 1 shows the occurrence of values of R less than 1 50 and greater than 2 16 during the 60-month period Samples were collected at each of the seven stations in 44 months, during which time the Danish samples were analysed in Copenhagen for the first 21 months The results are expressed in the contingency tables (Table 2) which give the number of occasions on which none, one, two, three or four of the four Swedish and Norwegian stations experienced low (or high) values of R tabulated against the simultaneous occurrence of

low (or high) values at none, one, two or three Danish stations Table 2a covers the 21 months during which two laboratories operated Table 2b covers the period when all samples were analysed in Stockholm

Table 2 shows that the two laboratories produce low (and high) values of R at different times In the first period, when the analysis was carried out in separate laboratories, on none of the three occasions on which three or more of the Stockholm results fell below 1 50 did more than one Danish result fall below 1 50 From Table 2a (i), we see that of the five occasions on which two or three of the Danish stations recorded low results, on none of these did more than one Swedish or Norwegian station record a low result Similarly with the occurrence of high values, in Table 2a (ii), although the situation is less clear in this as only thirteen high values were recorded at the seven stations in 21 months

In the second period, when all samples were analysed in Stockholm, a clear association appeared between high (or low) values in Denmark and high (or low) values in Sweden and Norway Table 2b (i) shows that on four occasions low values were recorded for two or more stations in each section of the network, and b (ii) shows that on three occasions high values were recorded at at least two stations in each section of the network

What does this tell us about the records of the Network? There is a factor, unrelated to the chemistry of sea salt aerosol or precipitation, which leads occasionally to the finding of Cl–Na ratios in precipitation which deviate significantly from the sea salt ratio If we can take the simultaneous presence of three or four deviant values out of a possible four as evidence of its occurrence then the results of most of the Norwegian and Swedish stations are affected by it one month in four In assessing the significance of the factor to the records of the EACN we must consider not the number of occasions on which it occurs but the number of observations which are changed by the factor The occurrence of three low values of R

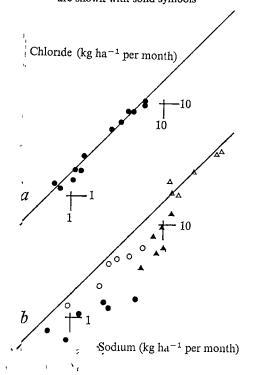
in Denmark and three in Norway and Sweden n one month, counted as a single occurrence of the factor in the contingency tables above, will affect the records as much as single occurrences of low values of R on six different months Seen in this light Table 2b (i) and (ii) indicates the following score for seven stations during 23 months (Table 3)

If this interpretation is accepted then it seems that at least 23% of the coastal precipitation sample analyses in Stockholm deviate significantly from R_s because of the factor Not more than 17% deviate from R_s because of other causes Thus, there is no strong evidence for a deviation from the sea salt ratio as a result of natural causes such as have been proposed by Rossby and Egnér[6] or by Eriksson[9] If any such deviation does occur at coastal stations it is so subtle as to be masked by an artefact of the network which we believe to be a laboratory factor

In the UK, where precipitation sampling and chemical analysis has been performed since 1957 by the Meteorological Office in the traditional EACN way, a second programme has been commenced by the Atomic Energy Research Establishment (AERE) using neutron activation, X-ray fluorescence and other techniques which differ from those used by the EACN The AERE results which we quote here have been taken from a report which was published in 1972[10] The AERE monthly results for Wraymires, in Cumbria, in 1971 are plotted on Fig 2a with Cl and Na on logarithmic scales In all months R falls close to R_s When the excess Cl, or Na, is estimated for each month the total of each for the year is a 3% excess of Cl and a 5% excess of Na, which are barely greater than the measurement errors At the EACN station at Eskdalemuir, for which the monthly amounts of Cl and Na are shown in Figure 2b, there were no months with excess Cl The excess Na amounted to 97% of the Na from a presumed sea salt source It would not be unreasonable to assume that at Eskdalemuir, 110 km north of Wraymires, there is a and source which, throughout the year, contributes as much sodium to the precipitation as does the sea Such an assumption s not borne out by an examination of the Lerwick results for the same period

At Lerwick, which is a maritime site receiving ten times as much sea salt as Eskdalemuir, there is also a great excess of sodium, as seen in Fig 2b Could this come from a local land source? The excess amounts to 25% of the sea salt sodium over the year and in total quantity is 2 5 times the excess at Eskdalemuir It would require a very strong land source of sodium in the Shetlands for such an observation to be real But if there were a Shetlands source it would have to operate in sympathy with that near Eskdalemuir because the two stations experience high, and low, values of R in the same months Figure 2b shows that in 1971 the low values of R occurred at both stations between April and September It is most unlikely that so many common factors relate the chemistry of precipitation at Lerwick and at Eskdalemuir, which are 550 km apart and very differently exposed to sea and land sources, while Eskdalemuir and Wraymires, which are 110 km apart and similarly exposed, have little in common if the data is all to be believed The significant factor relating Lerwick and Eskdalemuir is that samples from both are analysed in the one laboratory Yet it is the Wraymires results, from a different laboratory using quite different analytical methods, which conform to the most reasonable expectation about the

Table 3

	Number	%
Total number of observations	161	
Observations of R between 1 50 and 2 16	96	60
Low values attributable to the factor	21	13
Low values not necessarily attributable	20	12
High values attributable to the factor	16	10
High values not necessarily attributable	8	5


chemistry ofprecipitation This is that the predominant source of both chloride and sodium is the sea, and that these two ions remain associated during their transport on the wind in just the way they are associated in seawater It seems that the system which produces the EACN results should be examined to discover thecause of the incorrect sodium or chloride analyses J L Browrscombe and M S Porter (Meteorological Office, private communication) report that the phenomenon to which B C Oddie referred has recurred in some but not all of the later years ind that it does not occur in all of the three rain ranges nowoperating at Lerwick

The UK is just one of a number of countries which are participating in the EACN Although there are minor local variations, ill laboratories are using a similar set of analytical methods Only in the UK can we be reasonably certain about the deficiencies of the EACN precipitation analysis We would like, thougl, to point out certain similarities in results from other countries which might indicate that similar deficiencies exist there

In Fig 3a the annual total of Cl and Na are plotted for a number of UK stations for the years 1960–62 The most maritime station, Lerwick, receives an apparently small fractional excess of sodium and the inland stations, including Eskdalemuir, receive larger fractional excesses That exces was less in 1960–62 than in 1971, also shown in Fig 3a, the year for which we have compared Eskdalemuir and Wraymires But the previous section of this paper has demonstrated that the excess at Eskdalemuir is almost certainly illusory On common-sense grounds, and the basis of the experience at Scandinavian coastal stations which were discussed at the beginning of this paper, there is even more reason to believe that the excess sodium at Lerwick is illusory Thus, the fractional deviations from R_s, which are largest where the amount of salt is least, seem to be generated by deficiencies in the system But the UK is not the only country to record such characteristics In Fig 3b are plotted for various countries he annual amounts of chloride and sodium for several stations in the years noted on the diagram It is evident that in broad terms the results from each of these are similar to those for the UK This is not indisputable proof that there are deficiencies in analysis in each of these countries But before the

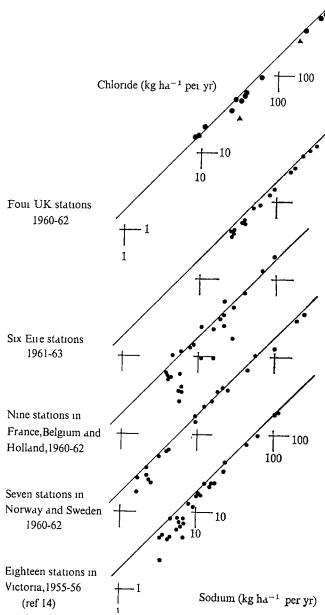
Fig. 2 For 1971, the monthly amounts of Cl and Na in precipitation recorded a, by the AERE at Wraymires (●), b, by the Meteordogical Office at Eskdalemuir (O, ●) and at Lerwick(△, ▲) In b the months between April and September are shown with solid symbols


Fig. 3 Annual amounts of chloride and sodium in precipitation at a number of stations of the EACN in various countries, and in Victoria, Australia In each country there is a tendency for excess sodium to occur, the fractional excess over sea salt being greater where salt amounts are least

excess sodium is advanced as evidence of either land sources of sodium or chemical processes in the air transforming the sea salt aerosol, as for example that by Oddie[11], the possibility that it is an artefact of the system of chemical analysis should be considered Before any further monitoring is done such artefacts should be eliminated

There is an increasing awareness that data quality control programmes must be built into routine monitoring of the environment[12,13] The EACN experience with sodium and chloride analysis should alert us to one hazard of such programmes if all laboratories cooperating in a programme of sample exchange are using the same analytical methods, or perhaps the same sample bottles, there is a possibility that all are recording the same bias, thereby allaying justified fears about the various possible forms of interference with results While the internal consistency of data from coastal stations has given us a sufficient test when sea salt is plentiful, it was only the availability of a novel analysis which allowed us to determine that sea salt is the principal source of both sodium and chloride in precipitation at some inland stations

Paracoccus denitrificans and the evolutionary origin of the mitochondrion

Philip John & F. R. Whatley

Botany School, South Parks Road, Oxford OX1 3RA, UK

It is demonstrated that Paracoccus denitrificans *resembles a mitochondrion more closely than do other bacteria, in that it effectively assembles in a single organism those features of the mitochondrial respiratory chain and oxidative phosphorylation which are otherwise distributed at random among most other aerobic bacteria A feasible evolutionary transition from the plasma membrane of an ancestral aerobic bacterium resembling* P denitrificans *to the inner mitochondrial membrane is suggested*

ACCORDING to the endosymbiotic theory of the evolutionary origin of the eukaryotic cell, as developed by Margulis[1], the mitochondrion has evolved from a free-living prokaryote resembling a present-day aerobic bacterium, which had been taken up by a plastid-free, amoeboid cell, the protoeukaryote, that depended on fermentation for the production of ATP In time the prokaryote suffered a progressive loss of autonomy, its proliferation kept pace with the cell division of its host, many of its biosynthetic capabilities were lost or taken over by its host, and its metabolism became integrated with that of its host

The endosymbiotic theory implies that the outer mitochondrial membrane is derived from the protoeukaryote, and that the inner mitochondrial membrane and its invaginations (the cristae) are homologous with the plasma membrane of present-day bacteria Here we describe the modifications of the bacterial plasma membrane which would be necessitated by the evolutionary transition from a free-living, aerobic bacterium resembling *Paracoccus denitrificans* (previously *Micrococcus denitrificans*[2]) to a mitochondrion In this transition the ATPase and the constitutive components of the respiratory chain are retained, the adaptive components of the respiratory chain are lost, and the transport properties of the plasma membrane are altered so that, in its new role as the inner mitochondrial membrane, it is able to integrate the metabolism of the organelle with that of the surrounding cell We chose *P denitrificans* as a plausible ancestor because, when all possible biochemical parameters are compared, it resembles a mitochondrion much more closely than do other aerobic bacteria This comparison is summarised below and will be presented in detail elsewhere[3]

Comparison

Those mitochondrial features which *P denitrificans* possesses, and which have a widespread (or perhaps universal) distribution among those bacteria which can make a respiratory chain, include nicotinamide dinucleotide trans-

hydrogenase[4,5], NADH and succinate dehydrogenases[6-8], and the tricarboxylic acid cycle[9,10]

Those mitochondrial features which *P denitrificans* possesses, but which have a limited distribution among other bacteria, include phosphatidyl choline as a major constituent of the membrane phospholipid fraction[11,12], straight-chain saturated and unsaturated fatty acids accounting for nearly all the membrane fatty acids[11,13,14], ubiquinone-10 as the sole functional quinone of the respiratory chain[6,15,16], two *b*-type and two *c*-type cytochromes as easily distinguishable components of the respiratory chain of aerobically grown cells[16-19], cytochrome *aa₃* as the cytochrome oxidase[6,16,20], and a sensitivity to low concentrations of antimycin A and rotenone, both of which are inhibitors of mitochondrial electron transport[16,21] (see Fig 1) Furthermore, mitochondrial cytochrome *c* more closely resembles the soluble cytochrome *c* isolated from *P denitrificans* than the *c*-type cytochromes isolated from other bacteria, in both physical and structural properties[22-24] The soluble cytochrome *c* of *P denitrificans* is unusual among bacterial *c*-type cytochromes in that it is to a large extent interchangeable with mitochondrial cytochrome *c* in its ability to react with mitochondrial cytochrome oxidase[22,25-27] and with the two cytochrome oxidases of *P denitrificans*, that is, the constitutive cytochrome *aa₃*[27,28] and the inducible cytochrome *cd*, which functions *in vivo* as a nitrite reductase[28,29]

Furthermore, *P denitrificans*, like *Hydrogenomonas eutropha*[31] but unlike *Escherichia coli*[32] and *Bacillus megaterium*[33], resembles a mitochondrion[34,35] in the stoichiometry of oxidative phosphorylation as indicated by measuring H⁺/O ratios Phosphorylating particles prepared from the plasma membrane of *P denitrificans* show a mitochondrial type of respiratory control[36,37] that is rarely observed in other phosphorylating bacterial preparations[8,38] As in mitochondria the respiratory rate is increased by the addition of ADP (respiratory control), or by the addition of carbonylcyanide-*p*-trifluoromethoxyphenylhydrazone (FCCP) (an uncoupler of oxidative phosphorylation) and decreased by the addition of venturicidin which, like oligomycin, inhibits ATPase[39] (Fig 2)

We should like to emphasise that although none of these mitochondrial features is unique to *P denitrificans* no other species of bacterium possesses as many[3] *Rhodopseudomonas spheroides*, however, when grown aerobically in the dark has a mitochondrial type of respiratory chain[19], but the stoichiometry of oxidative phosphorylation and the presence of respiratory control are not known Future research will probably reveal that *P denitrificans* is not unique in the degree to which it resembles a mitochondrion, and it will then be viewed as a representative of a small group of aerobic bacteria (probably including *Rps spheroides*) all having an obvious affinity with the mitochondrion

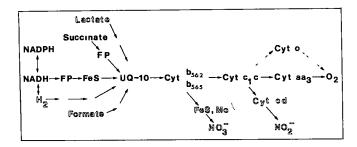
In addition to the mitochondrial features found in *P*


Fig. 1 The respiratory chain of mitochondrion and of *P denitrificans* Components of the mitochondrial respiratory chain, and of the constitutive respiratory chain of *P denitrificans* are in heavy print, the additional adaptive components of the respiratory chain of *P denitrificans* are in lighter print Cytochrome *o* has been found in the mitochondria of only a few organisms[68], and its significance in the constitutive respiratory chain of *P denitrificans* is not known From ref 3

denitrificans described above, there seems to be no significant feature of the mitochondrial respiratory chain or ATPase which is present in another bacterium, but known to be absent from *P denitrificans*

Most of the differences between the respiratory chains of a mitochondrion and *P denitrificans* can be accounted for by the presence in *P denitrificans* of adaptive components which are absent from mitochondria These adaptive components may be viewed as *ad hoc* additions to the constitutive portion of the respiratory chain, which is itself essentially similar to the mitochondrial respiratory chain (Fig 1) The constitutive components of the respiratory chain of *P denitrificans* are nicotinamide nucleotide transhydrogenase, NADH and succinate dehydrogenases, flavoprotein, iron–sulphur proteins, ubiquinone-10, cytochromes of the *b*-type and *c*-type, and cytochrome *aa₃* The adaptive components are hydrogenase, formate and lactate dehydrogenases, nitrate reductase, and nitrite reductase (cytochrome *cd*) (Fig 1)

In their criticism of the endosymbiotic theory, Raff and Mahler[40] pointed out that, although aerobic bacteria possess cytochrome respiratory chains similar in function to mitochondrial cytochromes, "there are significant differences which suggest a considerable evolutionary divergence between mitochondrial and bacterial cytochromes" The differences cited are (1) the insensitivity of bacterial electron transport systems to some of the generally used inhibitors of mitochondrial electron transport, (2) the greater variety of bacterial cytochromes, (3) the poor cross reactivity of mitochondrial cytochrome *c* with most bacterial cytochrome oxidases, and vice versa, and (4) the dissimilarities in the primary sequence, redox potential and isoelectric point of bacterial and mitochondrial *c*-type cytochromes We have noted above that while differences (1), (3) and (4) may apply to bacteria in general, these differences do not apply to *P denitrificans* and *Rps spheroides* since in these respects these bacteria resemble the mitochondrion while most other aerobic bacteria do not Furthermore, it is shown below that the presence in *P denitrificans* of "bacterial" cytochromes in addition to "mitochondrial" cytochromes raises no serious objection to an evolutionary transition from an aerobic bacterium resembling *P denitrificans* to a mitochondrion, since these "bacterial" cytochromes are readily dispensed with under the appropriate environmental conditions

Hypothetical evolutionary transition

A hypothetical transition from an aerobic bacterium resembling *P denitrificans* to a mitochondrion, as envisaged by the endosymbiotic theory[1], would involve the loss of the adaptive components and the retention of the constitutive components of the respiratory chain of *P denitrificans*

(Fig 1) The synthesis of the adaptive components in *P denitrificans* is readily suppressed in the presence of alternative electron donors or electron acceptors that are "more acceptable" Hydrogenase, for example, is present only when cells are grown in the presence of hydrogen and in the absence of organic compounds such as glucose[41], and nitrate reductase is absent from cells grown aerobically in the presence of nitrate[42] Similarly cells of *P denitrificans* grown anaerobically in the presence of nitrate can use either nitrate or oxygen as terminal electron acceptors but, when both are supplied, use oxygen in preference to nitrate[3,43]

The postulated evolutionary transition does not require the adoption of new features by the constitutive respiratory chain of *P denitrificans*, although modification of some components may occur The limited extent of such changes is clear from X-ray structure analyses[24] of the readily solubilised *c*-type cytochromes of *P denitrificans* and of the mitochondrion The indications are that there is a very considerable similarity in the amino acid sequences of the two cytochromes[24] The exact extent of this similarity will be revealed by the detailed amino acid sequencing now being carried out (E Margoliash, personal communication)

The similarity in the H^+/O ratios observed with *P denitrificans* and with the mitochondrion imply that the respiratory chain is arranged in a similar way in the plasma membrane of *P denitrificans* and in the inner mitochondrial membrane The ATPases are also essentially similar in their mode of operation in *P denitrificans* and in a mitochondrion[44], suggesting that the process of oxidative phosphorylation need not be altered during the evolution of the mitochondrion

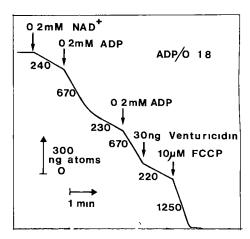
So far, the proposed evolutionary transition from an aerobic bacterium resembling *P denitrificans* has not necessitated the acquisition by its plasma membrane of any entirely new features, nor has it involved a significant alteration in the mode of operation of those features already present When the respective transport systems of *P denitrificans* and a mitochondrion are compared, however, it becomes apparent that there are mitochondrial features not found in bacteria, such as *P denitrificans*, as well as bacterial features not found in mitochondria Furthermore, some carriers operate in a different way in bacteria and mitochondria


Fig 2 Mitochondrial type of respiratory control in particles prepared from *P denitrificans* Membrane particles were prepared by a slight modification of the procedure of John and Hamilton[37] The reaction mixture contained, in a total volume of 3 ml 30 μmol Tris-acetate (pH 7 3), 15 μmol magnesium acetate, 30 μl ethanol, 0 1 mg alcohol dehydrogenase (Sigma A7011), and 0 54 mg particle protein Further additions were made as indicated Oxygen uptake was measured in a Clark-type oxygen electrode at 30 °C The ADP/O ratio was calculated as described for mitochondria by Chance and Williams[69] The numbers alongside the traces refer to the rates of oxygen uptake in ng atoms per min per mg protein
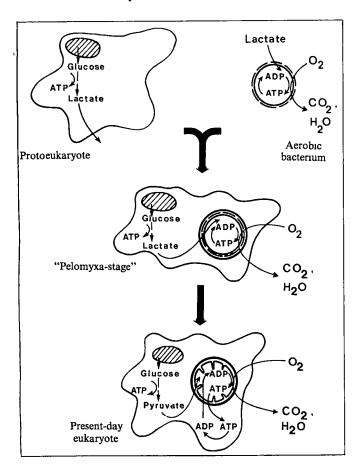

Fig 3 Hypothetical evolutionary transition from a free-living aerobic bacterium to a mitochondrion A fermenting proto-eukaryote takes up a respiring bacterium to the advantage of both partners (the "Pelomyxa-stage", where lactate, the end product of fermentation, serves as the respiratory substrate for the bacterium) By the acquisition of an adenine nucleotide carrier the ATP synthesising potential of the bacterium is made available to the host cell (present-day eukaryote, containing mitochondria)

As with those features of the respiratory system, which are present in *P denitrificans* but are absent from mitochondria, so also the transport systems which are uniquely bacterial can be related to the potentially more varied and unstable environment of bacteria compared with that of mitochondria These bacterial transport systems, which would be lost in the transition to a mitochondrion, include carriers responsible for sugar transport, the periplasmic binding proteins and the extracellular iron chelators[45,46]

Both the plasma membrane of *P denitrificans* (J Burnell, P J , and F R W , in preparation) and the inner mitochondrial membrane[47] contain a sulphydryl-sensitive, phosphate carrier which mediates the uptake of P_i coupled to the simultaneous uptake of protons by an electroneutral process equivalent to the proton-symport of Mitchell[48] Thus this carrier, already present in the plasma membrane of *P denitrificans*, would require no modification to operate in the mitochondrion

On the other hand, the sulphate carriers in *P denitrificans* and in a mitochondrion seem to operate by different mechanisms In *P denitrificans* sulphate is accumulated by an electroneutral proton-symport (J Burnell, P J , and F R W , in preparation) whereas, in mitochondria, sulphate permeates the inner mitochondrial membrane principally in exchange for succinate or malate[49] Similarly, while carboxylate carriers in a number of aerobic bacteria[50-53] probably bring about the uptake of carboxylates coupled to the simultaneous uptake of protons[46], mitochondrial di- and tricarboxylate carriers act as exchange

diffusion carriers, mediating the electroneutral, equimolar P_i-dicarboxylate, dicarboxylate–tricarboxylate, and heterologous dicarboxylate–dicarboxylate exchanges[47] The carboxylate exchange carriers of the inner mitochondrial membrane clearly function to integrate the operation of the tricarboxylic acid cycle in the mitochondrial matrix with extramitochondrial metabolism[54] On the other hand, the carboxylate carriers of the bacterial membrane function simply in the accumulative uptake of carboxylates from the bacterial environment Thus in an evolutionary transition from an aerobic bacterium resembling *P denitrificans* to a mitochondrion, modification would be necessary to the mechanism of the sulphate and carboxylate carriers from a proton-symport (equivalent to an hydroxyl-exchange) to a sulphate–carboxylate, carboxylate–carboxylate, and carboxylate–P_i exchange

The only new component necessary for an evolutionary transition from the plasma membrane of *P denitrificans* to the inner mitochondrial membrane is the adenine nucleotide carrier[55], which seems to be absent from all bacteria and present in all mitochondria This carrier makes ATP, synthesised on the matrix (inner) side of the mitochondrial membrane[56], available to the ATP-utilising sites in the rest of the cell

If it be assumed that the protomitochondrion was tolerated by its host for a sufficient length of time for a stable symbiotic relationship to have developed before the acquisition of the adenine nucleotide carrier by the protomitochondrion, then it is necessary to consider what advantage this protomitochondrion may have conferred on its host for the symbiotic relationship to have survived the selective pressures to which it was exposed We suggest that the protomitochondrion, by virtue of its tricarboxylic acid cycle and respiratory chain, was able to completely oxidise fermentation products such as lactic acid and ethanol, which may have accumulated to potentially toxic levels in a relatively large and undifferentiated protoeukaryote dependent on the Emden–Meyerhof pathway for the production of ATP (Fig 3) In support of this conjecture we may note that the giant amoeba *Pelomyxa palustris*, which lacks mitochondria but contains respiratory, endosymbiotic bacteria[57-59], uses the Emden–Meyerhof pathway to supply its energy needs, produces lactic acid but has a requirement for oxygen[60], presumably for its endosymbiotic partners[58] *P denitrificans* could serve in such a role, since it can utilise both lactic acid and ethanol as sources of energy and carbon[61]

The most conspicuous morphological features of the mitochondrion are the invaginations of the inner membrane, termed cristae By contrast the plasma membrane of *P denitrificans* does not project into the interior of the cell, but remains applied to the internal surface of the cell wall[62,63] Presumably the development of cristae would be associated with the progressive specialisation of the aerobic bacterium resembling *P denitrificans* essentially into a generator of ATP by oxidative phosphorylation As this bacterium assumed its new role as a mitochondrion, the plasma membrane, as the site of oxidative phosphorylation, would increase in importance relative to the bacterial cytoplasm, which, as the site of redundant metabolic activities, would decrease in importance Reflecting these changes, we could expect an expansion in the surface area of the plasma membrane, and a contraction in the volume of the cytoplasm, thus leading to the development of cristae

Integration

By endowing the ancestor of the mitochondrion with the properties of the present-day bacterium *P denitrificans*, we have provided a plausible account of the evolutionary origin of the inner mitochondrial membrane from the bacterial

plasma membrane The major changes involved in this transition are first, the loss of redundant components of the bacterial respiratory chain and, second, a modification in the transport properties of the bacterial plasma membrane, so that effective biochemical communication is attained between the mitochondrial matrix and the rest of the cell

Many of the components of the mitochondrion that we believe to have come from the ancestral bacterium are now coded for in the nucleus and not in the mitochondrion[64,65] This implies that gene transfer has occurred during the evolution of the mitochondrion from a *Paracoccus*-like ancestor Support for this conclusion may well come from comparing the amino acid sequence of the soluble cytochrome cytochrome *c* from *P denitrificans* (when it is published) with the amino acid sequence of mitochondrial cytochrome *c*

The evidence provided here lends support to the endosymbiotic theory, firstly, by removing some of the objections raised by previous authors[40], concerning the affinity of bacterial and mitochondrial respiratory chains and, secondly, by offering a feasible evolutionary transition from a bacterial plasma membrane to the inner mitochondrial membrane This evidence on its own is, however, not incompatible with the non-symbiotic evolutionary origin of the mitochondrion proposed by Raff and Mahler[40], since their theory considers features common to bacteria and mitochondria to be "retained primitive states"[66] Furthermore, the changes which we have described for an evolutionary origin of the inner mitochondrial membrane from the plasma membrane of an aerobic bacterium resembling *P denitrificans* would also apply to an evolutionary origin of the inner mitochondrial membrane from the plasma membrane of an aerobic protoeukaryote possessing a respiratory system similar to that of *P denitrificans* Having noted these points, however, we agree with Taylor[67] that it is "unrealistic to discuss the origin of mitochondria independently from that of chloroplasts" Thus it is in the context of the greater applicability of the endosymbiotic theory to explain the evolutionary origin of the eukaryotic cell as a whole[67] that we have chosen to compare *P denitrificans* with the mitochondrion and to show how a relationship of limited advantage to both symbiotic partners could readily have developed into the present close relationship between a mitochondrion and its "host" cell

letters to nature

Search for continuous gravitational radiation

WE have given[1] results of a search for short pulses of gravitational radiation carried out with two gravitational radiation detectors operating in coincidence over a frequency range from 650 to 1,450 Hz Detectors of that type may also be used within this frequency region to set upper limits to fluxes of gravitational radiation of either continuous or incoherent waveform The latter may include pulses which occur at a high rate but are too small to be detected individually We describe here a preliminary experiment designed to search for any such signals in a general way

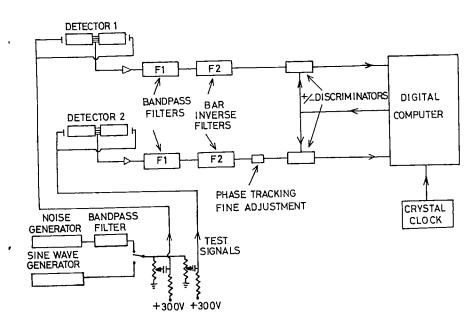
If the expected signal waveform is known there are specialised methods which can optimise the sensitivity of such an experiment For example a continuous repetitive waveform of known repetition rate and wave shape, buried in the noise from a detector, can be recovered with high sensitivity by cross correlation against a reference waveform of the same characteristics,


Fig. 1 Simplified block diagram of the cross correlation experiment The sine wave and noise generators shown are used for calibration F2 is a special filter with a null in its response at the resonant frequency of the bar and has the effect of giving an approximately flat non-resonant response to the whole system within the bandwidth of the bandpass filter F1

or a monochromatic continuous signal can be detected by means of a Fourier transform technique In a search for a signal of unknown type and waveform from a gravitational wave detector in the presence of noise, however, a more general technique is required The technique used in this experiment was the cross correlation of the outputs from two gravitational wave detectors This procedure allows signals common to both detectors in the presence of noise (which may contain a number of spurious detector resonances) to be recovered

Although our search was sensitive to gravitational radiation of several different waveforms, for simplicity in this preliminary experiment we tested our apparatus and set upper limits for two types of radiation first, continuous monochromatic radiation as may be produced by a rapidly rotating neutron star, and second, broadband gravitational radiation

Previous searches for gravitational waves of monochromatic and broadband type have been made at very low frequencies, although a search for monochromatic radiation from pulsars at frequencies up to 125 Hz has been reported[2] An upper limit to broadband radiation has also been set by a laser interferometer gravitational radiation detector operating above 1 kHz (ref 3) Our experiment sets a more sensitive upper limit for both broadband and monochromatic radiation in the frequency region around 1 kHz

Each of our detectors consists of two separate aluminium masses linked by piezoelectric transducers to monitor changes in separation, this arrangement giving relatively high coupling between the mechanical and electrical systems The signal from the transducers passes to a very low noise field effect transistor preamplifier and then through filters F1 and F2 (Fig 1) The overall bandwidth was set at 160 Hz, centred on 985 Hz, this being estimated as the optimum bandwidth for the detection of white noise signals This is narrower than the optimum bandwidth for a pulse search[1]

The signals from the filter F2 represent the forces acting on the detectors and are further processed and then cross correlated by a small on line computer During most of our runs the polarity of the signals from one of the preamplifiers was reversed periodically and data for reversed and normal operation were recorded separately This procedure is a useful test for any electronic coupling between the signals from the two detectors occurring at any point in the whole system after the preamplifiers The recorded data were subsequently combined taking account of the polarity reversal

Cross correlation entails the multiplication of the signal from one detector $x(t)$ by the signal from the other detector delayed by a time τ, ($y(t-\tau)$), and the cross correlation function

$R(\tau)$ for this delay is the average value of the product over the time of the experiment T

$$R(\tau) = (1/T) \int_0^T x(t)y(t-\tau)\mathrm{d}t$$

If both signals are sampled every Δt seconds for input to a computer the correlation function R_n becomes

$$R_n = (1/K') \sum_{k=1}^{k=K'} x(k\Delta t)y(k\Delta t - n\Delta t), \quad n \ll K'$$

and the variation of R_n with n can give information as to the waveform of any signal common to the two detectors In conditions of low signal-to-noise ratio, little information is lost[4,5] if the correlation is performed on polarity alone The filtered signals from the detectors are sampled and have their sign determined at regular intervals by a discriminator–latch circuit controlled through our computer by a crystal clock A '1 bit' cross correlation on the data is then computed The signs of the signals at each sampling time are recorded and a number of successive sign samples from the first detector are stored in order, this store being updated each time a new sample is taken The current sample from the second detector is compared with each of the samples from the first one and the result ($+1$ if they are of the same sign, -1 if they are different) is added to the results for previous samples In this way a number which is related to the cross correlation function is found as a function of delay between the detectors, and these numbers are displayed as our delay curves

Our maximum possible sampling rate was limited by the length of programme to 2 kHz and with this 17 correlation points 0 5 ms apart were obtained To record the delay curve with more detail in the region near zero delay, some runs were made in which the data were recorded on an analogue tape recorder and subsequently slowed down by a factor of 4 for analysis off line

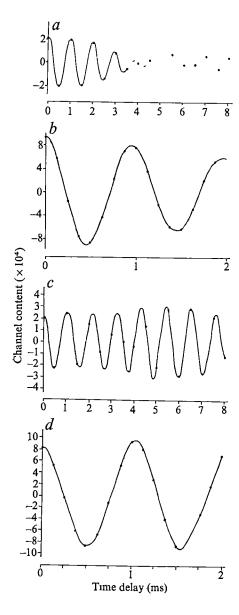
Calibration was carried out by applying signals of known waveform to the capacitative endplates of both detectors simultaneously Both broadband noise and sine waveforms off the resonant frequencies of the detectors were used, the energy deposited per unit time in the detectors being measured in the first case and the force applied known in the latter case From these the amplitudes of the delay curves were found in


Fig. 2 Delay curves for calibration force waveforms applied to the detectors by means of capacitative endplates, *a* and *b* are the curves for an applied broadband noise waveform *a*, Obtained by on-line analysis of the data, *b*, off-line analysis of the same data recorded and slowed down by a factor of 4 *c* and *d* are equivalent curves for a sinusoidal calibration waveform at 910 Hz

number of short experiments The dotted lines in the figures indicate the root mean square deviation from the mean expected from uncorrelated data, found in this way In making a comparison with the experimental curves, allowances have to be made for the fact that successive points in any one delay curve are correlated among themselves over a time scale of about 3 ms because of the bandwidth of the system The experimental data do not show to any significant extent the waveforms in the test curves of Fig 2, do not show any persistent pattern from run to run and are in fact quite consistent with completely independent noise inputs from the two detectors The curve with the largest amplitude near zero delay is that in Fig 3*c* but the most extreme point corresponds to only 1 4 standard deviations from the mean

We conclude that the data give no indication of correlated signals from the two detectors From the measured properties of the detectors it is possible to set upper limits to fluxes of gravitational radiation signals of various types, and as mentioned earlier we can set limits on wideband gravitational flux and on monochromatic radiation in our frequency band

Fig. 3 Delay curves with no calibration forces applied to the detectors *a*, The result of an on-line analysis of a 90 h experiment (September 6–10, 1974) *b* and *c* were obtained by off-line analysis of data from two parts of a separate 24 h experiment (August 6–7, 1974), slowed down by a factor of 4 before analysis

terms of gravitational radiation flux The flux was calculated by the standard formulae[6]. Figure 2*a* and *b* shows the delay curves (measured over 52 min) for a broadband white noise signal equivalent to a gravitational wave flux of 4 3 × 10⁴ W m⁻² Hz⁻¹ averaged over the system bandwidth The shape of the curves is a characteristic decaying sinusoid the fall time of which is related to the system bandwidth of 160 Hz Figure 2*c* and *d* shows the equivalent response over 52 min for a sine wave test signal at 910 Hz, the corresponding gravitational wave flux being 2 7 × 10⁷ W m⁻²

The delay curve obtained in a run lasting 90 h with no calibration signals applied is shown in Fig 3*a*, with delays up to 8 ms Expanded delay curves obtained by analysis of recorded data from two interleaved parts of a separate 24-h run are shown in Fig 3*b* and *c* To assess the significance of the delay curves it is necessary to know the magnitude of the fluctuations which may be expected to arise purely from the uncorrelated noise in the detectors, and in the rest of the system This may be estimated, but we have also determined it empirically from independent measurements of the delay curves for a large

From the 90-h run we set an upper limit at a level of 3 standard deviations of about 2×10^3 W m^{-2} Hz^{-1} for wideband unpolarised gravitational radiation and an upper limit, again at a level of 3 standard deviations, of about 1×10^6 W m^{-2} for a continuous sinusoidal signal in the frequency range of 910–1,070 Hz, assuming the radiation is unpolarised and incident normal to our detectors for the total length of the run in each case

Our corresponding upper limit for isotropic wideband unpolarised radiation[7] is about 4×10^3 W m^{-2} Hz^{-1} and for an unpolarised monochromatic source is about 2×10^6 W m^{-2}, the exact value depending to some extent on the relative orientation of the source and the detectors

This work has some relevance to the interpretation of the pulse experiments of J Weber Observations from several groups seems to be in conflict with Weber's results but we feel that because of the differing signal processing techniques used it has not been clear that an explanation in terms of a very large flux of small gravitational radiation pulses is completely ruled out But a flux consisting of 5,000 or more pulses per day depositing an aggregate energy of about 500 times the mean thermal energy per mode in one of our detectors (500 kT), would have been observed at the three standard deviation level in the present experiment, independent of details of pulse duration and waveform If Weber's coincidences were the result of pulses corresponding to energies of 0 2 kT or less in his detectors our estimate of his experimental sensitivity, as well as the more detailed analysis of Levine and Garwin[8], suggests that the total energy flux required would be greater than the limit above

Our negative result thus provides evidence against the hypothesis that the signals reported by Weber are caused by a large flux of very small pulses

Fig. 1 Mossbauer absorption spectrum of ^{57}Fe in thoro-steenstrupine Other spectra, spanning velocities up to 4 0 mm s^{-1} showed no evidence of any Fe^{2+} ions

bauer absorption spectrum of a 100 mg cm^{-2} sample of thoro-steenstrupine powder The spectrum is consistent with the iron appearing as Fe^{3+} in two different sites, both with octahedral symmetry[2] Most of the Fe^{3+} ions occupy a M$_2$ site with an isomer shift (relative to metallic iron) of $+0$ 40$\pm$0 03 mm s^{-1} and a quadrupole splitting of 0 34$\pm$0 03 mm s^{-1}, a very small amount (less than 5 %) of iron atoms occupying a more distorted M$_1$ site with an isomer shift of $+0$ 37$\pm$0 06 mm s^{-1} and a quadrupole splitting of 0 95$\pm$0 07 mm s^{-1} The consistency of these parameters with the systematics for other minerals[2]—which allowed the site assignments—and the relatively large intensity of the absorption lines show that the Mossbauer pattern is not affected by the radiation damage that precluded a X-ray diffraction study of the same sample, although thorium-free thoro-steenstrupine is known to crystallise with the apatite structure (J Metcalf, personal communication) This would be expected, since quadrupole splitting and isomer shift depend primarily on the immediate surroundings of the iron atom Moreover, if the crystalline environment around the metal ion were damaged appreciably, a more complex pattern with strong interactions could be expected[4]

I thank J Metcalf for the loan of the sample and informal teachings of mineralogy, and the Institute of Physics, University of Aarhus, Denmark, for the use of the Mossbauer equipment

Mossbauer absorption in a metamict mineral

The technique and application of ^{57}Fe Mossbauer spectroscopy to minerals have been discussed fully[1-3] in the context of the determination of oxidation states, coordination numbers, and site symmetry and population This report shows, with the particular example of metamict thoro-steenstrupine {Na$_2$Ce (Mn,Fe,Ta)(La,Th,)[(Si,P)O$_4$]$_3$H$_2$}, that the Mossbauer technique can yield structural information even when X-ray diffractometry is not possible because of the destruction of the lattice ordering by the damage produced by radioactive decays

The Mossbauer spectrometer used was of conventional design, using a ^{57}Co in copper source and metallic iron calibration foils, as described previously[3] Figure 1 shows the Moss-

Mossbauer spectroscopy of Chinese glazed ceramics

For over 1,000 yr the Chinese have manufactured glazed ceramic objects renowned for their aesthetic qualities The colour of a glaze is generally achieved by the incorporation of transition metal ions[1] of which iron is the most important, being used in at least nine recognised glaze types, ranging in colour from pale blue, through green, to yellow, brown and red Although reflectance spectra of the glazes allow a simple division into types expected to contain Fe^{2+} and Fe^{3+} ions, a study of the environment of the iron in each type is of interest Such data may throw light on the technology of production

Table 1

Glaze type	Colour	Isomer shift*		Quadrupole splitting	
		Fe²⁺	Fe³⁺	Fe²⁺	Fe³⁺
Chun	Pale blue	1 08		1 04	
Celadon	Pale green	1 1	0 26	2 55	1 29
		0 82†		1 29†	
Celadon	Pale green	1 12		1 81	
		0 69†		1 38†	
Northern Celadon	Olive green		0 37		1 16
Chien (surface)‡	Rust brown		0 30		1 3
(interior)	Dark grey	1 16		2 16	
Mirror Black	Black	1 08	0 30	2 02	1 29

All measurements made at 300 K, those marked ‡ also made at 77 K Units are mm s⁻¹,
*With respect to metallic iron
†These values may be tetrahedral species
‡Also gave the spectrum of haematite

of the glazes and permit archaeological distinctions between apparently similar glazes, for example, the famous pale green Celadons

Here, I report results from a preliminary study of the Mossbauer spectra of the iron in a selection of Chinese glazes This technique has already been applied to the elucidation of the structural role of iron in experimental silicate, phosphate and borate glasses[2,3], often in conjunction with optical and electron spin resonance spectroscopic and magnetic susceptibility measurements In glasses, Fe is generally coordinated to O atoms, although traces of S or Se may coordinate to the Fe in glass, with a marked effect on the spectrum In silicate glasses the evidence suggests a fourfold or sixfold coordination for Fe³⁺ (that is, substituting for Si^{4+} in SiO_4 tetrahedra, or for such ions as Na⁺), whereas Fe²⁺ is probably always in a sixfold coordination[2] Since the ligand field and distribution of energy levels change with coordination geometry the visible spectrum is strongly influenced by the site geometry of the ions The Mossbauer spectrum is modified by the electronic charge density, by the electric field gradient, and by any magnetic field at the nucleus These are manifested as a shift in the absorption energy (isomer shift), a doublet (quadrupole) splitting, and a splitting into hyperfine structure, respectively Measurement of the isomer shift provides information on the oxidation state and coordination of the iron Values of the quadrupole splitting indicate the degree of distortion from octahedral symmetry, and moreover help to identify a particular environment, being characteristic for particular compounds Excess linewidth, beyond that found for crystalline iron compounds, gives a measure of the spread of differing environments for the Fe atoms The presence of phases with internal magnetic fields may be established from hyperfine structure in the spectrum Mossbauer spectra can decide various questions that arise in glaze studies is the range of colour from blue to green in 'reduced' glazes caused by changes in the Fe²⁺/Fe³⁺ ratio, or by changes in the Fe²⁺ environment? Is the yellow in Imperial Yellow (a lead glaze) caused by Fe³⁺ (d–d) transitions, by colloidal Fe_2O_3, or by Fe³⁺ charge transfer bands? What glazes owe their colour to Fe²⁺–Fe³⁺ charge transfer spectra? The Chien glaze (opaque rusty-brown) is believed to be caused by the formation of Fe_2O_3, how well controlled is the growth and precipitation of this phase? Is Fe_2O_3 used to produce the 'Coral Red' type of glaze? How is the 'Tea Dust' (green-brown) glaze produced?

The samples consisted of a Chun glaze (pale blue), two Sung period Celadons, a Northern Celadon (olive green), an Imperial (Ming) Yellow, an interior and surface sample from a Chien glaze, and a Mirror Black glaze Several important types are not represented, the samples were chosen by their availability for destructive analysis About 100 mg of fine powder was obtained by grinding off the glaze using a diamond wheel with the object immersed in water to prevent any atmospheric oxidation from the heat evolved by friction Mossbauer

spectra were recorded from 20–100 mg samples enclosed in thin plastic The Fe content varies from 5% (Chien glaze) to less than 1% (reduced glazes), and several days were necessary to achieve satisfactory spectra for some samples A conventional constant acceleration spectrometer was used in the transmission mode Typically, $1–2 \times 10^6$ counts were accumulated in each channel, with a maximal absorption in the range 0 5–5% Only one sample (Chien) was studied at low temperature (77 K) Most of the spectra could be satisfactorily fitted with a combination of Lorentzian curves characteristic for quadrupole doublets

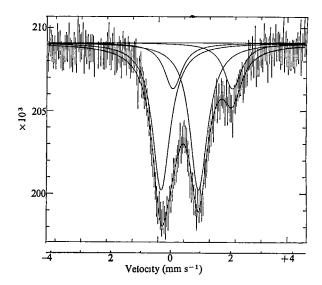
The results of analysis of the spectra are presented in Table 1 and an example of the spectra obtained, together with computer-fitted component curves, is displayed in Fig 1 In general, the


Fig. 1 Mossbauer spectrum of the Mirror Black glaze, showing its resolution into Fe²⁺ and Fe³⁺ doublets

spectra could be interpreted as sums of Fe²⁺ and Fe³⁺ quadrupole split doublets (for details, see legend to Table 1) Measured linewidths are about twice that found in crystalline compounds As is commonly found, it seems that sites giving larger splittings, within a given glaze, also have larger isomer shifts

Chun glaze. The blue colour has been attributed to the formation of vivianite, as the glaze contains phosphorus[1] The quadrupole splitting does not, however, correspond to that for the mineral, nor to that for a phosphate glass It is not evident whether the colour is caused by a modification of the characteristic 1μm Fe²⁺ band, or by a radical change in the energy level structure

Celadon glazes. Curve fitting to the weak and complex spectra is difficult, but nevertheless reveals unusual values for the isomer shift for Fe²⁺, the presence of tetrahedrally coordinated iron being indicated Despite the close visual similarity of the glazes, the two Mossbauer spectra are quite distinct

Northern Celadon. Assumed to be a more oxidised version of a Celadon glaze, this sample seems to be almost entirely Fe³⁺, with typical parameters

Chien glaze. The 300 K spectrum shows mainly a typical Fe³⁺ doublet, with a small contribution from the six-line magnetic spectrum of haematite At 77 K the spectrum is dominated by the magnetically split contribution The relaxation of a magnetically split spectrum with temperature is characteristic of a temperature-dependent spin-lattice relaxation time or of a bulk phase with large surface area Measurement of the magnetic splitting gives a magnetic field equal to that for haematite (α-Fe_2O_3) Haematite in the bulk phase does not show appreciable relaxation at 300 K, and it seems likely that the appearance of the Chien glaze is caused by the presence

of colloidal size (20–1,000 Å) particles of Fe_2O_3 (superparamagnetic behaviour) There is evidence for similar superparamagentic behaviour of haematite in clays[4] The production of such particles in a glass is of considerable intrinsic interest, and is also informative on the technical control of glaze production The interior of the Chien glaze, which is dark grey, has a spectrum characteristic of Fe^{2+}, probably as a simple doublet There may be a small contribution from magnetic phases (for example, Fe_2O_3 or Fe_3O_4) resolvable with improved signal-to-noise ratio This suggests that the Chien glaze is first developed in a reducing atmosphere, and is then superficially oxidised Such a process may be important in the production of colloidal Fe_2O_3

Mirror Black. This glaze has a very uniform reflectance spectrum in the visible region, and is produced by adding cobalt and manganese to a glaze containing 5–10% Fe The visible spectrum may be a superposition of the absorption spectra of Fe^{3+}, Co^{2+}, and Mn^{2+}, or more complex equilibria may be involved, perhaps leading to charge-transfer spectra In any case, it is interesting that the Mossbauer spectrum shows the presence of appreciable Fe^{2+} (of the order of 25%)

Imperial (Ming) Yellow. No spectrum was obtained because of the strong absorption of the lead content of the glaze

Further work on Chinese glazes must await the construction of a Mossbauer spectrometer working in the reflection mode, and capable of obtaining complex spectra from samples containing less than 1% Fe This would enable a set of representative samples to be examined without destroying the source This work is now in progress

I thank Dr A G Maddock for his help and interest, and Professor E T Hall for his encouragement Some of the sherds were kindly donated by Sir Harry Garner

Matrix synthesis and characterisation of dichromium

MATRIX isolation has been widely used to trap reactive species in the cavities of an inert host for subsequent spectroscopic observation[1] Occasionally, spectral features appeared which could not be ascribed to the single trapped species and had to be attributed to an aggregate These bands were generally regarded as parasitic and their origin was not pursued We have discovered that metal dimers can be readily formed in large quantities in matrix conditions and that the bands associated with these entities can be identified readily using a novel technique which makes use of the fact that the metal atoms being deposited are capable of diffusion either on the matrix surface or within a narrow region (the reaction zone) near the surface before its kinetic energy is dissipated sufficiently to immobilise it

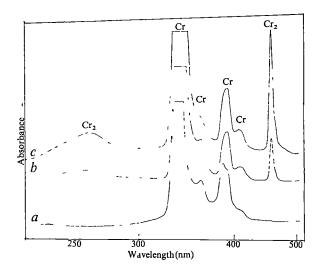
This process can be explained in terms of a kinetic model which assumes that at constant deposition rate of matrix material a steady state exists in the concentrations of the various species within the moving reaction zone Metal dimers and higher aggregates form within the reaction zone to a much greater extent than indicated by a statistical analysis based on the matrix ratio The dependence of the concentration of the various species on the rate of deposition of metal can then be


Fig. 1 A portion of the spectrum of chromium atoms and dichromium molecules in argon *a*, Low metal flow, *b* and *c*, progressively higher metal flow

calculated and compared with the observed dependence of the absorbance of bands on metal deposition rate

Using this technique we have formed and identified dimers of V, Cr, Mn, Co, Ni, and Cu and observed their spectra in the ultraviolet and visible region We use chromium to illustrate this technique

Our experimental apparatus has been described elsewhere[2] The crucial aspect of this experiment is the deposition of metal at an accurately known and constant rate A quartz crystal microbalance was used for this purpose[3] Argon (Matheson) was deposited at approximately 2 mmol h^{-1}. Chromium (McKay, New York) was deposited from a Knudsen cell lined with boron nitride at various rates ranging from a few parts per thousand to a few per cent of the argon rate.

Figure 1 shows a portion of the spectrum of chromium in argon As the rate of chromium metal deposition is increased the features at 260 and 455 nm grow Figure 1*a* was obtained by depositing Cr into argon at such a slow rate that mainly chromium atoms are found in the matrix. This spectrum is nevertheless quite different from those reported by Mann and Broida[4] and by D Gruen (unpublished) which also differ from one another Our experiences with this system suggest that the discrepancies are probably attributable to impurities and/or higher chromium aggregates in the earlier studies In Table 1

Table 1 Frequencies and assignments for matrix isolated Cr and Cr_2 in argon

$V_{Ar\ matrix}$	V_{gas} (ref 6)	$\Delta v = V_g - V_{Ar}$	Assignment	Species

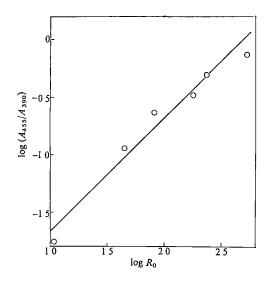
26,900(w)	$\begin{cases} 24,971 \\ 25,010 \\ 25,089 \\ 25,206 \\ 25,359 \\ 25,548 \\ 25,771 \end{cases}$	$\sim -1,700$	$a^7S \to z^7F^0$	Cr
$\left.\begin{array}{l} 25,800(s) \\ 25,500(s) \end{array}\right\}$	$\begin{cases} 23,499 \\ 23,386 \\ 23,305 \end{cases}$	$\sim -2,200$	$a^7S \to z^7P^0$	Cr
24,300(vw)			?	Cr
38,500				Cr_2
22,000				Cr_2


Fig 2 A log–log plot of the ratio of the absorbance of a line attributed to Cr_2 to that of a Cr resonance absorption as a function of the chromium metal deposition rate at constant argon deposition rate

we compare the frequencies of the lines measured for Cr in argon with those of the gaseous atom[5] A blue matrix shift of approximately 2,000 cm^{-1} is observed for all the lines

Unambiguous assignment of the broad band at 260 nm has not been made We know, however, that at least the band at 455 nm belongs to Cr_2 Consider the reaction

$$M \xrightarrow[k_1]{M} M_2 \xrightarrow[k_2]{M} M_3$$

which we assume takes place in the reaction zone At constant metal deposition rate R_0 a steady state exists in the concentrations of M, M_2 and M_3 given by the equations

$$dM/dt = R_0 - k_1 M^2 - k_2 M M_2 - rM = 0 \qquad (1)$$

$$dM_2/dt = \tfrac{1}{2}k_1 M^2 - k_2 M M_2 - rM_2 = 0 \qquad (2)$$

$$dM_3/dt = k_2 M M_2 - rM_3 = 0 \qquad (3)$$

where r is related to the rate at which these species are frozen out and is proportional to the argon deposition rate At low metal-deposition rates the ratio of dimer concentration to atom concentration is proportional to R_0 and the ratio of trimer concentration to atom concentration is proportional to R_0^2 (J Hulse, E P K, M M, and G A O, unpublished)

Figure 2 is a plot of log A_{455}/A_{390} as a function of log R_0 together with a line of unit slope, where A_{455} and A_{390} are respectively the absorbances of the unknown 455-nm line and the 388–392-nm Cr atom doublet The excellent correlation between the unit slope line and the experimental points suggests that the 455-nm line belongs to Cr_2 and not to a higher aggregate

The apparent absence of Cr_3 could be a result of a low extinction coefficient, or a low k_2 value, or both The latter reason may be a result of the activation energy required in the reaction

$$Cr_2 + Cr \rightarrow Cr_3$$

in which the Cr_2 bond may have to be weakened before the reaction can proceed The kinetic result, incidentally, also suggests that Cr_2 is formed in or on the matrix rather than in the gas phase This last fact is also borne out by the intriguing observation that for a given metal deposition rate the dimer–monomer ratio decreases as one increases the molecular weight

of the noble gas used to isolate them, with neon giving the most dimers and xenon the least This is understood to be a consequence of the formation of Van der Waals' complexes between the metal and the noble gas molecule with the most polarisable noble gas atom forming the strongest complexes A metal atom complexed in this fashion can either be construed to be quenched or at least its diffusion slowed down considerably

Characteristics of a rocking wave power device

THE possibility of extracting a large proportion (more than 80%) of the total wave power from water waves has been demonstrated experimentally[1] using a specially contoured rocking device In considering the possibility of large scale power generation, it is necessary to understand how such a device would respond to the variable Atlantic ocean conditions where wave periods are between 7 s and 14 s for 99% of the time[2] We here present the results of initial investigations of the bandwidth of wave periods covered by Salter's[1] device

The essential features of Salter's rocking shape (Fig 1) are a circular rear section which has a constant displacement (and therefore does not transmit any energy) and a front section with a non-uniform radius When it is matched to a wave of wavelength λ, the front section is designed to move so that it does not perturb the fluid motion of the incoming waves—which decays exponentially with depth, y, as $v_0 \exp(-2\pi y/\lambda)$—and which thus does not reflect any energy In principle, therefore, the only energy not absorbed by the device is that proportion which propagates underneath, from simple theory this would amount to $\exp(-4\pi d/\lambda)$ where d is the depth of immersion[3]

A measure of the effectiveness of the matching is provided by the difference between the body velocity and the unperturbed fluid velocity along the submerged surface, s, in the direction normal to the surface An estimate of the proportion of the

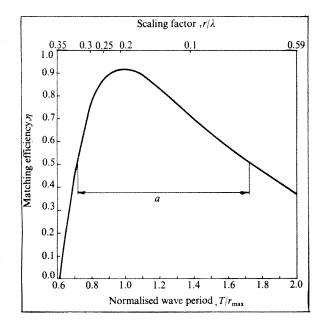
Fig 1 The Salter cam[1] TW, Transmitted wave, IW, incident wave, RW, reflected wave, NWD, normal wave direction, RWD, reversed wave direction L, load $(=T_0 K\theta)$


Fig. 2 Theoretical matching efficiency of a Salter cam. *a*, Half power bandwidth.

incident energy reflected or, more properly, scattered from this surface is given by

$$R = \int \overline{(v_n - u_n)^2} ds / \int \overline{u_n^2} ds \qquad (1)$$

where v_n and u_n are the body velocity and unperturbed fluid velocity (normal to the surface), respectively, and the integrations are time averaged. Equation (1) has been evaluated for the Salter shape[1], oscillating sinusoidally, and the minimum value of R has been found for a range of wavelengths in terms of a characteristic dimension of the device, r, which is taken to be the back radius. The overall absorption efficiency, η, is defined as

$$\eta = (1 - R_{min})[1 - \exp(-4\pi d/\lambda)] \qquad (2)$$

where $[1 - \exp(-4\pi d/\lambda)]$, takes account of the proportion of the incident energy transmitted underneath the device. It is plotted in Fig. 2 against the normalised dimensions r/λ and normalised wave period. Efficiencies of over 90% are predicted for $0.16 < r/\lambda < 0.20$ and the half power bandwidth exceeds 2:1.

These are most encouraging theoretical results which imply that a device 50 m in diameter, tuned to a wave of period 10 s ($\lambda \simeq 150$ m) would couple with at least 50% absorption efficiency to waves with periods of between 7 s and 17 s (75 m $< \lambda < 450$ m). We have tested these findings experimentally on a small scale in a wave tank.

The load on a device 10 cm in diameter, of the type described by Salter[1], was tuned to give maximum power output as measured by a calibrated dynamometer, from incident waves with periods, T, ranging between 0.38 and 1.0 s ($0.03 < r/\lambda < 0.22$). For periods longer than 1.0 s, assumptions of deep water conditions ceased to apply in our tank. Waves with periods of less than 0.38 s were attenuated significantly. Over the intermediate range, attenuation could be ignored and then the incident and reflected wave amplitudes, A and B, respectively, were calculated from the standing wave ratio, S, defined by:

$$S = (A - B)/(A + B)$$

where $(A - B)$ and $(A + B)$ are, respectively, the minimum and maximum amplitudes measured on the standing wave in front of the device. The amplitude, C, of the wave transmitted past the

device was also measured. The incident, reflected and transmitted powers were calculated (see ref. 3) from these amplitudes respectively:

$$(P_i, P_r, P_t) = (\rho g^2 T/8\pi)(A^2, B^2, C^2)$$

and the proportion of power lost from the wave, W, is

$$W = [P_i - (P_r + P_t)]/P_i$$
$$= 1 - (B^2 + C^2)/A^2$$

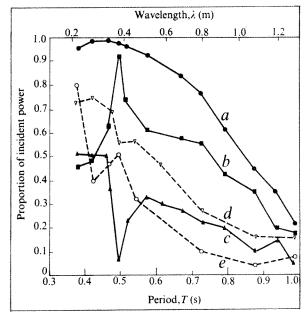
W is plotted against T in Fig. 3*a*. This curve is very similar to the predicted efficiency curve (Fig. 2). We also obtained a direct


Fig. 3 Efficiency and losses for the Salter cam. *a*, W (tuned); *b*, η_g; *c*, losses (tuned); *d*, W (free); *e*, W (fixed).

measurement of the power absorbed by the device at the dynamometer, and this is plotted (Fig. 3*b*) normalised to the incident power P_i, and corresponds to the actual efficiency of power extraction η_g. Though both curves peak at over 90%, the useful power output curve suggests that the device/load combination is resonant at $T = 0.5$ s ($r/\lambda = 0.13$) with a rapid fall off in efficiency to about 60% on either side. The difference between Fig. 3*a* and 3*b* represents the proportion of the incident power lost from the wave system because of turbulent and other nonlinear effects (Fig. 3*c*). Although small at the 'resonant' period (about 5%) these losses are, in general, surprisingly large, as high as 50% for the shorter periods.

Losses will be very important in practical systems and so they warrant further investigation. To assess the importance of the motion of the device in causing these losses, the experiments were repeated with the device either oscillating freely or held rigid (Fig. 3*a* and *b*). As no power can be extracted by the device in these cases, W can only represent system losses. Over most of the period range the losses measured for optimally loaded system lie between those for the two extreme cases. This is not an unexpected result and suggests that the system losses increase monotonically as the amplitude of motion of the device increases. At the 'resonant' period, however, the matched device losses are only about one-tenth of the fixed and free device losses which are both about 50%, which suggests that velocity mismatch in the normal direction contributes more to losses than do shear velocity gradients.

To see whether power was being lost or propagated in some preferred direction of rotation, the reciprocity of the system[4]

was measured by repeating our measurements with waves incident in the reverse direction, that is, on the rear of the device. We found that the same fraction of power $(C/A)^2$ was transmitted in either direction within experimental error over the whole range of wavelengths, and so the system was reciprocal.

For those losses caused by boundary layer effects and turbulence, the fractional power loss will be dependent on the Reynold's number (Re). As λ is proportional to T^2 (ref. 3), Re is proportional to T^3 and the Reynold's numbers at full scale will be nearly 10,000 times greater than in our experiments, and these losses would be greatly reduced.

Experiments with our model have shown that good power conversion efficiencies (more than 50%) can be obtained over the range of wave periods (a 2:1 bandwidth) corresponding to that found in ocean waves. Further work is needed to establish in detail the response to complex wave fields with multiple frequencies from various directions, the effects of real sea conditions, the effect on performance of alternative loading systems and the precise way in which losses scale. It is, however, already clear that the rocking boom device is very promising as the basis of a wave power system. The practical effects that we have investigated, of losses and bandwidths, do not seem to represent serious limitations on performance.

This work was carried out at Marchwood Engineering Laboratories and at the University of Edinburgh, which provided experimental facilities and equipment.

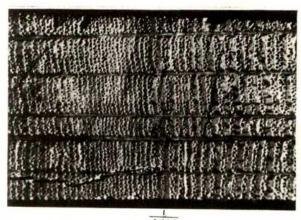
Relation of abnormal earlywood in oaks to dendrochronology and climatology

TREE-RING investigations in Europe are largely based on the method initiated by Huber in 1938 at Tharandt (near Dresden)[1] by which the widths of the rings are measured and the resulting sequence charted and compared both visually and by computer. In temperate zones such as England and the Low Countries oak panels are ideal for the study of dendrochronology as they were prepared from the butt logs of elite trees of slow and even growth. A panel used as a support for a painting has the added advantage that its edges are accessible[2]. Since 1971 I have worked on 115 of those used by portrait painters in South-east England or Flanders between 1450 and 1620 (refs 3, 4). The boards (there are more than one on some panels) have an average of 200 rings of mean width 1.5 mm.

At an early stage a curious feature was noticed on the panel of Holbein's portrait of Robert Cheseman; all the vessels in the earlywood of two of the annual rings are abnormally small (Fig. 1). This peculiarity has subsequently been observed in about 0.4% of the 24,000 rings measured on these panels and often, but not invariably, appears in the same annual ring on both ends of a board as well as on separate boards prepared from the same tree. I have also found examples on the boards of a late mediaeval cupboard (Fig. 1) made for an Oxford College[5], and on timbers used for the Roman quay to the Thames at London, but none in the stems of 30 trees[5] felled recently at an age of about 150 yr.


For the panels (almost all their ring-width charts have been matched and dated by reference curves) it soon became apparent that the effect was mainly confined to three specific years in the period 1433–55. At present this period is covered by 109 dated boards derived from 81 trees. Examples occur on 47 of these boards (derived from 36 trees) there being 36 occasions for the year 1437; 12 for 1443; and 21 for 1454. Six of the same boards also had earlywood vessels smaller than usual for one or more of the years 1438, 1439, 1444, 1445, and 1455, the total of such instances being ten. In the fourteenth century the abnormality appears for 1348 and 1390 (with eight and five occasions respectively); the remaining 20 examples are distributed sporadically between 1260 and 1540.

The presence of earlywood vessels has proved to be diagnostic for dating. They were observed in two rings separated by 17 yr on the portrait of Elizabeth Woodville in the Royal Collection at Windsor Castle. With the dates 1437 and 1454 thus suggested for the two rings, the 116-yr sequence matched well with signatures on one of our reference curves (Fig. 2). It is therefore dated with high reliability even though it is relatively short in length because of an imperfection on part of the edge.

Vessel development commences almost simultaneously throughout the stem cambium of a large oak by very complex processes[6]. When the buds flush in April–May, the vessels expand apparently under the stimulus of auxin and other compounds. K. A. Longman and K. R. Shephard have suggested (personal communication) that interference with cambial activity by a climatic factor, perhaps limited to only a few days and directly or indirectly related to flushing, might cause earlywood vessels to be abnormally small. A purely local cause can be dismissed as examples occurred in 1433 in woodlands near Oxford, near London and in the Low Countries. The effect in the period 1433–55 may

Fig. 1 Part of the edge, 1.8 cm wide, of an oak board, with 277 annual rings spanning 1209–1485, showing abnormally small earlywood vessels for 1437. This board and another form one of the 18 doors of a large cupboard made for Corpus Christi College, Oxford, in the period 1515–20, when the College was newly founded.

Direction of growth ⟶

We have also attempted to study the dependence of the photovoltaic effects of the Chl-*a* sandwich cells on the electrode materials[5]. A correlation between the photovoltaic activity and the work function of the metals is observed, which further indicates that the Schottky barrier is directly responsible for the photoactivity. For instance, in a (Cr|Chl-*a*|Ga) cell, where Ga has a lower work function than Cr, the dominant Schottky barrier is established at the back, Chl-*a*|Ga, contact. The observed photovoltaic activity is dramatically different. The sign of the i_{sc} is now in a direction opposite to that seen in the (Cr|Chl-*a*|Hg) cell. Furthermore, the i_{sc} spectral response shows maxima in the spectral regions where the Chl-*a* film only absorbs slightly, that is, an "inner filter" effect is observed.

Table 1 Photovoltaic characteristics of ten (Cr|Chl-*a*|Hg) cells

Cell	V_{oc} (V)	i_{sc} (in 10^{-8} A)	P_{max} (in 10^{-8} W)	P_{max}/P_{in} (in 10^{-2} %)
1	0.32	8.0	1.00	1.6
2	0.31	6.0	1.08	1.0
3	0.18	3.9	0.43	0.43
4	0.19	7.3	0.47	0.68
5	0.18	5.0	0.30	0.50
6	0.21	5.0	0.38	0.63
7	0.18	8.0	0.48	0.80
8	0.30	7.5	0.80	1.40
9	0.20	6.0	0.50	0.83
10	0.25	2.5	0.40	0.67

V_{oc} is the open circuit voltage, i_{sc} is the short circuit current at the 745 nm light intensity of 7.6×10^{-4} W cm^{-2}. P_{in} is the incident radiative power on the cell (no correction is made for the power absorbed by the Cr). P_{max}/P_{in} is the photovoltaic power conversion ratio.

The Schottky barrier model for the system predicts an activition energy for a forward bias current which consists of a voltage dependent term, $-eV/n$, and the barrier height (contained exponentially in i_0) at the Cr|Chl-*a* contact[8]. Accordingly, after correcting the observed activation energy for the forward bias voltage, barrier heights on the order of 0.4–0.7 eV are obtained, depending on the sample. Measurements of activation energies on a single sample at different bias voltages, or with cells having different electrode materials should test further the contact barrier model for the Chl-*a* system. The activation energy seen for the photovoltaic current seems to be exceptionally low for organic systems. Evidently, the steps leading to charge generation and transport following light absorption by Chl-*a* involve at most very weakly activated processes.

Can linguistic competence be dissociated from natural language functions?

The preservation of non-verbal intellective functions in spite of severe disruption of natural language has been well documented by studies of aphasia[1]. But are the cognitive functions specific to normal verbal communication also preserved in the absence of language? In addition to its theoretical significance, this question has practical importance with respect to both infrahuman primates and severe aphasics[2]. These groups cannot use natural language because of the destruction or apparent absence of crucial cortical zones of the brain and effective communication may depend on their mastering an alternative symbol system which captures relevant cognitive properties of natural language. A crucial test of the hypothesised dissociation between natural language and its cognitive prerequisites is whether aphasic subjects can use arbitrarily designed symbols to represent elements of experience (events, properties, actions and so on); encode meaningful relationships in terms of the configurational properties, or syntax, of the symbol sequence; and have the capacity to encode such relationships in alternative syntactic forms[3,4].

We have verified the preservation of these cognitive concomitants of natural language in a severely aphasic patient. W.S. is a 21-yr-old right-handed male who was evaluated for language after surgical removal of a large, acute subdural haematoma of the left tempero-parietal lobe following severe head trauma. Ten weeks after surgery, at the time of admission to our unit, he had mild weakness in his right seventh cranial nerve and probable loss of smell sensation on the left; the remainder of his neurological and physical examination was normal. At this time he was observed to have very poor comprehension of spoken and written language. His speech was markedly paraphasic and devoid of information. On the Boston Diagnostic Aphasia Examination[5], he scored near zero on subtests of auditory comprehension, naming, reading comprehension and writing. But he seemed to be extremely well oriented and alert, and when his intelligence was tested he executed the block design, picture arrangements and object assembly subtests of the Wechsler Adult Intelligence Scale at a superior level (scale scores of 12).

W.S. entered our research–therapy programme called VIC (Visual Communication) in which messages are formed by laying out—from left to right—index cards on which arbitrary or ideographic symbols stand for nouns and verbs, grammatical morphemes, sentence modality and tense markers, and metalinguistic signals. The patient observes VIC communicators 'converse' with one another and then is gradually drawn into the conversation himself. Within two 30-min sessions W.S. had mastered the basics of the system; he demonstrated knowledge of the meaning of VIC symbols and the rules of the syntax governing VIC communication. Specifically, he could follow commands, answer simple questons, and describe events, with the total number of possible transactions running into the hundreds. After 14 additional 30-min sessions of VIC, W.S. could transmit and receive information involving direct and indirect objects, antonymic contrasts of verbs and of prepositions, judgments on the truth value of statements, and shifts in sentence modality, for example, from the interrogative to the declarative. More practically, W.S. was able to use the cards to express certain feelings and ideas; clearly VIC served as an alternative for his vitiated natural language capacity.

Here is a sample annotated exchange, translated into English. Word sequences designated by a single ideograph are connected by hyphens.

(1) Command involving a reordering of the element in the surface form of the utterance: Therapist (T): ! W.S. please-put spoon or fork to-the-right-of-the pencil. W.S. executes act with fork.

(2) Answering question requiring multiple specification of nouns and expansion of constituent: T gives pencil and razor to Y. T: ? Who give(s)-to what (to) whom. W.S.: T give(s)-to pencil and razor (to) Y.

(3) Appropriate response when confronted with a novel surface form: T picks up a cookie. T: ? What T pick-up [rather than normal form: ? T pick-up what]. W.S.: T pick(s) up cookie.

(4) Spontaneous utterance in VIC: T takes out pack of cigarettes. W.S.: W.S. want(s) cigarette (a few seconds elapse) and matches.

To establish that this success was not the result of a mapping of VIC on to residual or recovering natural language functions, W.S. was given an extensive test of spoken and written English, with all items equivalent to VIC messages. He performed without error on items in VIC, but scored only 12.5% correct in English.

The design of VIC suffices to demonstrate important conceptual operations entailed in ordinary language. First, W.S. seems to understand and use the symbols in terms of the normal categories of perceptual experience (for example, actor- action- object and indirect object of the action). Second, W.S. seems to understand the meaning relations among the categories in terms of a small number of configurations and to deal appropriately with novel mesages; both of these capacities suggest that he can understand VIC sequences in terms of the relations among the component elements. Third, W.S. is not bound by referentially constrained situations in his use of VIC. Finally, W.S. seems to exhibit the beginnings of productive use of VIC, by virtue of his ability to expand on constituents that request information.

The case of W.S. shows that certain cognitive capacities entailed in natural language can be preserved in its absence. This patient was unique among VIC communicators in the speed and facility with which he mastered the system. The fact that five out of eight patients tested have mastered the basic components of the system within 6 weeks, however, and have performed at a level superior to their performance with English, indicates at least some dissociation among the two functions in severely aphasic patients.

The performance of W.S. can be compared usefully with those of Sarah[6], Washoe[7] and Lana[8], primates used in communication studies; however, his achievement differs not only in its overall level of proficiency, but also in the apparent fact that Sarah has not used her symbol system for spontaneous communication while Washoe has not used syntax consistently. The skill of W.S. at mapping his knowledge of the environment on to a symbol system without the apparent aid of a mediating system is most reminiscent of that found in young children, and, perhaps, in Lana. Possibly our patient is in the paradoxical position of retaining cortical capacity for communication using symbols while having lost, at least temporarily, the ability to handle natural language.

Intensification of the alcohol withdrawal syndrome by repeated brain stimulation

SINCE the discovery that electrical stimulation of discrete sites of the brain can influence behaviour, there have been numerous reports of its application[1]. Such procedures, however, may lead to kindling[2]; stimulation of some sites at currents initially too low to produce a behavioural response may lead to a gradual development and then intensification of seizures evoked by the stimulation[3]. Thus when the brain is repeatedly stimulated for therapeutic purposes, seizures may be elicited unless procedures not conducive to kindling are used[2]. Two questions arise: can kindling leave an organism more susceptible to seizures produced by agents other than local brain stimulation, and are elicited convulsions necessary for this change in susceptibility? Our findings indicate that whether or not overt convulsions are produced by brain stimulation, repeated electrical stimulation of the brain potentiates the effects of subsequent alcohol withdrawal.

To answer the first question we studied the interaction of kindling and alcohol. When large quantities of ethanol have been metabolised an organism is in a state of heightened seizure susceptibility[4]. In alcoholics this withdrawal syndrome is often characterised by tremors and other mild epileptic symptoms, and *grand mal* convulsions and death can ensue. Even in organisms that display no obvious symptoms, there is an increased susceptibility to seizures induced by other agents after withdrawal[4]. Hence, if kindling affects general seizure susceptibility, this should be reflected in an intensification of the alcohol withdrawal syndrome.

Twenty-seven, male, black-hooded rats (Canadian Breeding Farms, La Prairie, Quebec) were implanted with unilateral, bipolar electrodes aimed at the centre of the amygdaloid complex. After 1 week of recovery, 12 randomly selected rats were kindled with 45 brain stimulations (1 s, 400 µA, 60 Hz) administered three times per day, 5 d per week. The animals were kindled successfully in that each eventually displayed at least one bilateral seizure involving clonic activity of the head, mouth and fore-limbs accompanied by rearing and loss of equilibrium. The remaining implanted animals served as unstimulated controls.

Three days after the last stimulation, rats in both groups received 45 intubations of a 20% volumetrically prepared alcohol solution (1,000 mg kg^{-1}) as before[5]. Intubations were at 8-h intervals and intoxication was tested 1 h after each intubation. An animal was considered intoxicated when it exhibited two or more of the following symptoms: (1) unconsciousness before handling, (2) inability to manoeuvre on a vertical screen or (3) ataxia. If there were no signs of intoxication, subsequent doses were increased by 200 mg kg^{-1} until intoxication was produced. All animals developed a tolerance to the alcohol; the mean difference between the first and last intoxicating dose was 870 mg kg^{-1} and every animal showed an increase of at least 200 mg kg^{-1} ($\chi^2 = 20.02$; $P < 0.001$). Before withdrawal the body weights (mean = 342 g) and effective intoxicating doses (mean = 2,018 mg kg^{-1}) were similar for stimulated and unstimulated animals.

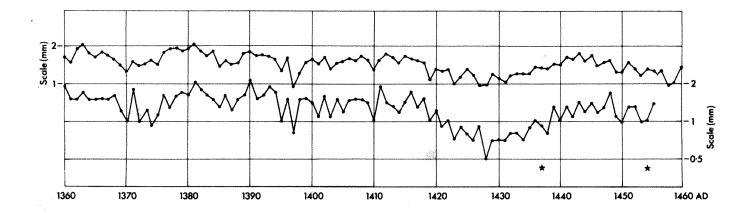
Commencing 9 h after the last intubation each animal was placed under formal observation for 2 min every 3 h by an experimenter, unaware of the animal's experimental history, who recorded the presence or absence of the following seven withdrawal symptoms: rhythmic activity of the mouth, facial tremors, rhythmic eye or ear twitching, myoclonic body jerks, tail tonus, rhythmic head nodding and hyperreactivity to handling. Since there were six observation sessions, the maxi-


Fig. 2 A 100-yr section of the ring-width chart (semi-log scale) for the oak panel support of the portrait of Elizabeth Woodville It agrees closely with the signatures on the reference curve. The stars mark the two years with abnormally small earlywood vessel. Upper, Reference curve (18 trees, left hand scale); lower, Elizabeth Woodville (right hand scale).

well be linked with the exceptionally severe winters and cold springs[7-9] in central and western Europe between 1428 and 1450, but more specific factors must have been involved as it did not coincide with each. Whatever the cause, there is no indication that the width of the subsequent latewood was significantly altered.

Both Flohn[10] and Lamb[8,9] associate the cold winters and springs of the 1430s and 1440s with a long period of blocking conditions which lessened the frequency of the westerly winds over Britain and much of north-western Europe. Since the annual rings of numerous oaks that have remained buried from about 6000 BC are now being measured at Stuttgart[11], Cologne[12] and Belfast[13], observations of abnormal earlywood may extend our knowledge of variations in Europe's climate in Flandrian times.

This research has been supported by the Leverhulme Trust Fund. It owes much to the permission graciously granted by Her Majesty The Queen to work on paintings at Windsor Castle, and to the co-operation of the Surveyor of the Queen's Pictures, the Director of the National Portrait Gallery, the Society of Antiquaries and owners of private collections. I thank the members of the Department of Forestry for help with the computer work.

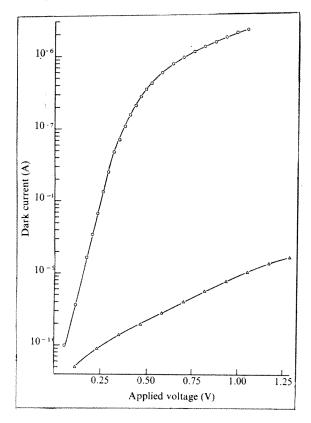
Chlorophyll-*a* photovoltaic cells

ALTHOUGH the properties of an organic photovoltaic cell in which the photoactive material is microcrystalline chlorophyll-*a* (Chl-*a*). In a sandwich configuration having chromium and mercury as the electrodes, the Chl-*a* cell, (Cr|Chl-*a*|Hg), achieves a power conversion efficiency of the order of 10^{-2}%, which is among the highest ever reported for organic photovoltaic cells[1,2]. In contrast to the usual methods for preparing thin films (such as vapour deposition), a thin microcrystalline Chl-*a* film is prepared on a Cr electrode surface by he simple method of electrodeposition[3]. Such a film is fairl; uniform and is uniquely efficient in the photocharge generation. The microcrystalline form of Chl-*a* differs from the aggregated form of monomer Chl-*a* in that it has an ordered structure and has a strong absorption band in the far red, peaking at 740-745 nm. A water-Chl-*a* adduct structure has been proposed for this type of Chl-*a* (ref. 4).

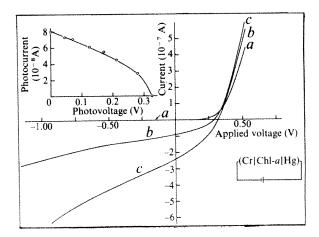
The fabrication of the metal-Chl-*a*-metal sandvich cells (including the (Cr|Chl-*a*|Hg) cell has been descrbed elsewhere[5]. The electrodeposited Chl-*a* films used in most of the Chl-*a* photovoltaic cells are about 1,500 Å thick as measured by interferometry. The corresponding optical density of the Chl-*a* film at 745 nm is about 1.5. Monochromatic ilumination is through the semitransparent Cr electrode (~ 30% transmission). The intensity of the light incident on the Cr electrode is about 10^{-3} W cm^{-2} at 745 nm.

The electrical conduction of the (Cr|Chl-*a*|Hg) cell in the dark exhibits a strongly non-ohmic or rectifying behaviour. The cell is found to be forward biased when a negaive voltage is applied to the Cr electrode. Figure 1 shows a semiogarithmic plot of the dark current against applied voltage, the $-V$ characteristics, of a (Cr|Chl-*a*|Hg) cell. The rectification ratio (forward bias current/reverse bias current) is as high as 10^3. The photoconduction behaviour is shown in Fig. 2. Curve (*a*) represents the same dark *i*-*V* characteristics as in Fig. 1 but plotted on a linear scale. Curves (*b*) and (*c*) represent the photocurrent as a function of applied voltage photo *i*-*V* characteristics). These two curves are obtained when the cell is illuminated by 745 nm light having intensities o 7.6×10^{-4} and 2.7×10^{-3} W cm^{-2} respectively. The insert in Fig. 2 represents the photovoltaic *i*-*V* characteristics. Hee there is no applied voltage. Instead, photovoltage alone is present and


the cell current is varied by changing the external load resistance, R_L in series with the cell from 10^4 to $10^{11}\Omega$. In this case the cell is under constant illumination by 745 nm light at a level of $.6 \times 10^{-4}$ W cm^{-2}. Note how the shape of this purely photovoltaic i-V curve is very similar to the lower right quadrant portion of the i-V curve (1). The area of the largest rectangle enclosed by such an i-V curve represents the maximum power obtained from the cell at this light level. This maximum power of 1×10^{-8} W is found to couple through a R_L of $3 \times 10^6\Omega$. With an incident power of 6×10^{-5} W at 745 nm on the Hg contact area (0.08 cm^{-2}), the power conversion efficiency is about $1.6 \times 10^{-2}\%$. If correction for the light absorbed by the Cr layer is made, the efficiency is more nearly $5 \times 0^{-2}\%$. The open circuit voltage, V_{oc}, is about 0.32 V for this cell, and is nearly independent of the light intensity at this light level. On the other hand, the short circuit current, i_{sc} shows a linear dependence on the incident light. The ratio i_{sc}/I, where I is the photon flux upon the Chl-a (that is, corrected for absorption by Cr) is 0.007. This represents the minimum quantum yield of charge generation in Chl-a when the cell is operating in the photovoltaic mode.

It must be noted the cell described above is one of the best found in this study. The performance can vary by as much as an order of magnitude from the poor to good cells. Table 1 summarises the data obtained from ten (Cr|Chl-a|Hg) cells. The average power conversion efficiency is about $5 \times 10^{-3}\%$. These cells are very stable and retain their characteristics for at least a month (in the dark) without obvious deterioration. Slow degradation under more intense light ($> 10^{-2}$ W cm^{-2} at 745 nm) is seen. At the light level of 10^{-3} W cm^{-2}, a good cell can sustain a constant i_{sc} of the order of 0.1 µA over a period of hours.

Temperature dependence studies have also been performed on some of the cells. Between room temperature and ~ -40 °C the photovoltaic i_{sc} exhibits a very small dependence on

Fig. 2 i-V characteristics. (a), Cell unilluminated; (b) and (c), cell illuminated by 745 nm light of intensities 7.6×10^{-4} and 2.7×10^{-3} W cm^{-2} respectively. The insert is the photo i-V characteristics of the (Cr|Chl-a|Hg) obtained by varying the load resistance while the cell is constantly illuminated by 745 nm light.


temperature, whereas the dependence of the dark forward-bias current is considerably stronger. The Arrhenius plots give an activation energy of less than 0.05 eV for the photovoltaic i_{sc} and for the dark forward bias current values of 0.2 to 0.5 eV are found, depending on the sample.

The remarkable properties of the (Cr|Chl-a|Hg) photovoltaic cell may be explained in terms of the existence of a contact potential barrier (or Schottky barrier) at the Cr|Chl-a contact. Chl-a has been shown to exhibit p-type semiconduction[6]. It is generally true that a potential barrier often exists at the contact between a p-type semiconductor and a metal of low work function[7]. Thus, in the (Cr|Chl-a|Hg) cell the dominant Schottky barrier is at the Cr|Chl-a boundary, while the Chl-a|Hg contact possibly can be ohmic, or only slightly blocking. The asymmetric potential distribution provides the basis for the dark current rectification and the photovoltaic characteristics. The forward bias dark current in Fig. 1 is seen to follow a modified Shockley equation[8] for a rectifying contact: $i = i_0[\exp((eV - iR_s)/nkT) - 1]$ where $i_0 = 2 \times 10^{-11}$ A and $n = 1.6$. The iR_s term represents the potential drop across the series resistance, R_s, in the (Cr|Chl-a|Hg) photovoltaic cell. Its value is found to be $1.2 \times 10^5\Omega$ and is orders of magnitude larger than that found in inorganic photovoltaic cells such as the silicon solar cell[9].

The action spectrum of i_{sc} of the (Cr|Chl-a|Hg) cell is seen to match closely the absorption spectrum of the Chl-a film[5]. The optical thickness of the Chl-a film at 745 nm is such that were the photoactive domain located at the back contact, Chl-a|Hg, a significant "inner filter" effect (a quenching of the photoelectric response) would be seen. More detailed analysis[5] has shown that the width of the photoactive region in the Chl-a film adjacent to the Cr electrode is a few hundred angstroms. Light absorbed by the bulk of the Chl-a beyond this region is presumably not very effective in producing free carriers. The minimum quantum yield of charge generation in the Chl-a film which is 0.007 with no bias, is found to increase under reverse bias (see lower left quadrant of Fig. 2). The reverse bias, which increases the barrier dimensions, evidently serves to partially overcome otherwise inefficient steps involving primary charge generation or subsequent recombination events, or both[10]. Meilanov et al.[6] have studied (|Al|Chl-a (non-crystalline) Al) cells at thicknesses far exceeding ours and at much higher applied voltage. Studies in the photovoltaic mode were not presented. A voltage dependent yield as high as 0.1 was observed however.

mum score an animal could receive for each symptom was 6, with an overall maximum of 42 for all symptoms combined.

The withdrawal syndrome observed in kindled animals was much more severe than that of the controls in terms of each symptom. To make an overall statistical comparison each animal was given a score for each symptom that was a percentage of the mean score obtained for the unstimulated control animals for that symptom. Thus, the mean of the control animals for each symptom was 100% and the control mean for all seven symptoms was also 100%. In contrast, the mean of these overall scores for the kindled animals was 249.8% ($U = 16$; $N_1/N_2 = 11/110$ $P < 0.005$, one-tailed). The incidence of seizures characterised by rhythmic head nodding, synchronous jaw movements and facial spasms over the six observation periods was also significantly greater in kindled animals (mean = 3.5) than controls (mean = 1.2) ($U = 18.5$; $N_1/N_2 = 11/11$; $P < 0.005$, one-tailed).

Repeated brain stimulation not only leads to seizures but also to a permanent decline of the afterdischarge (AD) threshold[6]. Kindling occurs only when the stimulation levels are above the AD threshold, but this threshold can be reduced even when stimulation has no electrographic or behavioural effects[6]. Thus even stimulation with no obvious effects can produce a lasting change in brain function.

To investigate whether such stimulation can intensify subsequent alcohol withdrawal, or whether elicited convulsions are necessary 11 animals were implanted with electrodes as before and an initial AD threshold was determined for each. Each animal was stimulated for 1 s with 25 µA, then, if no AD was elicited, with 50, then 75 and so on at increments of 25 µA every 6 h until an AD was produced. The intensity that evoked an AD was considered the threshold for that animal. Each animal was stimulated until only one AD was produced and then handled without stimulation until all thresholds had been determined. Subjects were then divided into two groups on the basis of their thresholds. One group ($n = 6$; mean = 131.2 µA) was placed on a stimulation regimen similar to the schedule of the first experiment, with an initial stimulation intensity for each animal 15% below the threshold for that animal. Whenever an AD was produced, the intensity of subsequent stimulations was reduced by another 15%. In this way most stimulations were kept below the AD threshold. Thus, although the average threshold drop for the stimulated groups was 62.2%, no animals developed full motor seizures, and only one displayed mild behavioural symptoms in response to stimulation. The remaining animals ($n = 5$; mean = 134.3 µA), served as unstimulated controls. Two days after the last stimulation all animals received alcohol intubations and underwent withdrawal as in the first experiment.

The raw scores for each withdrawal symptom were again converted to a percentage of the control mean for respective symptoms. As in the first experiment each symptom was more frequent in stimulated animals than in controls and the overall means (100.0% compared with 197.1%) differed significantly ($U = 3$; $N_1/N_2 = 5/6$; $P < 0.02$).

Our data show that repeated brain stimulation not only increases susceptibility to seizures produced by subsequent stimulations, but also renders the organisms more susceptible to other convulsive agents. Intensification of withdrawal symptoms by stimulation above or below the AD threshold suggests that the effect does not depend exclusively on the production of overt seizures, and that the reduction of the threshold increases the severity of withdrawal.

If brain stimulations are repeated for several months, spontaneous seizures occur, even after all stimulation ends[7,8]. Thus, we think kindling reflects the development of an epileptic focus. Since the effects of various convulsive agents interact with epileptic foci, alcohol is probably not the only agent whose withdrawal symptoms are potentiated by prior kindling. More importantly, as ADs have been produced repeatedly in humans[9,10] and as clinical evidence exists of kindling-like phenomena[10], it may be necessary to re-evaluate some clinical practices, with regard to both possible kindling in brain stimulation treatments,

and the subsequent administration of convulsive drugs. The important consideration in such a re-evaluation is that even when the current intensities are too low to produce any electrographic or behavioural effects, enduring changes in brain function may be produced.

Aggression and mating success in *Drosophila melanogaster*

THE value of *Drosophila melanogaster* as an experimental animal for the study of the genetics of behaviour increases as more specific behaviours are shown to exist in this species. Although aggressive behaviour has been reported for *D. subobscura*[1] and some Hawaiian[2] species, and has been briefly mentioned for many other species[3], it has not yet been described for *D. melanogaster*. We have repeatedly observed behaviours which we interpreted as aggressive and here, report an experiment designed to investigate aggression and its relationship to mating success—an important component of fitness.

Flies from a mass-bred stock (Haren) which has been in the laboratory since July, 1971 were used in this experiment. To identify individuals, 12-h-old males were marked on the dorsal surface of the thorax with dots of acrylic paint while under light etherisation. They were kept singly in vials containing standard *Drosophila* medium until they were 3 d old. At this time, six males were placed in a cylindrical Perspex arena (7 cm diameter, 4 cm high) containing a small dish (2.5 cm diameter) with *Drosophila* medium. After an 18-h settling period, flies were observed with a binocular microscope. All interactions occurring on the food surface and their outcomes were recorded over a period of 3 h. In addition the

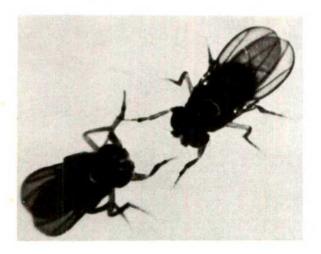
Fig. 1 A charging male of *D. melanogaster:* wing threat, wings spread, raised and twisted.


Fig. 2 Two males boxing.

position of the individuals in relation to the food surface was was noted every 5 min. We then started to introduce 3-d-old virgin females at intervals of approximately 50 min, recording which males were successful in copulation. At the end of each day the females were removed.

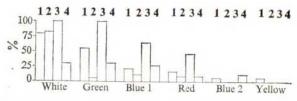
The interactions observed were primarily aggressive or sexual. We found three frequently occurring aggressive behaviour patterns: wing threat (Fig. 1) which is often directed to other males just before a very quick charge, in which the aggressor usually rises on his hindlegs shortly before impact is made, and boxing (Fig. 2) which comprises several variations of very vigorous slashing and tapping with the front legs, often while both males rise on their hindlegs.


Fig. 3 Activities of each male, expressed as percentages. (1) Time spent on the food, 100% = total time of observation; (2) attacks initiated, 100% = total number of attacks made by all flies; (3) fights won, 100% = total of a given animal's fights; (4) copulations, 100% = total number of copulations by all males = 19.

The six males showed large differences in the frequency with which they stayed on the food surface, with which they attacked, were attacked, won and lost bouts of aggression and copulated (Fig. 3). The winner is defined as the animal which remains on the food surface after an aggressive encounter. Clearly, 'white' stayed on the food surface most often ($\chi^2 = 64.1$, 5 d.f., $P < 0.005$), initiated most threats and attacks relative to the amount of time spent on the food ($\chi^2 = 31.0$, 3 d.f., $P < 0.005$) and won 100% of his fights. Ranking the animals on the proportion of fights won gives the following result: 'white' = 'green' > 'blue 1' > 'red' > 'blue 2' = 'yellow'. This rank order is significantly correlated ($r = 0.95$, $P < 0.01$) with the number of copulations achieved by each male.

Drosophila males do court other males, and other investigators who have encountered the behaviours we have described may have interpreted them as sexual in nature. In well over 1,000 videotaped single pair courtships, however, none of the behaviour patterns that we define as aggressive has previously been observed. Milani[1] has described a behaviour

similar to our wing threat in *D. subobscura* and interpreted it as aggressive in nature. Brown[4] dismisses this notion and prefers to call it counter-signalling. According to our observations, however, it cannot be a counter signal since a male engages in this behaviour before an interaction initiated by him. In *D. melanogaster*, wing flicking serves as a counter signal which is given in interactions involving physical contact between individuals of either sex.

The adaptive nature of aggression on a food source might be that males monopolise a food resource for reasons of energy requirement and/or because females will be attracted to it. Our results provide evidence that the more successful a male is in fights the fitter he is in terms of mating success.

The function of phytochrome in plants growing in the natural environment

MANY aspects of plant development are subject to photocontrol by way of the chromoprotein photoreceptor phytochrome. Phytochrome exists in two forms, P_r, which absorbs maximally at 660 nm, and P_{fr}, which absorbs maximally at 725–735 nm[1,2]. Absorption of light by either form results in phototransformation to the isomeric form. These properties make phytochrome a unique photoreceptor and raise important questions concerning the function of phytochrome in plants growing in the natural environment[3,4]. In the physiological experiments which have been so successful in elucidating the details of the structure and properties of the molecule, and which are beginning to provide evidence on its cellular mode of action, aetiolated plants are usually used and are given abnormal irradiation treatments involving brief or prolonged exposure to radiation of restricted wavelengths. Such conditions do not occur in the natural environment and, therefore, such experiments provide no evidence on the role of phytochrome in plants growing in the field. Suggestions have been made that phytochrome may enable the plant to detect shading by other plants and thus induce the alteration of metabolism and development in an appropriate manner[5,6]. These proposals point out that radiant energy below 700 nm is almost completely reflected or absorbed by vegetation, whilst that between 700–800 nm (that is, the far red) is largely transmitted[7-10]. The relative enhancement of the far red will presumably alter the photoequilibrium of $P_r \rightleftharpoons P_{fr}$ in plants growing under vegetation canopies, presenting a possible mechanism for the detection of shading. No systematic attempts have yet been made, however, to determine the extent of the spectral energy changes in the natural environment, to correlate them with effects on phytochrome photoequilibria and to assess the possible regulatory role of phytochrome under these conditions. In this report we present preliminary evidence along these lines which is consistent with the above hypothesis.

Measurements of the spectral energy distributions (SED) of natural radiation between 400 and 800 nm were made using a spectroradiometer (Gamma, San Diego) equipped with a

flexible fibre-optic light guide and a remote miniature cosine-corrected receptor head. The instrument scanned the wavelength range in 40 s and the receptor head could be placed in any position within and outside crop canopies without disturbing the vegetation. The scanned spectra were corrected for instrument response by calibration against standard lamps (National Physical Laboratory, Teddington, UK). Phytochrome photoequilibria were determined by exposing freshly prepared aetiolated bean (*Phaseolus vulgaris*) hypocotyl hook sections in a plastic cuvette to the various natural and artificial radiation sources. The cuvette was cooled to 0 °C in an ice bath and exposed for a sufficient period of time for photoequilibrium to be reached. The P_{fr}/P_{total} proportions were then determined in a modified Perkin Elmer 156 dual wavelength spectrophotometer using standard procedures[11,12]. All P_{fr}/P_{total} data presented are the means of at least 12 determinations.

Table 1 Photoequilibrium dependence on $E_{660}:E_{730}$ ratio

	$E_{660}:E_{730}$	P_{fr}/P_{total}
Midday daylight	0.99–1.17	0.59–0.62
Wheat canopy	0.21	0.33
Sugar-beet canopy	0.033–0.045	0.06–0.10
Incandescent	0.71	0.55
Fluorescent	13.5	0.76
Red	20.1	0.80
Far red	0.002	0.04

The values for the wheat canopy are the means of measurements taken at ground level on June 27, 1974. For sugar-beet, a typical range of values are presented from measurements in the dense shade below one or more leaves on June 11, 1974. Red light was produced by filtering the light from eighteen 2 foot × 20 W red fluorescent tubes through two layers of No. 14 ruby Cinemoid (Rank Strand Electric, London). Far red light was produced by filtering the light from 40 150 W incandescent bulbs through two layers of No. 5A deep orange and two layers of No. 20 deep blue (primary) Cinemoid.

In a series of measurements made throughout the growing seasons of 1973 and 1974, only slight variation was observed in the SED of natural daylight; more was seen in daylight filtered through wheat and sugar-beet crop canopies. 'Typical' midday SED scans of natural daylight and canopy light (that is, daylight filtered through a vegetation canopy) are shown in Fig. 1. The very large relative enrichment of far red wavelengths in canopy light is apparent. When seeking to correlate changes in SED with phytochrome photoequilibria, it is useful to have a single parameter to describe the SED data. The simplest, though possibly not the best, is the ratio of absolute energy, in quantum terms, of the wavelengths of maximum absorption of P_r and P_{fr}, that is, $E_{660}:E_{730}$. It is possible to derive this value from the spectroradiometer scans, and we have been able to show that terrestrial plants normally exist under conditions in which the $E_{660}:E_{730}$ ratio ranges from about 1.2 in full sunlight, to about 0.05 in dense vegetation.

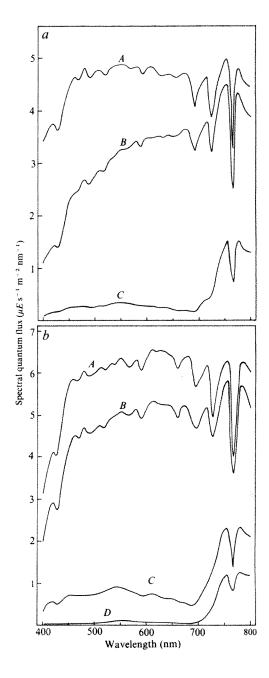
Using a variety of characterised natural and artificial radiation sources providing $E_{660}:E_{730}$ values from almost 0 to 20 we have


Fig. 1 SED of daylight above and below two crop canopies. *a*, Winter wheat canopy with a partially clear sky measured between 1000 and 1020 GMT on June 14, 1974: *A*, above canopy; *B*, ground level in sunfleck; *C*, ground level in shade. *b*, Sugar-beet canopy with a partially clear sky measured between 1320 and 1335 GMT on August 6, 1974: *A*, above; *B*, ground level between rows; *C*, and *D*, ground level within rows.

The light sources were adjusted to produce equal quantum fluxes in the 400–700 nm waveband. *T. maritimum* seedlings were grown in a glasshouse until 9 weeks old, then transferred to fluorescent lighting in a growth chamber for 1 week before starting the treatments which were carried out in 8-h days. *C. album* were collected from an open situation in the field, potted and grown under fluorescent lighting for 10 d. The plants were then divided equally between the fluorescent and incandescent sources; 16 h photoperiods were used.

attempted to correlate SED to phytochrome photoequilibria. The results are shown in Table 1 and illustrate that natural conditions (E_{660}:E_{730} from 0.05 to 1.2) provide P_{fr}/P_{total} values ranging from near 0 to about 0.6. The theoretical maximum P_{fr}/P_{total} is 0.81, resulting from the overlapping absorption spectra of P_r and P_{fr}. A relatively small change in E_{660}:E_{730} causes a substantial change in P_{fr}/P_{total}, indicating that phytochrome may be a highly sensitive detector of SED in the red and far-red regions.

Although the typical values of photoequilibria presented here follow a predictable relationship to actinic flux quality, it would be incorrect for several reasons to predict actual P_{fr} levels in plants grown in light from these data. First, differential attenuation of light by masking pigments will alter intracellular light regimes. Second, the molecular environment of phytochrome is an important factor in determining the photoequilibria, and this cannot be assumed to be identical in aetiolated and light-grown tissues[13]. Third, a substantial proportion of phytochrome may be in the form of phototransformation intermediates under conditions of natural irradiation[14]. There are no methods presently available, however, which allow the determination of phytochrome photoequilibria in green tissue.

The crucial question is whether or not the changes in phytochrome photoequilibria which we suspect occur in the natural environment actually control development. To test this, various species are being grown for prolonged periods under artificial irradiation conditions which give equivalent rates of photosynthesis, but have widely different E_{660}:E_{730} ratios. Preliminary data of the effects of a fluorescent source and an incandescent source on the development of two common arable weeds are presented in Table 2. The light sources provided equal quantum fluxes in the 400–700 nm photosynthetically active region, but established different phytochrome photoequilibria (fluorescent source, 0.76 P_{fr}/P_{total}, and incandescent source, 0.55).

The pattern of development under the two sources is clearly very different, with the source providing lower P_{fr}/P_{total} causing markedly increased internodal elongation and reduced leaf size. It should be borne in mind that the photoequilibria under the incandescent source was only marginally lower than that in normal summer daylight, whereas that under the fluorescent source was higher than values ever observed in nature. It will therefore be necessary to carry out the technically much more difficult exercise of constructing irradiation sources giving high photosynthetic rates but very low P_{fr} levels before definitive growth experiments can be carried out. Even so, the striking developmental effects of the small reduction of the P_{fr}/P_{total} from 0.76 to 0.56 are consistent with the view that phytochrome acts to perceive the changed quality of natural radiation resulting from shading by other plants. On the basis of this admittedly circumstantial evidence we support the working hypothesis that the function of phytochrome is to enable the plant to react appropriately to shading. This property would be of undoubted adaptive value and would ensure the persistence of phytochrome throughout evolution.

Male sterility in wheat plants deficient in copper

In higher plants, copper deficiency affects the reproductive phase more than the vegetative. Yields of grain may be markedly reduced or nil without much effect on yield of vegetative parts[1-3]. Failure to produce seed may be caused by lack of sufficient photosynthate production or translocation, or to the absence of fertilised embryos. Although soluble carbohydrates were low in copper-deficient wheat leaves, the evidence reported here points to the non-viability of pollen as the primary cause of failure to set grain. Possible mechanisms for the induction of male sterility by copper deficiency are proposed, and its potential for use in plant breeding is discussed.

Copper-deficient wheat plants developed small anthers, commonly less than half as long as those of normal plants and of about one-tenth the volume (Fig. 1). Pollen grains were fewer in number, small, and often dented like deflated footballs (Fig. 1). Copper-deficient pollen did not stain with iodine-potassium iodide solution (Table 1 and Fig. 1), indicating non-viability[4].

Table 1 Effect of copper on pollen production and viability in wheat

Copper status of plants	Pollen grain numbers per anther	Stained pollen grains (%)
Copper-deficient	76	0
Copper-sufficient	3,400*	95

Values are the means for nine anthers.
*This value was not determined in this study but from counts of pollen grains in four anthers of healthy plants of the same cultivar in another study.

Cross pollination experiments (Table 2) confirmed the non-viability of copper-deficient pollen and also showed the viability of the ovule. With the exception of two grains in one head, no seed was set from copper-deficient pollen; in contrast, pollen from copper-sufficient plants set grain with both copper-sufficient and copper-deficient ovules. In copper-deficient ovules, normal pollen set grain in 30% of the florets. Most ovules may have been viable since pollen was applied only once, and fertile florets were found in all parts of the heads.

Time-of-application studies showed that grain set from deficient plants responded dramatically when copper was applied until 12 weeks after sowing, after which there was no response, except in later tillers. The critical period in copper-deficient plants was the early boot stage, which approximates to meiosis in microsporogenesis. Synchronised meiotic divisions in a large number of pollen mother cells[5] may produce a localised demand for copper exceeding that which the deficient plant can supply. This hypothesis could be tested by studying

Table 2 Grains set by cross pollination between copper-deficient and copper-sufficient wheat plants

Cross ♀ × ♂		No. of grains set	Total no. Florets	Heads
CD	CD (selfed)	0	76	3
CS	CD	2	76	3
CD	CS	47	157	7
CS	CS (selfed)	86	86	3

The values for the selfed heads are typical of many heads produced during these studies.
CD, copper-deficient; CS, copper-sufficient.

Fig. 1 *a*, Florets excised from copper-deficient (left) and copper-sufficient wheat plants. The copper-deficient anthers are much smaller than normal and the ovule is slightly smaller; one anther is still attached to the receptacle. The filaments do not elongate. (× 5). *b* and *c*, Pollen grains (treated with iodine) from copper-deficient (*b*) and copper-sufficient (*c*) wheat plants. The copper-sufficient grains stain strongly and are 55–60 μm in diameter; copper-deficient grains are 40–45 μm in diameter and do not stain. Wheat plants (*Triticum aestivum* cv. Halberd) were grown in a copper-deficient siliceous sand from Tintinara, South Australia (Laffer sand) in an evaporatively cooled glasshouse. Each pot contained 12 kg of soil which supported three plants sown on July 2, 1974. Appropriate amounts of nutrients N, P, K, Ca, Mg, S, Fe, B, Mn, Zn, Mo and Cl were added with or without Cu (at 4 mg per pot). Plants supplied with copper grew normally while copper-deprived plants showed typical deficiency symptoms: wilting, wither-tip, rat-tailed ears, delayed maturity and failure to set grain (first reported by Lipman and Mackinney[1]).

meiosis in relation to the time of application of copper, and if confirmed, would explain why a supply of copper, just sufficient for vegetative growth, may be inadequate for the reproductive phase.

An alternative hypothesis is that non-viability is caused by the lack of accumulation of starch in the developing pollen. This could be related to low soluble carbohydrate levels in copper-deficient plants (R. D. G., unpublished). Because the responsiveness to copper changes quite suddenly, however, it seems that the effect is occurring at a more critical stage of pollen formation than starch accumulation.

These findings may assist cytological and biochemical studies of microsporogenesis as well as being of potential practical use for the production of hybrid seed. It should prove possible in reproducible and well defined low copper environments, both in the field and in the glasshouse, to grow wheat, and probably other species, which are consistently male sterile. This would be especially useful where emasculation is unusually difficult or time-consuming.

Environmental conditions such as moderate water, temperature or nutritional stress can induce male sterility in genetically normal plants. Copper deficiency is a good example, and similar responses to boron deficiency have been reported[6].

This type of plant response may be important in their evolution as, by the increased possibility of cross pollination caused by male sterility in a harsh environment, adaptation would be more rapid.

Elimination of mycoplasmas from cell cultures with sodium polyanethol sulphonate

MYCOPLASMAS are common contaminants of cell cultures, though rarely of primary cultures[1–3]. The organisms can have a variety of effects on cells in cultures[5]. They can severely interfere with the metabolism of the cells. Depletion of the culture medium content of arginine causing chromosomal changes and morphological alteration of the cells have been observed, although cytopathogenic changes similar to those caused by viruses are less common. The use of cell cultures contaminated with mycoplasmas may supress the yield of viruses, but occasionally enhance it. Since some species of *Mycoplasma* may haemadsorb and haemagglutinate, the presence of such organisms in cell cultures may be mistaken for that of certain viruses.

Methods to eradicate mycoplasmas from cell cultures[3] are usually of restricted value, since the organisms, although not detectable for some time, usually reappear. Such methods include treatment of the cultures with antibiotics[6], and/or antisera homologous to the contaminating species of *Mycoplasma*[3]. Heating of the cultures at 41 °C or treatment with N-tris-(hydroxymethyl)methylglycine (TRICINE) buffer has also been reported[7]. An intracellular localisation of the mycoplasmas would explain why contaminated cell cultures are refractory to treatment, but it is not yet known whether mycoplasmas do occur intracellularly.

Sodium polyanethol sulphonate (SPS) is an anticoagulant, which also inhibits the bactericidal activity of serum[8,9], and is therefore used in transport media for blood specimens to be cultured for bacteria. A 5% solution of SPS impregnated on paper disks inhibits the growth on solid medium of the vast majority of species of *Mycoplasma*, but not those of *Acholeplasma*[4]. SPS (Koch-Light) was used for eliminating mycoplasmas contaminating cell cultures of the following contaminated cell lines. Human embryonic lung fibroblasts (HEL), HeLa (strain S3), MASA (originally derived from bone marrow[10]) and McCoy cells.

SPS (10%) was sufficient to eradicate the mycoplasmas from the HeLa and McCoy cell lines after incubation for 22 h (Table 1). The cultures remained free of mycoplasmas within the 4 months of follow-up. The HEL cells were more susceptible to SPS and did not survive treatment for 6 h with a 5% solution. Lower concentrations of SPS were not enough to kill the mycoplasmas in the HEL cell cultures. As for the MASA cells, the mycoplasmas could not be eradicated by one treatment with SPS in concentrations which did not also kill the cells. The mycoplasmas were, however, reduced by 10^4 colony-forming units (CFU ml^{-1}) in the culture medium by the first treatment. After treated a second time with 10% SPS for 6 h the cell cultures were free from mycoplasmas and remained so for at least 4 months.

Eradication of the mycoplasmas was successful only when the culture bottle was completely filled with the mixture of the

Table 1 Susceptibility of some cell lines and of contaminating mycoplasmas to SPS

Cells	SPS (%)	Period of treatment (h)	Myco-plasmas eliminated	Cell line killed
HeLa	5	22	—	—
	10	22	+	—
McCoy	5	22	—	—
	10	22	+	—
HEL	2	6	—	—
	5	6	NT†	+
MASA	5	6	—	—
	10	6	—*	—
	10	22	NT†	+

*The treatment reduced the number of mycoplasmas in the culture medium with 10^4 CFU ml^{-1}. Repeated treatment with 10% SPS for 6 h after the cells had been passaged, eliminated the mycoplasmas completely from the cell culture for at least 4 months.

†Not tested.

Cells were grown in MEM (Flow) with foetal calf serum (final concentration 10%), and propagated with the aid of versene. Before and after treatment with SPS, cultures were tested for mycoplasmas in serial dilutions of the tissue culture medium in liquid mycoplasma medium, and by direct inoculation on to agar plates[11]. The culture medium specimens tested also contained cells. In some instances, the cell suspensions were also frozen and thawed before culture for mycoplasmas. Mycoplasmas isolated from the cultures before treatment belonged to the *M. orale* (type 1) species. The culture medium contained at least 10^6 colony-forming units (CFU) of *Mycoplasma* ml^{-1} before treatment with various concentrations of SPS, at which time they produced a confluent layer of cells in Carrel bottles. The mixtures were incubated at 37 °C for various periods after which the cells were passed to new bottles. Attempts were made to isolate mycoplasmas before each new passage of the cells. If not stated otherwise, the results presented are based on those obtained from a single treatment with SPS.

culture medium and the SPS. The treatment also killed a large proportion of the cells, but did not disturb further propagation of the cell lines. Cells cultured in suspension proved more susceptible to SPS than when the corresponding cells were cultured in monolayer.

In many laboratories the majority of cell lines used are presumably contaminated with mycoplasmas. We found mycoplasmas in more than 60% of a series of 400 specimens of cell culture media from such cultures. The route of infection of cell cultures with mycoplasmas is often obscure, although contamination of the cultures by mycoplasmas from the respiratory tract of the persons handling the cultures and the use of contaminated constituents of the cell culture medium, particularly serum, have been considered the commonest sources of infection. The former may be suspected for the cell cultures we studied, since the mycoplasmas isolated belonged to the species of *M. orale* (type 1).

The mechanism by which SPS kills mycoplasmas is not known, but it is probably by lysis. The presence of cholesterol in the cytoplasmic membrane of mycoplasmas but not that of acholeplasmas would explain the difference in susceptibility to this compound, the former organisms being more susceptible. When tested with the disk-diffusion technique a 5% solution of SPS did inhibit mycoplasmas, with the exception of certain strains of *M. anatis*, *M. gallinarum*, *M. gatae*, *M. iners* and *M. maculosum*, but not acholeplasmas[4]. The mycoplasmas isolated from the cell cultures we studied belonged to one species, *M. orale* (type 1). The susceptibility to SPS of the great number of other species of *Mycoplasma* known to contaminate cell cultures is to be tested. The susceptibility of *M. orale* (type 1) does not seem to differ, however, from that of the majority of other species of *Mycoplasma*[4]. The presence of cholesterol in the cytoplasma membrane of mycoplasmas and its absence in that of acholeplasmas has also been offered as an explanation of the differential effect of lysolecithin on these organisms[12]. We also tested whether lysolecithin could

be used for eliminating mycoplasmas from cell cultures, but the differential between the concentrations that killed the mycoplasmas and the cells proved too small for lysolecithin to be of use for this purpose, at least for the cell lines studied. This also seems to hold for certain cell lines with SPS.

Penicillin-binding proteins and cell shape in *E. coli*

β-LACTAM antibiotics (penicillins and cephalosporins) have attracted considerable attention as probes of cell growth and division[1,2]. Although extensive studies have been made on both penicillin-sensitive enzymes and penicillin binding proteins[3], there has been no clear indication of the role of any of these components in the effects of β-lactam antibiotics on cell growth. We report the identification of a minor penicillin binding protein which we believe to be the target at which the amidinopenicillanic acid designated FL1060 (ref. 4) acts to affect the shape of *Escherichia coli*. This is the first example of the identification of a penicillin binding protein with an essential and defined role in bacterial cell growth.

Whereas low concentrations of typical β-lactam antibiotics specifically inhibit cell division in *E. coli*, FL1060 at its lowest effective concentration causes the conversion of *E. coli* rods into ovoid shaped cells[4,5]. The atypical effects of FL1060 are paralleled by its failure markedly to inhibit any of the three known penicillin-sensitive enzymes of *E. coli*[5,6] and by its apparent failure to compete with the binding of ^{14}C-benzyl-penicillin to *E. coli* membranes[6]. As these experiments measured total enzyme, or total binding, it is still possible that FL1060 inhibits a minor enzyme species or competes with a minor penicillin-binding protein in the cell envelope. We have re-examined the binding of FL1060 to the *E. coli* penicillin binding proteins using an improved method for the detection of the individual binding proteins, and have shown that FL1060 does indeed compete with high affinity for a minor penicillin binding protein in the *E. coli* inner membrane.

^{14}C-benzylpenicillin (54 mCi mmol^{-1}; Searle Amersham) was bound to purified membranes of *E. coli* K12 (strain KN126 obtained from Dr T. Nagata). The membrane proteins were solubilised and fractionated on sodium dodecyl sulphate (SDS) polyacrylamide slab gels. As conventional autoradiography was too insensitive to allow rapid detection of the binding proteins, they were detected by incorporating the scintillant 2,5,-diphenyloxazole (PPO) into the gel matrix (fluorography[7]) and exposing the dried gel to Kodak RPRoyal X-ray film at -70 °C (ref. 7). Figure 1a shows the pattern of six penicillin-binding proteins consistently obtained from the membranes of *E. coli* K12. As all six proteins are found exclusively in the inner (cytoplasmic) membrane (our unpublished results) we routinely removed the outer membrane after binding ^{14}C-benzylpenicillin (taking advantage of the insolubility of the outer membrane in 1% Sarkosyl at room temperature[8]) and fractionated only the

Fig. 1 Competition of FL1060 and 6-APA for penicillin-binding proteins. Membranes were prepared from *E. coli* KN126 growing exponentially in Difco antibiotic medium No. 3 as described previously[9], washed twice in 0.01 M sodium phosphate buffer, *p*H 7.0, and resuspended at 20 mg ml^{-1} in 0.05 M sodium phosphate buffer, *p*H 7.0; 10 mM MgCl$_2$. To assay penicillin binding proteins 20 μl of ^{14}C-benzyl-penicillin (50 μCi ml^{-1}, specific activity, 54 mCi mmol^{-1}) was added to 200 μl of washed membranes for 10 min at 30 °C. The final concentration of benzylpenicillin was 34 μg ml^{-1}, sufficient to saturate the binding proteins in 10 min at 30 °C. The reaction was stopped and the inner membrane was solubilised by addition of 10 μl of 20% (w/v) Sarkosyl (Geigy) and 5 μl of cold benzylpenicillin (120,000 μg ml^{-1}). After 20 min at room temperature the samples were centrifuged at 100,000*g* for 40 min and 100 μl of the supernatant was added to 50 μl of SDS buffer (0.2 M Tris-HCl, *p*H 6.8; 3% SDS; 30% glycerol; 0.002% bromophenol blue). After addition of 15 μl of β-mercaptoethanol, the samples were heated at 100 °C for 2 min and 50 μl was loaded on a 12% discontinuous SDS polyacrylamide slab gel using the buffer system and apparatus described by Laemmli and Favre[10]. After fixing the gel, the scintillant PPO was incorporated into the gel and the binding proteins were detected by fluorography[7] on Kodak RPRoyal X-ray film for 23 d at −70 °C. *a*, Membranes preincubated with 10 μl of distilled water for 10 min at 30 °C. *b*, Membranes preincubated with 10 μl of FL1060 (100 μg ml^{-1}) for 10 min at 30 °C (final concentration of FL1060 was 5 μg ml^{-1}). *c*, Membranes preincubated with 10 μl of 6-APA (1 mg ml^{-1}) for 10 min at 30 °C (final concentration of 6-APA was 50 μg ml^{-1}.) Electrophoresis was from the top to the bottom of the figure.

Sarkosyl-soluble inner membrane. As radioactive FL1060 is not readily available, we have studied the binding of FL1060 to the penicillin binding proteins by competition with ^{14}C-benzylpenicillin. Figure 1*b* shows that prebinding FL1060 (5 μg ml^{-1}) for 10 min at 30 °C resulted in the complete blocking of the subsequent binding of ^{14}C-benzylpenicillin to binding protein 2 without affecting any other binding protein. A more detailed analysis showed that FL1060 (0.013 μg ml^{-1}) produced a 50% inhibition of the binding of a saturating concentration of ^{14}C-benzylpenicillin to binding protein 2. This is in good agreement with the minimal inhibitory concentration (MIC) of 0.05 μg ml^{-1} required to inhibit the growth of this strain. A similar blocking of binding to protein 2 was observed if ^{14}C-benzylpenicillin was added to membranes prepared from cells grown for 60 min in the presence of FL1060 at 0.1 μg ml^{-1}.

To implicate binding protein 2 further in the effects of FL1060 on cell shape we screened a number of penicillins and cephalosporins to find those which produced similar morphological effects to those produced by FL1060. Among the compounds screened, only the penicillin precursor molecule 6-aminopenicillanic acid (6-APA) resulted in the production of ovoid cells at the lowest effective concentrations, and at no concentration did it produce the specific inhibition of cell division typical of most β-lactam antibiotics. 6-APA was

markedly inferior to FL1060 in its action on cell shape as it was only effective at relatively high concentrations (MIC 14 μg ml^{-1}) and over a narrow concentration range above which lysis occurred. Figure 1*c* shows that as expected 6-APA at 50 μg ml^{-1} completely inhibited the binding of ^{14}C-benzylpenicillin to binding protein 2. A concentration of 2 μg ml^{-1} 6-APA produced 50% inhibition of binding to protein 2. Significant inhibition of binding proteins 1, 3 and 4 was also produced by 6-APA at 50 μg ml^{-1}. This is probably the cause of cell lysis by 6-APA as the binding of β-lactams to these latter proteins is thought to be the cause of the effects of typical β-lactam antibiotics on cell growth and division (our unpublished results).

Binding protein 2 has an apparent molecular weight of 66,000 as measured by its relative mobility on SDS polyacrylamide slab gels compared with that of 7 standard proteins, and constitutes 0.5% of the total penicillin binding at saturating concentrations of ^{14}C-benzylpenicillin. This represents about 10 copies of binding protein 2 per cell. Typical β-lactam antibiotics that affect cell division and cause cell lysis either fail to compete with binding protein 2 (for example, most cephalosporins) or bind with low affinity. These latter antibiotics do not result in the production of ovoid cells as they bind to other proteins thought to be involved in cell division and cell elongation with greater affinity than they do to binding protein 2 (our unpublished results).

We believe that penicillin-binding protein 2 is the target at which FL1060 acts to affect the shape of *E. coli*. The protein is presumably an enzyme involved in the terminal stages of peptidoglycan metabolism. At present it is not clear whether this is a previously unknown enzyme or a minor component of one of the established penicillin-sensitive enzymes[3]. As FL1060, unlike typical β-lactam antibiotics, is much more effective against Gram-negative than Gram-positive organisms it has been suggested that it acts on a target which is unique to the former class of organisms[3] (R. James, J. Haga and A.B.P., unpublished).

Immunological and bacteriological basis for vaccination against dental caries in rhesus monkeys

A REPRODUCIBLE model for dental caries has been established in rhesus monkeys[1]. The development of caries is comparable to that found in man because caries is induced by maintaining the animals on a human type of diet, this is associated with an overgrowth of a naturally acquired *Streptococcus mutans* and caries develops in teeth that are morphologically similar to human teeth. The incidence of

smooth surface caries was reduced by subcutaneous or submucous immunisation with a heat-killed *Strep. mutans* in Freund's incomplete adjuvant (FIA)[2]. Protection has been correlated predominantly with the rate of development of serum complement fixing antibodies to a hydroxyl apatite fraction of the culture supernatant (HACS) of *Strep. mutans*. The aims of this investigation were to attempt to elucidate the mechanism of prevention of dental caries in rhesus monkeys by immunisaion with a monkey passaged *Strep. mutans*. The relative effects of saliva and crevicular fluid on *Strep. mutans* were tested by developing a differential sampling technique across the plaque and the adjacent saliva and crevicular fluid. This revealed that the very low caries score in the immunised animals was correlated with serum antibodies and with a reduction in the number of *Strep. mutans* in crevicular fluid and the adjacent bacterial plaque zone.

A series of 11 young rhesus monkeys were caged, examined and maintained on a human type of diet, containing 15% sucrose as described previously[1]. All animals had a fully erupted deciduous dentition but no permanent teeth and their ages were assessed to range from 11 to 21 months (ref. 3). The animals were examined at monthly intervals and a steady increase in weight was recorded in all animals.

A streptomycin resistant *Strep. mutans* (serotype c) was successfully implanted into the mouth of another rhesus monkey, then reisolated and a heat-killed vaccine containing about 10^9 of the passaged *Strep. mutans* per ml was prepared and used as described previously[2]. The animals were randomly distributed into three groups and there was a comparable sex distribution in each of these groups. One

group of three monkeys was given the first subcutaneous injection of 0.5 ml of the vaccine in an equal volume of FIA into the contralateral limbs. This was followed by four injections of 1 ml of the vaccine alone at weeks 4, 8, 16, and 56. The adjuvant control group of four animals was given subcutaneous injections of 1 ml of FIA, followed by four saline injections; the saline control group of four animals was given five subcutaneous injections of saline at the same time intervals.

Blood was taken from the femoral vein at monthly intervals and always before immunisation, and the serum was stored at $-20\,°C$. The blood indices remained within the normal range throughout the investigation. Serum antibodies were assayed by the complement fixation (CF) test in microplates, as described previously[4]. The immunised group showed a rapid increase in CF antibodies from a mean baseline titre of $\log_2$ 1–4 within four weeks and reached a maximum of $\log_2$ 6 by week 24 (Fig. 1). A small decrease in titre followed, but the booster injection at week 56 induced a secondary antibody increase to $\log_2$ 6. Both control groups had a very low serum antibody titre of less than $\log_2$ 3.

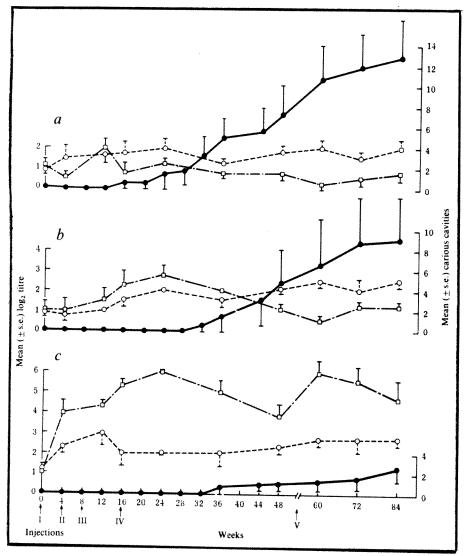
Whole saliva was collected at monthly intervals, after subcutaneous injection of 0.5 mg per kg of pilocarpine[1], and the haemagglutinating antibodies were determined by a modified micromethod[4]. The immunised group showed a modest increase from a mean titre of $\log_2$ 1.2–2.3 and remained between $\log_2$ 2–3 from week 4 to 84. Both control groups showed little initial change but from week 24 to 48 titres between $\log_2$ 1 and 2 were found in the saline group and between $\log_2$ 2 and 3 in the adjuvant group.


Fig. 1 Sequential serum and salivary antibody responses to immunisation and caries score over a period of 84 weeks. *a*, Saline group; *b*, adjuvant group, *c*. *Strep. mutans*/adjuvant group. ●, Caries index; □, serum antibodies; ○, salivary antibodies.

Clinical and X-ray examination for dental caries was performed at monthly intervals and caries was scored as described previously[1]. The mean onset of smooth surface caries was 28.5 ($\pm$4.6) weeks in the saline group, 54.5 ($\pm$10.8) weeks in the adjuvant group and more than 55 weeks in the immunised group (one animal had no caries by week 84). Both control groups showed a rapid increase in smooth surface caries (Fig. 1) and by week 84 a mean of 12.75 ($\pm$3.6) cavities per animal was found in the saline group and 9.0 ($\pm$4.3) cavities in the adjuvant group of monkeys. In contrast the immunised group had developed only 2.7 ($\pm$1.4) cavities per animal. The results suggest that immunisation had delayed the onset of caries and had decreased both the rate of development and the incidence of caries. The serum CF antibodies seemed to be associated with this protection, as was found previously[2]. Fissure caries appeared from week 20 in the saline and week 28 in the adjuvant group; by week 84 there were 2.0 ($\pm$1.3) and 2.5 ($\pm$1.0) cavities per animal respectively. Fissure caries was not found in the immunised group by week 84.

No attempt was made to implant *Strep. mutans* into any of the animals. A sequential analysis of randomly pooled plaque, from the buccal and approximal surfaces of teeth was carried out at monthly intervals from 0 to 6 months. Samples of plaque were placed into transport medium and then cultured, under anaerobic conditions, on TYC medium[5]. *Strep. mutans* and *Strep. sanguis* were identified by their colonial morphology, production of dextran and carbohydrate fermentation reactions. *Strep. mutans* (serotype c) was isolated from dental plaque from week 4 and all animals harboured a large number of these *Streptococci* from week 24 to 84. The mean time of isolation of *Strep. mutans* from the saline group was 15.5 ($\pm$5.0) weeks, from the adjuvant group 19.5 ($\pm$1.5) weeks and from the immunised group 20 ($\pm$2.0) weeks. In contrast, *Strep. sanguis* was isolated from all animals between 0 and 4 weeks and persisted throughout the experimental period.

Once the *Streptococci* were established in all animals, a quantitative analysis was performed, to find out if immunisation had any effect on colonisation by *Strep. mutans*. Weighed samples of plaque were collected in 2 ml of transport medium, at monthly intervals, from 6 to 12 months. The samples were dispersed by shaking vigorously with glass beads and then plated out in serial tenfold dilutions on TYC medium. The results were expressed as a percentage of colony forming units (CFU) of *Strep. mutans* and *Strep. sanguis*, in terms of the total number of *Streptococci* per mg of plaque grown on the TYC medium. Little difference was found between the mean CFU of *Strep. mutans* of saline injected (67 $\pm$7.7), adjuvant treated (46$\pm$9.4) and immunised (54 $\pm$15.0) animals. In view of this and the fact that serum and not salivary antibodies seem to be associated with protection against caries both in rhesus monkeys[2] and in man[4], the question was posed whether protection was mediated by serum through crevicular fluid. The hypothesis to be tested was that according to the immune state of the animal there should be a quantitative difference in *Strep. mutans* in the 4 zones adjacent to the tooth (Fig. 2); crevicular fluid, crevicular fluid plaque and salivary plaque zones and saliva.

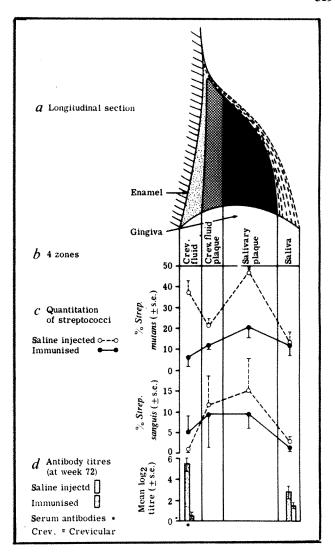
An aliquot of 0.1 ml of the whole saliva was placed directly into transport medium. The salivary plaque zone was collected by lightly removing with a probe all plaque from about the cervical third of the buccal surfaces of the left maxillary molars and placing this into transport medium. The 'crevicular fluid-plaque zone' was sampled by rubbing the blunt end of a sterile root canal paper point against the surface from which the 'salivary-plaque zone' had just been removed and cutting off the end of the paper point into transport medium. Finally, crevicular fluid was collected from the same site by placing the needle of a 50 µl syringe between the two deciduous molars and flush-


Fig. 2 Salivary and crevicular fluid immune mechanisms affecting *Strep. mutans* in the four zones adjacent to the tooth.

ing through and immediately aspirating 10 µl of transport medium[6]; this was repeated and the washings were collected into transport medium. The four specimens were suitably diluted and the CFU of *Strep. mutans* and *Strep. sanguis* were determined monthly between 12 and 18 months. The results were expressed by comparing the sum of the means ($\pm$s. e.) of the six serial determinations in each animal in one group with those in another group (Fig. 2) Although three of the four sampling sites showed a lower percentage of *Strep. mutans* in the immunised than control groups this reached significant levels only in crevicular fluid (t=4.035; P<0.02) and the crevicular fluid–plaque zone (t=2.77; P<0.05). The results for the adjuvant group were intermediate between the saline and immunised groups. A significant difference in the corresponding results with *Strep. sanguis* was not found; indeed there were about nine times more *Strep. sanguis* in the crevicular fluid of immunised than saline injected animals. It is also of considerable interest that the crevicular fluid of saline injected animals yielded about 60 times more CFU of *Strep. mutans* (38) than *Strep. sanguis* (0.6), whereas the corresponding ratio in the immunised animals was about 1:1, or 6 CFU in each group. Preliminary determinations of the percentage of *Strep. mutans* in terms of the total anaerobic bacterial growth on blood agar showed that crevicular fluid of the saline injected group yielded about 25 times more *Strep. mutans* than the immunised group.

There are two mechanisms which may be involved in

prevention of caries: first salivary IgA preventing adherence of *Strep. mutans*[7], and second, crevicular fluid mediated serum antibodies and blood leucocytes inhibiting *Strep. mutans* or its products, suggested here. The relative roles of saliva versus crevicular fluid were put to the test by developing a differential sampling technique across the plaque and the adjacent two fluid layers. This revealed that the very low caries score in the immunised animals was correlated with a low percentage of *Strep. mutans* in crevicular fluid and the crevicular fluid–plaque zone and an increased serum antibody titre to *Strep. mutans* (Fig. 2). A similar relationship was not found with salivary haemagglutinating antibodies and *Strep. mutans* in saliva and the salivary–plaque zone which probably constitutes the bulk of dental plaque as tested conventionally. A significant reduction in *Strep. mutans* in plaque of immunised animals was not found by others[8-10], with the exception of one out of seven groups of animals in one series.[10] It is assumed that the immune responses in crevicular fluid are mediated by serum antibodies and possibly leukocytes, but this will have to be tested directly on crevicular fluid. The bacteriological results are consistent with the hypothesis that the immune components of crevicular fluid are responsible for protection against smooth surface caries, and that crevicular fluid may act as a functional analogue of blood.

Photopigment conversions expressed in receptor potential and membrane resistance of blowfly visual sense cells

IN spite of the fact that intracellular recordings from photoreceptor cells have been possible for many years and knowledge regarding the photochemistry of these cells has been steadily increasing, it is still unclear how resistance changes and potential changes of the cell membrane are mediated by photoconversion of the pigments located in that membrane. It is generally supposed that a link does exist between the photochemistry and the membrane phenomena, but evidence is sparse.

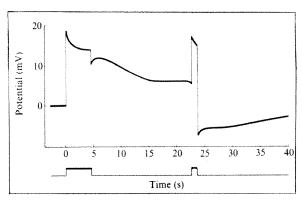
Recent evidence is provided by the work of Hochstein *et al.*[1] on the barnacle and Minke *et al.*[2] on *Limulus* who demonstrated that light-evoked changes in resistance and potential of the receptor cell membrane depend on the photopigment conditioning. Their experiments are founded on two crucial facts in the photochemistry of these and many other invertebrate species. First, the photopigment has two thermostable states instead of one, and second, practically all pigment can be converted into either the rhodopsin or the metarhodopsin state when illuminated with carefully chosen wavelengths. It proved that stimulation with a metarhodopsin-generating wavelength of a receptor cell harbouring mainly rhodopsin, caused resistance and potential changes which persisted in the dark and could only be undone by a wavelength causing renewed rhodopsin production.


Fig. 1 Upper trace, membrane potential of a visual receptor cell (blowfly wild type) measured intracellularly with a glass microelectrode. Lower trace, light stimulus. Positive deflection represents membrane depolarisation. The cell has been preadapted to intense red light (603 nm). The first stimulus shown in the figure, delivered after 2 min in the dark, is a blue flash (460 nm), causing a depolarisation. Apart from a short dip, switching off the blue light does not change the light adapting course of the receptor potential. A flash of red light (second stimulus in the figure) depolarises the membrane again and induces normal repolarisation at its termination.

For the blowfly, the particulars of rhodopsin and metarhodopsin are given by Stavenga *et al.*[3,4] who described optical work on the pupil mechanism of this species. Their results point in the same direction as those of barnacle and *Limulus*, if their hypothesis of the pupil pigment granules migrating in an intracellular force field created by the resistance changes, (which are simultaneously giving rise to the receptor potential) is correct.

Hence, we have attempted to demonstrate in the blowfly a link between the photoconversions and the light-induced changes in resistance and potential of the photoreceptor membrane. The latter were measured intracellularly in the photoreceptor cells of practically intact specimens, both wild type and the mutant Chalky.

We used the following procedures (Fig. 1). First, stimulation with red light (603 nm) brought nearly all photopigment molecules into the rhodopsin state. After 2 min in the dark, a metarhodopsin-generating blue flash was then presented, inducing a normal receptor potential, that is, a depolarisation of the cell membrane. This was, however, not followed at its termination by a normal quick return to the preillumination level, that is, a repolarisation of the cell membrane. The very slowly repolarising cell membrane could then become depolarised again by a flash of intense red light which, on being turned off, promptly caused membrane repolarisation to the former dark level.

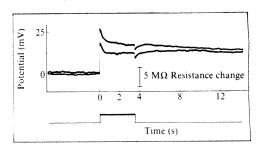
Such a recording of a blowfly wild type, is shown in Fig. 1,


Fig. 2 Upper trace, membrane potential and resistance changes of a visual receptor cell (blowfly wild type). The resistance changes are measured by a square wave (30 Hz) driven bridge circuit. With a balanced bridge a single trace is seen, but it seems to split in two as soon as the bridge becomes unbalanced; the distance between the two "parallel" traces indicates the changed membrane resistance with respect to the preflash value, while the membrane potential is represented by their mean. Lower trace, light stimulus (blue light). The cell has been pre-adapted to red light (603 nm) and blue light is presented after 2 min in the dark. After the blue light is switched off neither the membrane potential nor the resistance returns to the preflash value. The dip in potential is not accompanied by a dip in resistance.

in which termination of the blue flash is marked by a dip in the receptor potential, which otherwise does not seem to be deflected from the slowly repolarising course which normally occurs during dark adaptation. We call this sustained depolarisation a 'tail', following Hochstein et al.[1]. At the end of the subsequent red flash a rapid repolarisation was induced which markedly exceeded the former dark level (Fig. 1).

We will now compare these data with those obtained for photoreceptor cells of the barnacle[2] and *Limulus*[3]. With an essentially similar stimulus programme, but different wavelengths (because of the different absorption spectra of rhodopsin and metarhodopsin in these species), Hochstein et al.[1] elicited from the barnacle visual sense cells, tails which differ only slightly from ours. The barnacle tails markedly deflect from the slowly repolarising course normal during light adaptation, by repolarising more rapidly. The blowfly tails are in fact also characterised by a change in repolarising rate, but in the other direction. In *Limulus*, Minke et al.[2] did not observe any change in repolarising rate.

At the beginning of the tail in the barnacle there is no dip as in blowflies, but a small repolarising step, while *Limulus* has an even smaller step. But apart from these small differences of tail-slope and dip-shape which may well be explained by the differences in photochemistry, it seems certain that the underlying mechanism must be very similar if not the same in the three species.

Following the proposal of Hochstein et al.[1] and Minke et al.[2], we suggest the following scheme for the blowfly. A great number of hypothetical particles called "excitors", capable of lowering the membrane resistance, are made by the blue flash as a byproduct of metarhodopsin. These excitors continue exerting their influence on the membrane resistance, thus creating a tail, without being hampered by hypothetical anti-particles called "inhibitors" which are normally present to restore the membrane resistance as soon as the light is switched off. As a result of our experimental procedure these "inhibitors" are lacking because they have all been made ineffective by the preceding 2 min of darkness.

This happens after every such dark period, regardless of the preceding illumination history. But without the special measures taken in our experiment, illumination after the 2-min dark period encounters a mixture of both rhodopsin and metarhodopsin and immediately starts the production of, respectively, metarhodopsin + excitor and rhodopsin + inhibitor, so that the membrane can repolarise as soon as the light is turned off. But as a result of our preceding intense red illumination, all metarhodopsin has been turned into rhodopsin + inhibitor, so after the 2-min dark period there is no metarhodopsin left for the manufacture of new inhibitors and the old inhibitors have all become inactive. Only after extended blue illumination, resulting in a new photopigment equilibrium, is there sufficient metarhodopsin to ensure continuous reversal to rhodopsin + inhibitor, resulting in normal restoration of the membrane resistance and repolarisation of the cell when the light is turned off.

The results of simultaneous recordings of the receptor potential and the membrane resistance changes are shown in Figs 2 and 3. The membrane resistance change should resemble the receptor potential unless an electrogenic pump is present. Figure 2 presents a detail of a similar experiment to that in Fig. 1. The receptor potential is accompanied by measurements of membrane resistance changes which were made with an a.c. square wave driven bridge circuit. After the initial depolarisation and resistance decrease at the onset of illumination, it is seen that during as well as after the blue flash the resistance increases again, even rather more than is necessary to keep pace with the slow repolarisation. The dip in the latter, at the beginning of the tail is not accompanied by a similarly temporary change in resistance.

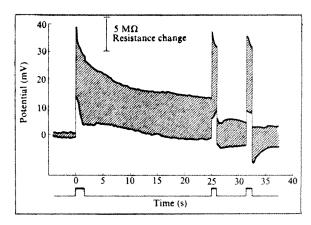
Neither can this be observed in the recording shown in Fig. 3, which stems from a pupil-less blowfly mutant, the variety *Chalky*. In this particular animal the measured resistance chan-


Fig. 3 As in Fig. 2. Measurements on a pupil-less blowfly, mutant *Chalky*. Blue light again causes a depolarisation and a decrease in membrane resistance and when the light is switched off, the cell again retains its light adapting course. Flashes of red light (second and third stimulus) depolarise the membrane as before and are followed by normal repolarisation while the resistance remains short of the former dark value.

ges were much greater than in the one represented in Fig. 2, but still, termination of the blue flash cannot be seen as a change in resistance, though again the dip in the receptor potential is present, even if rather small.

Yet another discrepancy between membrane potential and membrane resistance occurs when the tail is cut short by a red flash: at the cessation of the latter the receptor potential reaches or exceeds the former dark level, while the membrane resistance remains short of its former value.

At just this point a discrepancy also occurs in the barnacle, but here the resistance value exceeds the former dark value even more than the membrane potential does. For *Limulus* there are no data available in the same context. For an explanation of the blowfly and barnacle discrepancies between membrane resistance and membrane potential, the suggestion made by Koike, MackBrown and Hagiwara[5] of an electrogenic sodium pump which is stimulated by illumination seems a very valuable one.

Although the picture of photochemical conversions leading to electrophysiological events is far from complete as long as the particular nature of the excitors and inhibitors remains unknown, we think that our data support the supposition that a link can be demonstrated between the states of the photopigments (and their conversions into one another) and membrane phenomena. Meanwhile, the lack of a unique relationship between receptor potential and resistance changes might be held to lend support to the concept of an electrogenic sodium pump.

This study was supported financially by the Netherlands Organisation for the Advancement of Pure Research.

Note: added in proof: But even the action of such a pump cannot account for our most recent observation, namely that at the onset of illumination the resistance reaches a new value in less than 5 ms and maintains that value even though the receptor potential falls in 50 ms to half its initial height. On this time scale no pumping mechanism can be held responsible for deviations from a unique relationship, which thus must be discarded.

Axonal wiring and polarisation sensitivity in eye of the rock lobster

ARTHROPOD compound eyes consist typically of square or hexagonal facets beneath each of which lies a group of photo-receptor cells. Each photoreceptor or retinula cell gives rise to a microvillar fringe, called the rhabdomere, which consists of parallel tubules containing light-absorbing visual pigments. Axons arising from the retinula cells of each group are usually arranged in distinct bundles. These pass through the basement membrane and enter the first optic ganglion, the lamina, where they synapse with second-order neurones.

A modified organisation has been found only in Diptera[1] and now in Decapoda: in both these unrelated orders of arthropods, retinula cell axons interweave before they terminate on axons of the ganglion cells in the lamina cartridges. Whereas in Diptera this rather special arrangement is generally correlated with the 'open' type of rhabdom[2] (that is, each rhabdomere has its own visual axis and interweaving of retinula axons of several complete visual units, or ommatidia, results in a summation of like axes), the situation is different in rock lobsters, for they possess a 'fused' rhabdom characterised by centrally-connected rhabdomeres.

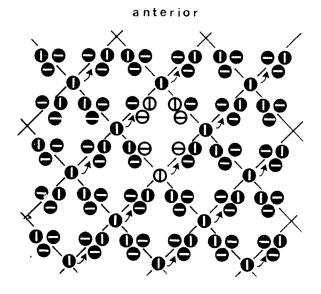
To determine the functional significance of the interweaving axons occurring in this type of compound eye, I traced the pathways of retinula cells and their axons in the eye of the rock lobster. Since Eguchi et al.[3] have identified the locations of colour-sensitive cells in the similar retina of the crayfish, and Hafner[4] has examined the fine-structural organisation of the lamina ganglionaris in the same animal, it also became necessary to know more about the region in between retina and lamina.

The rhabdom of *Panulirus longipes*, the Western Rock Lobster, is tiered and consists of seven large retinula cells. An eighth cell exists, but it is small and inconspicuous and apart from a tiny portion at the very distal end of the 'distal rhabdom' does not contribute to the rhabdom. As in *P. argus*[5] the distal rhabdom consists of alternate layers of perpendicularly-oriented microvilli belonging to the rhabdomeres of the seven contributing retinula cells. One set of alternative layers is made

Fig. 2 Serial sections (2 μm), stained with toluidine blue and examined under the light microscope, reveal how the regular interweaving pattern of retinula cell axons is produced. Erroneous combinations are extremely rare. Each retinula cell is approximately 15–18 μm in diameter.

up by the microvilli of three retinula cells, the other set, which has its tubules at right angles to those of the three cells, comprises microvilli of the remaining four cells. This type of rhabdom, commonly called 'banded' because of its appearance in longitudinal sections, seems to be typical of decapod crustaceans[5] and a few insects[6], and is thought to be significant for e-vector discrimination[7,8]. The proximal rhabdom in adult *P. longipes* (but not in larvae where it is also 'banded') differs from the thin cylindrical column of its distal counterpart in having a diameter which is ten times larger and microvilli which are not precisely oriented in two directions—as in the distal rhabdom—but run in all directions. In transverse section the proximal rhabdom resembles the leaf of a chestnut tree, in that there are seven large centrally-connected lobes.

The positions of the seven retinula cells are remarkably regular across the eye in each plane: in both left and right eye the seven retinula cells of each ommatidium are aligned diagonally so that four cells point anteriorly and three posteriorly (Fig. 1). The orientation of microvilli within these cells, however, may vary (Fig. 1a–d).

Serial sectioning revealed that some 50 μm above the basement membrane interommatidial bundles of retinula cell axons are formed (Fig. 2). The axons from seven retinula cells of one ommatidium interweave with those of their four neighbouring facets in such a way that four bundles of three fibres, heterogeneous with regard to their ommatidial origin, plus one single axon are produced (Fig. 3). The single axon consistently joins one particular bundle (Fig. 3), a few microns below the basement membrane. To find which of the seven retinula cells, in terms of microvilli orientation, became combined in these interommatidial bundles, transverse sections at the level of the distal rhabdom (that is, where the villi were precisely oriented in two orthogonal directions) were examined in the electron microscope.


Once it was realised that the position of the narrow cone cell processes between the retinula cells was extremely consistent, identification of retinula cells became easy. The only cell with cone cell processes on both sides was called cell 1 and numbering of the remaining seven cells continued counter-clockwise.

In only very few cases was the arrangement of the seven cells similar to that reported by Eguchi and Waterman[5] for *P. argus* (Fig. 1a). Equally rare (that is, less than 5%), was the arrangement shown in Fig. 1b. Had either of these two arrangements been realised more frequently, a surprisingly simple connectivity pattern of interconnections would have resulted from the particular way that retinula cell axons interweave before they penetrated the basement membrane: axons of cells with the same microvilli orientation would have been brought together. The most commonly observed configurations

Fig. 1 Transverse section through the right compound eye of *P. longipes*. The seven retinula cells can be seen under a good binocular microscope at ×80. Axons of one ommatidium interweave with those of four neighbouring ones so that a cross of five 'naked' facets results. a–d, Schematic representation of retinula cell positions and microvilli orientations of two superimposed layers of the distal rhabdom. The position of the four crystalline cone processes, indicated by small black circles, provides an excellent reference for identification of retinula cells, for example, cell 1 always lies between two processes. With regard to the interweaving pattern described in this paper and illustrated in Figs 2 and 3 arrangements (a)—modified after Eguchi and Waterman[5]—and (b) would result in bundles in which all axons originated from retinula cells with parallel microvilli. Most commonly found, however, were arrangements (c) and (d), which are mirror images and which give rise to the interweaving pattern shown in Fig. 3.

were, however, retinula cells with microvilli arrangements as in Fig. 1c and d. The interweaving pattern of retinula cells in these cases would bring together the axons from cells which had their microvilli oriented at right angles to each other (Fig. 3).

There is evidence that the wiring pattern described is commonly found in decapod crustaceans with a 'banded rhabdom', but not in insects with a similar rhabdom[9]. For example, it has been reported[10] that interweaving occurred in the eye of *Astacus* and that groups of three or four axons, derived from neighbouring ommatidia, penetrated the basement membrane. For the European lobster *Homarus* retinula fibres were reported[11] to "separate and end in different optic cartridges", but there was no further investigation.

Little is known so far of the functional significance of the described axonal arrangement but Horridge[12], who has correctly predicted interactions between retinula cells of one ommatidium with those of four neighbouring facets, believes

anterior

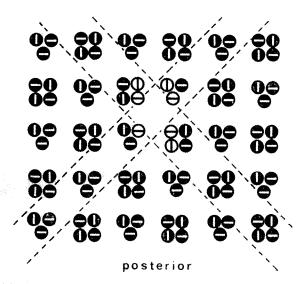
posterior


Fig. 3 Interweaving of retinula cell axons of one ommatidium (white circles) with those of four neighbouring facets results in four bundles of three fibres and one single axon (top). At 10 μm below the basement membrane (bottom) the single axon joins the anterior bundle to the right (= ventral in the right eye), thus producing an array which may be envisaged as two sets of bundles: each set being composed entirely of three or four axon bundles in rows. As symbolised by the bar in each circle, unlike the bundles containing three fibres, each bundle of four consists of equal numbers of axons originating from cells with microvilli oriented at right angles to each other.

that this could make movement perception independent of colour change or polarisation plane.

Although these findings do not support Muller[13], who believes that the frequently reported high polarisation sensitivity of individual retinula cells in crustaceans[7] is partly achieved by electrical coupling between cells which are sensitive to the same orientation of the e vector of polarised light, they do not automatically lead to the conclusion that polarisation sensitivity will be lost during transmission to the central nervous system. Even with our wiring pattern, connections which would ensure that some information on polarised light would reach the brain, are possible.

Alternatively, however, it could be argued that a two-channel–analyser, such as the banded rhabdom, is a convenient way to achieve a polarisation-independent system if receptor cell outputs are summed[14]. Because polarisation patterns are much more prominent in the sea than in air[15] (because of the dispersion of small particles in the water) it may be advantageous to a marine organism to be insensitive to them. The observed pattern of interweaving axons could be a direct consequence of this. The eighth retinula cell in the crab *Grapsus* with its microvilli arranged in two orthogonal directions[16], the relatively poor responses from adult crabs to polarised light in behavioural experiments[17], the failure to demonstrate an effect of polarised light on movement-sensitive fibres in the optic tracts of the crab *Podaphthalmus*[18] and the tendency for the axons of retinula cells with microvilli oriented at right angles to be brought together in *P. longipes*, certainly support the latter interpretation.

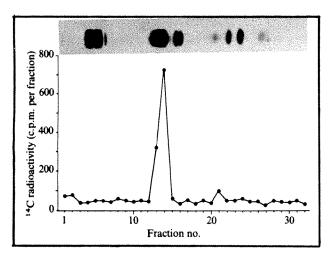
Membrane proteins related to water transport in human erythrocytes

CLASSICAL interpretations of the mechanism of water transport across mammalian red cell membranes assume the existence of aqueous membrane pores[1-3]. As the permeability coefficient to water measured under an osmotic pressure gradient is usually significantly higher than the corresponding value measured under diffusional flow, the human red cell membrane is thought to act both as a selective solvent and a molecular sieve. Its ability to function as a molecular sieve depends on the existence of the pores, which could be assembled from aggregates of integral membrane proteins which span the membrane[4]. It is generally agreed that at least two proteins span the human red cell membrane[5-7]. Using polyacrylamide gel electrophoresis we have found that a band which contains one of these proteins is selectively labelled by a water-transport inhibitor.

We used 5,5′ dithio-*bis*-(2-nitrobenzoic acid) (DTNB), one of a group of sulphydryl compounds[8-10] that inhibit osmotic


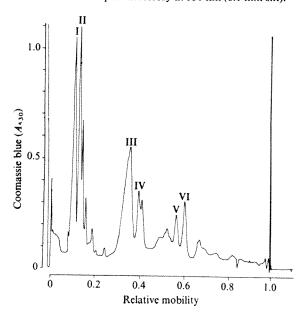


Fig. 1 Staining and labelling profiles of erythrocyte membrane proteins isolated from ^{14}C-DTNB-labelled cells. Ghosts isolated from red blood cells incubated with IAM, NEM and ^{14}C-DTNB were analysed for protein and radioactivity distribution by poly-acrylamide SDS gel electrophoresis. The gels contained 5.6% acrylamide and 1% SDS and were prepared and stained by the method of Fairbanks et al.[12]. Gels with radioactivity were sliced into 2-mm fractions, dissolved and analysed for distribution of ^{14}C-DTNB in a liquid scintillation counter. The amount of protein applied to each gel was 50 μg. Densitometry of gels is shown in Fig. 2. The identification of protein bands is according to the nomenclature of Fairbanks et al.[12].

water flow across some biological membranes. DTNB reacts with the smallest number of membrane thiol groups[11] (that is 10%, 2×10^{-17} mol per cell) of all the SH group reagents that inhibit water transport. Furthermore, it is specific for SH groups in that it only reacts by sulphydryl–disulphide exchange. To minimise nonspecific binding of DTNB to membrane proteins we preincubated cells with N-ethylmaleimide (NEM) plus iodoacetamide (IAM) which react with 60% and 30%, respectively, of the membrane SH groups[11]. These SH group reagents neither inhibit water permeability, nor do they affect the inhibitory action of DTNB[8]. NEM and IAM were also included in the cell lysing solution, as well as during the washing of the erythrocyte ghosts, so as to react with released SH-containing compounds which potentially could remove membrane-bound ^{14}C-DTNB.

Fig. 2 Densitometry of Coomassie blue stained gel in Fig. 1. Gels were scanned in a Gilford spectrophotometer with a model 2410 linear transport accessory at 530 nm (0.1 mm slit).

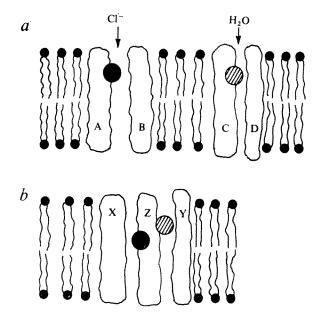
Fresh blood (25 ml) was mixed with 1 ml of 0.2M EDTA and an equal volume of cold 5 mM sodium phosphate–0.15 M NaCl (pH 7.4) and centrifuged at 1,000g for 10 min at 4 °C. Supernatant and buffy coat were removed and the packed cells were washed once and resuspended (30% haematocrit) in the buffered salt solution containing 1 mmol each of IAM and NEM. After incubation for 30 min at 37 °C, ^{14}C-DTNB (0.3 μmol) was added for a further hour, which is the time required for maximal inhibition of water transport. The cells were then collected by centrifugation and washed twice with the same incubation medium but without DTNB. Cell membranes were obtained by lysing 1.0–1.2-ml samples of the cell suspension in 40 ml of ice-cold 5 mM sodium phosphate solution, pH 8.0, containing 1 mM IAM and NEM. After centrifugation (20,000g for 30 min) the supernatant, which contained little radioactivity, was removed by aspiration. The ghost pellet was then obtained free from contaminating proteases in the tightly packed button, as described by Fairbanks et al.[12]. Ghosts were washed three times in this way and finally dissolved by addition of an equal volume of a solution containing 2% sodium dodecyl sulphate (SDS),


Fig. 3 a, Water and anion channels may be composed of entirely distinct polypeptide chains (although A may = B and C may = D) so that DIDS (filled circle) and DTNB (hatched circle) bind to separate polypeptide chains. b, Anion and water channels may be composed of several polypeptide chains, one of which is a common structural component of both (Z). DIDS and DTNB could react at different sites on Z thereby interfering with anion or water transport selectively.

20 mM Tris-HCl (pH 7.4) and 2mM EDTA. Aliquots of the dissolved membrane solution were then subjected to gel electrophoresis until the tracking dye ran 84 mm. The gels were stained with Coomassie blue, as described by Fairbanks et al.[12]. Duplicate gels, unstained, were sliced and dissolved for liquid scintillation counting of ^{14}C. The gels were calibrated with chymotrypsinogen (25,000 daltons), ovalbumin (45,000 daltons) and γ-globulin (160,000 daltons) as molecular weight markers. The gel staining pattern and the distribution of radioactivity are shown in Fig. 1. Only one Coomasie blue-staining band was labelled with ^{14}C-DTNB. This was band III which comprised about 30% of the total membrane protein[12], and had a molecular weight of about 95,000 (ref. 13). Labelling was not observed if NEM and IAM were omitted during lysis or if dithioerythaitol was added to lysed ghosts.

Gel densitometry was done using a Gilford spectrophotometer and model 2410 linear transport accessory, scanning at 530 nm (0.1 mm slit). The gel scans (Fig. 2) are essentially the same as those of Fairbanks et al.[12] except for the better resolution of the

two bands on the downward shoulder of peak II, and the resolution of peak IV into two bands. The latter was also observed by Fairbanks et al.[12] at lower concentrations of SDS. Figures 1 and 2 show that band III is quite dispersed and it may comprise more than one species of polypeptide[14]. This band has been reported to contain a phosphorylated intermediate of the (Na^+-K^+)-ATPase[15,16]. It also binds 4,4'-diisothiocyano-2,2-ditriostilbene-disulphonate (DIDS), a specific inhibitor of anion permeability.[13] The heterogeneity of protein band III is also indicated by the observation of Cabantchik and Rothstein[14] that after Pronase treatment the staining of this band decreased and three individual bands were revealed. Based on studies involving proteolysis with chymotrypsin or pronase, Cabantchik and Rothstein[14] concluded that ^{3}H-DIDS was bound to a hydrophobic 65,000-dalton fragment of the 95,000-dalton protein.

Thus the labelling of band III by DIDS, an anion permeability inhibitor, and DTNB, a water permeability inhibitor, may result because each agent binds specifically to a different polypeptide chain. Another possibility is that the anion and water channels are each formed from a common structural polypeptide chain plus one or more polypeptide chains specific for the particular functional requirement (Fig. 3). DIDS and DTNB could conceivably react at different sites on the common structural polypeptide chain thereby impeding the function of only one type of channel in each case. We conclude from these experiments that polypeptide chains of molecular weight about 100,000 form part of the structure of aqueous channels which regulate non-carrier mediated transport in human erythrocyte membranes.

Abnormalities in membrane microviscosity and ion transport in genetic muscular dystrophy

WE have demonstrated recently several functional differences between membrane-bound enzymes from tissues of muscular dystrophic chicks and of controls[1]. Several other membrane anomalies have been associated with this disease[2-7], but so far the only known biochemical anomaly in the affected membranes is a difference in lipid composition[8,9]. This could cause all the observed functional defects, including those in enzyme activities and permeability, through an alteration in the membrane microenvironment[10]. Certain physical properties of the microenvironment can be studied by fluorescent polarisation techniques that measure the mobility of a lipid-soluble fluorescent dye[11,12]. The basis for this approach is the fact that

membrane cholesterol, which strongly affects the microviscosity of liposomes[10], is present in significantly greater than normal amounts in genetic muscular dystrophy. Using this approach, we found (Table 1) that the membranes of muscle, liver and erythrocytes of dystrophic chicks have a significantly higher microviscosity than normal controls. The greatest difference was in muscle, the site of the clinical symptoms of this genetic disease. The higher cholesterol:phospholipid ratio characteristic of the diseased membrane is sufficient to account for the observed increase in microviscosity[11].

Probably the most significant pathological expression of the defect of muscular dystrophy is an alteration in ion transport. It has been demonstrated that potassium efflux from dystrophic mouse muscle and human erythrocytes is significantly greater than normal[13,14]. In view of the potential use of these observations in the screening and diagnosis of Duchenne muscular dystrophy (DMD), and in order to gain a deeper understanding of the defect we investigated the potassium and sodium transport properties of human erythrocytes. The results (Table 2) show that the potassium influx is significantly greater in both patients and carriers of the disease, relative to control. Ouabain, which inhibits the active component of the Na^+ and K^+ ion fluxes and the closely coupled ATPase activity[15], inhibited (at 10^{-4} M) the potassium influx and the sodium efflux in the erythrocytes of all three groups. Thus the erythrocytes of DMD patients and carriers have a functional cation pump. On the other hand, Brown et al. showed that in the presence of Na^+ and K^+ ouabain enhanced the ATPase activity of erythrocytes from DMD patients (while it inhibited the ATPase activity of matched controls)[16]. The patients with DMD represent the first example of dissociation of the ouabain-inhibited component of sodium efflux and potassium influx from the ATPase activity. Together with the observation of the increased potassium efflux, this finding points to an imbalance between the active (pump) and passive (leak) ion movements in this disease.

The following tentative explanation relates the abnormality in ion fluxes to the observed increase in lipid microviscosity. The higher cholesterol: phospholipid ratio causes a tighter packing of lipid molecules resulting in an enhancement of the Van der Waals' interaction between adjacent lipid molecules[17]. These changes may create a defect in the polar pathways in the protein moiety of the membrane. This would increase the passive ion movement and cause an imbalance between the

Table 1 Membrane microviscosity in muscle sarcolemma, liver and erythrocyte plasma membranes of normal and dystrophic chicks

Tissue	Membrane microviscosity, $\bar{\eta}$, (cP)
Normal muscle	61 ± 8 (7)
Dystrophic muscle	117 ± 7 (14)*
Normal erythrocytes	365 ± 30 (6)
Dystrophic erythrocytes	435 ± 20 (14)*
Normal liver	153 ± 15 (14)
Dystrophic liver	234 ± 15 (19)*

*Significantly different from control at $P < 0.01$.

Muscle sarcolemma, liver and erythrocyte plasma membranes were prepared as before[1,18-20] from the respective tissues of 20-d-old dystrophic chicks and age matched white leghorn (No. 25 Arbor Acre) control chicks. Steady-state fluorescence polarisation was measured with a Hitachi MPF-2A fluorescence spectrophotometer. Perylene at 10^{-6} M was used as the fluorescent probe. The dye was excited at 436 nm and emission was measured at 474 nm. Anisotropy of fluorescence was measured by polarising the exciting beam with a Polacoat ID5UV filter and observing the emission through the same type of filter. Fluorescence lifetimes were measured with a calibrated Ortec 9200-ns spectrometer. The calculation of the membrane microviscosity, $\bar{\eta}$, was based on the following relationship[11] $r_0/r = (1 + KT\tau)/\bar{\eta}V(r)$ where r_0/r, is the anisotropy τ is the mean fluorescence lifetime, K is Boltzman's constant, T is absolute temperature and $V(r)$ is the effective rotational molecular volume. Results represent the mean $\pm$ s.d. The number of determinations is given in parentheses.

Table 2 Potassium influx and sodium efflux in erythrocytes of DMD patients, carriers and controls (meq l^{-1} erythrocytes × h)

Source of erythrocytes	Potassium influx		Sodium efflux	
	Total	+Ouabain	Total	+Ouabain
Normal subjects	1.90 ± 0.05 (3)	0.35 ± 0.03 (3)	3.6 ± 0.5 (2)	1.4 ± 0.3 (2)
Duchenne dystrophy patients	2.20 ± 0.06 (4)*	0.43 ± 0.03 (4)	3.5 ± 0.4 (4)	0.9 ± 0.1 (4)
Genetic carrier patients	2.25 ± 0.10 (4)*	0.50 ± 0.04 (4)		

*Significantly different from control at $P < 0.01$.
Blood was collected in heparinised syringes, centrifuged for 15 min at 1,500*g*. The plasma and buffy coat were removed carefully and the cells were washed three times in buffer as before[21]. Flux measurements were carried out following standard techniques[21,22]. Results represent the mean and s.d. The number of determinations is given in parentheses.

active and passive ion transport. This study thus further supports the view that a lipid-related defect which affects the membrane microenvironment is the underlying genetic disorder of muscular dystrophy. The localisation of the pathological manifestation of the disease in the muscle is probably a reflection of the higher susceptibility of its specialised membrane system to this defect.

Association of actin and myosin with secretory granule membranes

ACTIN and myosin have been found in many non-muscle cells[1]. They are presumed to function in the generation of the force required in the various expressions of cytoplasmic or cell motility. Although both have been found in association with the plasma membrane[2-5], nothing is known about the nature or consequences of this association. Equally uncertain is the mechanism of movement of secretory granules : synaptic vesicles, for example, are transported along neurones at high rates (up to 20 cm d^{-1})[6], probably in association with microtubules[7]. Roles for actomyosin in this process[8] and in exocytosis[9] have been proposed. We have used a new approach to the problem of actomyosin-membrane interaction, and report here the binding of actin

and myosin *in vitro* to a purified cytoplasmic membrane component.

Chromaffin granules, the catecholamine-containing vesicles of the adrenal medulla, are homologous in origin to the synaptic vesicles of sympathetic nerve cells. Both contain antigenically identical storage proteins[10] and similar membrane enzymes[11]. Bovine chromaffin granules are easily purified[12] and their membranes are released by lysis. We modified the conventional preparative methods by isolating the granules in 0.15 M KCl, buffered with 10 mM HEPES pH 7.0, and purifying them by centrifugation (40 min at 4 °C and 150,000*g* through 1.5 M sucrose in the same medium. Suspension of the pellet in buffered 0.15 M KCl leads to extensive lysis of the granules. The resulting mixture of membranes and partially-lysed granules was collected by centrifugation and used in subsequent experiments at a concentration of about 6 mg protein per ml. This membrane preparation resulted in some differences in minor protein bands on SDS polyacrylamide gel electrophoresis when compared with membranes prepared at low ionic strength[12].

The adrenal medulla contains both actin and myosin (ref. 13 and K. B. and J. H. P., unpublished). We have investigated the binding of smooth muscle myosin from chicken[14] and of rabbit actin to chromaffin-granule membranes using the following method. Partially-lysed granules were incubated with the proteins under study (generally in 0.25 ml of 0.15 M KCl containing 10 mM HEPES and 1 mM $MgCl_2$ for 30 min at 24 °C); the suspension was then mixed with 0.5 ml 70% (w/w) sucrose in the same medium in a centrifuge tube (Spinco 2 × 0.5 inch), and overlaid with a linear gradient of sucrose (1.6 M to 0.6 M in the medium used for incubation). During the subsequent centrifugation (3 h at 4 °C and 200,000*g*), free proteins (storage proteins that have leaked from the damaged granules, together with test proteins that remain unbound) remain at the bottom of the tube, together with any unlysed granules; free membranes float up the tube to form a band at a position corresponding to their hydrated density (rather a broad band with a mean density of about 1.15 g ml^{-1} for membranes prepared by this method). Ten fractions were collected from each gradient and the proteins in each fraction were analysed by electrophoresis in polyacrylamide slab gels containing sodium dodecyl sulphate[15], followed by staining with Coomassie brilliant blue.

An analysis of granules incubated in the absence of other proteins is shown in Fig 1*a*. The major bands are chromogranins, the storage proteins found inside the granules. They are found in high concentration at the bottom of the gradient (fractions 1–3); the membranes, which are not obtained free of chromogranins, form a band in fractions 6–8. In some experiments the partially-lysed granules were subjected to freezing and thawing (Fig. 1*c* and *d*); in this case the membrane band is found further up the gradient, corresponding to a lower density.

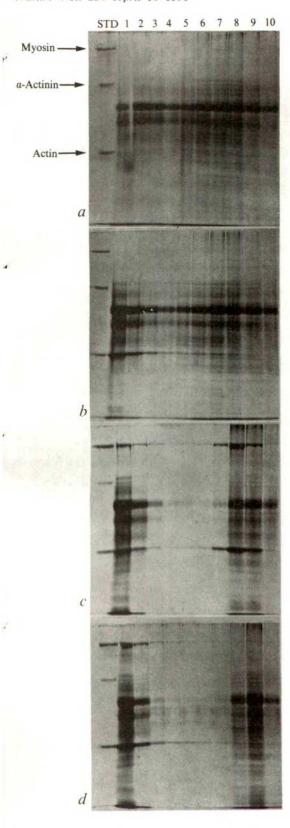
If F-actin is incubated with the granules subsequent analysis of the gradient on SDS gels (Fig. 1*b*) shows that actin is distributed throughout the gradient; it is now a sig-


Fig. 1 SDS polyacrylamide slab gel electrophoresis showing fractions of sucrose gradients of chromaffin-granule 'ghost' membranes after incubation with test proteins. *a*, Membranes only; *b*, membranes and rabbit F-actin; *c*, membranes and F-actin and myosin (from chicken smooth muscle); *d*, as (*c*) but with 5 mM Mg-ATP during incubation and in the gradient. The left-hand column (STD) of each gel contained standard protein markers, myosin, α-actinin and actin; 1 represents the bottom fraction and 10 the top fraction of each gradient. Every fraction of a gradient is shown. The membranes in (*c*) and (*d*) had been frozen and thawed once and consequently having a lower density band higher up the gradients. Sucrose gradients were run as described in the text.

nificant component of the membrane fractions. This distribution is not affected by increasing the centrifugation time to 14 h. If ghosts prepared by the conventional low ionic strength procedure are used little actin is taken up the gradient. If F-actin is incubated in the absence of granule membranes it remains at the bottom of the gradient (no trace is found above fraction 3).

A very small amount of myosin can be shown to bind in the same way when myosin is incubated with membranes in the absence of actin; this binding is not affected by the method of preparation of the membranes. If, however, both actin and myosin are included in the incubation simultaneously, there is a great enhancement of the binding of each (Fig. 1*c*), presumably because of actin–myosin interaction on the membranes. This effect is abolished by the addition of excess (5 mM) Mg-ATP; inclusion of this in the incubation and the gradient reduces the binding of both proteins to the levels found in the absence of each other (Fig. 1*d*). These background levels of binding do not seem to be sensitive to Mg-ATP or to 2 mM Mg-pyrophosphate. Two out of twelve preparations of granules tested failed to bind actin to the extent shown in Fig. 1*b* although they continued to bind myosin; preliminary experiments suggest that this is caused by proteolytic action. Such preparations fail to show the enhancement effect with actin and myosin, suggesting that this enhancement depends on the successful binding of actin to the membranes.

We tried to assess the specificity of actin and myosin binding by incubating the membranes with other purified proteins and with a post-microsomal supernatant fraction from the adrenal medulla. In the first case, β-galactosidase, catalase and pyruvate kinase failed to bind, although a trace of phosphorylase A and tropomyosin binding was detected. Of the total supernatant proteins only three bound significantly, their mobilities on the gel corresponding to molecular weights of approximately 90,000, 70,000 and 45,000, the last probably being actin.

Fractions from the sucrose gradients were examined using electron microscopy. Filaments were frequently found to be associated with chromaffin-granule membranes when material from the main band of a gradient such as that shown in Fig. 1*b* was examined (Fig. 2); control gradients (Fig. 1*a*) contained no filaments. Many gradients were examined: a striking finding was that filaments generally terminated in a membrane (Fig. 2) and were rarely found to cross membranes (Table 1). Attachment of membranes to the centres of filaments might have been expected if membrane-bound myosin was involved.

The number of membrane 'ghosts' bearing filaments varies greatly from one experiment to another. The maximum

Table 1 Association of chromaffin-granule 'ghosts' with actin filaments

Experiment	Number of filaments counted			
	First	Second	Third	Total
Unassociated	113	34	86	233
Centrally-associated	26	11	24	61
Terminally-associated	99	30	48	177
Terminally-associated, but crossing an additional 'ghost'	14	1	2	17
Total number of filaments counted				488

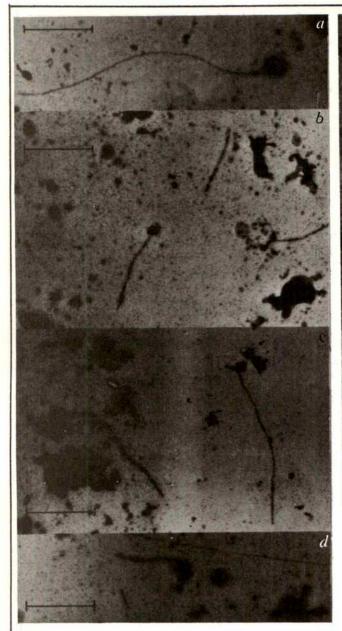
Each experiment represents a different batch of chromaffin granules. Grids (see Fig. 2) were scanned at a magnification of 10,000 or 20,000, higher magnifications being used if necessary. Every filament found in a grid square was counted unless it could not be assigned unambiguously (for example, filaments crossing grid bars). 'Association' refers to apparent contact between a filament and an intact or fragmented membrane 'ghost' (see Fig. 2). Filaments which completely crossed, or which were tangential to membrane 'ghosts' were counted as 'centrally-associated'. The number of terminally-associated filaments which cross an additional 'ghost' is dependent on the frequency of 'ghosts' on the grid; this suggests that many 'centrally-associated' filaments are filaments with membranes inadvertently lying over them.


Fig. 2 Electron micrographs of chromaffin granule membranes with associated actin filaments. After incubation with F-actin the membranes were purified from unattached protein by sucrose gradient centrifugation. Material from the peak membrane fractions was placed on carbon grids, 'decorated' with myosin subfragment 1 (ref. 16) and stained with 1% uranyl acetate. *a*, *b*, *c* and *d*, Low power views of typical grids (the bar represents 2 μm). Some of the membranes show associated actin filaments. Free filaments are also visible. *e*, *f* and *g*, Membrane–F-actin terminal associations at higher magnification (bar represents 0.5 μm). In (*e*) the arrowhead polarity of the myosin S_1 is towards the membrane, and in (*f*) and (*g*) the polarity is away from the membrane.

number found has been about 10% per preparation. All preparations contained unattached filaments, however, even though specimens were taken from the main band on the gradient; such filaments were often short and may have arisen by fragmentation on the grid.

The attached actin filaments had both polarities as judged by their 'arrowhead' directions : 46 out of 68 examined had 'arrowheads' pointing away from the membrane. ('Decoration' of a filament attached to a muscle Z line shows 'arrowheads' pointing uniformly away from the attachment point[16].) We did not find a convincing case of more than one filament attached to a 'ghost', although aggregates of 'ghosts' with several emerging filaments were sometimes observed.

Our experiments demonstrate that myosin and filamentous actin interact independently with secretory granule membranes. Because of the complexity of the present assay it has been difficult to investigate the specificity of these interactions and their optimal conditions, and we do not yet know whether protein–protein interactions are involved. In view of the high frequency of interaction of membranes with the ends of actin filaments, it is attractive to speculate that there may be an actin-binding site in these membranes. Our finding that 'ghosts' prepared conventionally at low ionic strength bind very little actin is consistent with such a binding site being an α-actinin-like protein[17], which is extracted at low ionic strength. Such a suggestion becomes more plausible now that one of us has identified a protein similar to α-actinin, in molecular weight and actin binding properties, from the particulate fractions of brain and fibroblasts (K. B., unpublished). If further work confirms a binding site, then the attachment of actin to these membranes could have a role in the transport of secretory granules from their site of formation in the Golgi apparatus to sites of exocytosis at the plasma membrane.

Stewart for helping us with the electron microscopy K B acknowledges the support of an MRC scholarship

Thiamine increases the specific activity of human liver branched chain α-ketoacid dehydrogenase

THIAMINE pyrophosphate (TPP), the active derivative of vitamin B_1, functions as a coenzyme in dehydrogenase reactions such as the oxidative decarboxylation of α-ketoisovaleric (KIV), α-keto-β-methylvaleric (KMV) and α-ketoisocaproic (KIC) acids in humans[1] Impairment of these reactions produces the group of disorders known as maple syrup urine disease[2,3] In the classic form of the disease, the ketoacids and their amino acid precursors accumulate in homozygous affected individuals and depress the function of the central nervous system early in life Therapy involves restriction of branched chain amino acids in the diet to decrease their concentrations in the body fluids[4] Further reduction in plasma leucine, isoleucine and valine has been achieved by supplementing this diet with thiamine for patients with partial (60%) and severe (95%) reduction in enzyme activity[5,6] Other investigators found no effect in patients lacking all enzyme activity[7,8] We are seeking an explanation for the clinical response at the enzyme level and have already reported that branched chain α-ketoacid dehydrogenase activity was increased in peripheral white blood cells This occurred after 3 weeks of oral thiamine treatment in patients with 5% activity and in normal controls[5] In contrast, activity in mitochondrial inner membranes from cultured normal and mutant skin fibroblasts was not stimulated directly by TPP/Mg^{2+}, but was prolonged by the presence of TPP/Mg^{2+}, suggesting that the cofactor increases the half life of the dehydrogenase complex We have now found that thiamine supplementation of normal diets increases normal human liver branched chain α-ketoacid dehydrogenase activity

Mitochondrial inner membranes were isolated from human liver obtained by open biopsy, and branched chain α-ketoacid dehydrogenase was measured before and during *in vivo* administration of 100 mg thiamine per day Tissue was kept in ice cold 0 27 M mannitol buffered with 1 0 mM Tris-HCl, pH 7 3, and 0 1 mM EDTA (MTE) Tissues were assayed within 30 min after samples were taken A decrease in mitochondrial dehydrogenase activity was noted if tissues were stored, cold or frozen After homogenisation with a glass–Teflon tissue grinder, mitochondria were isolated by differential centrifugation and washed once with MTE Mitochondria

Table 1 Effect of oral thiamine on normal adult human hepatic branched chain α-ketoacid dehydrogenase

Substrate	Duration of 100 mg d⁻¹ oral thiamine		
	0 d (6)	5–15 d (9)	18–28 d (3)
	(nmol CO_2 per 15 min per mg protein)		
KIV	18 92±5 34	19 84±3 90	35 29±6 96
KMV	9 53±2 15	8 38±2 24	12 79±2 65
KIC	8 25±2 73	6 88±1 24	14 89±2 61

$P < 0 001$

Assay conditions for CO_2 evolution are as follows in 0 25 ml cofactors were present at a final concentration of 0 2 mM TPP, 0 3 mM $MgCl_2$, 0 2 mM CoA and 0 2 mM NAD^+ in 50 mM Tris-HCl, pH 7 4 and 0 2 mM EDTA, and substrate at 2 mM Mitochondrial protein was between 60 and 600 µg $^{14}CO_2$ evolved, was trapped and quantitated as previously described[1] The number of patients in each time group is shown in parentheses Values represent the mean and standard deviation of at least quadruplicate observations *P* values were obtained using Student's *t* test and represent the probable difference between conditions after 5–15 d and 18–28 d for all three substrates

were then suspended in MTE and mixed with an equal volume of MTE containing digitonin so that the final concentration was 1 mg digitonin per mg mitochondrial protein Detergent action was stopped by addition of an equal volume of MTE after the reaction had proceeded for 20 min at 0 °C Inner membranes were isolated immediately by centrifugation at 10,000g for 15 min and then suspended in an appropriate amount of MTE for use in the experiment

Two methods of assay were used to follow dehydrogenase complex activity according to the products formed in the overall reaction

$$R\text{-}C\text{-}*C\text{-}O^- + CoASH + NAD^+ \xrightarrow{TPP/Mg^{2+}} R\text{-}C\text{-}SCoA + *CO_2 + NADH$$

Using 1-^{14}C-labelled ketoacids as substrate, $^{14}CO_2$ produced was trapped in hyamine for quantitation by liquid scintillation This assay was sensitive at pmol quantities of evolved product The concentration of NADH was determined by spectrophotometry using an $\varepsilon = 6\ 22 \times 10^3$ Mcm⁻¹ at 340 nm under assay conditions as described in Table 1 Optical clarity was required for this assay One mole of CO_2 was released for every mole of NAD^+ reduced In a typical experiment with 2 mM KIV as substrate, 13 82 nmol CO_2 per 15 min per mg were produced while the rate of NADH formation was 13 65 nmol per 15 min per mg

Thiamine was administered orally (100 mg d⁻¹) to individuals with presumed normal branched chain dehydrogenase activity for up to 28 d before surgery, when open liver biopsy was performed for other diagnostic purposes The dehydrogenase activity of mitochondrial inner membranes from these samples was measured and compared with activity in untreated controls

Thiamine did not influence the branched chain α-ketoacid dehydrogenase activity until supraphysiological loading had been present for at least 18 d (Table 1) After this time, a 1 5–2 0-fold increase in specific activity was observed towards all three substrates

There are several explanations for these results First, thiamine could increase synthesis of these mitochondrial proteins Second, thiamine or TPP could activate preformed inactive components of this complex This is unlikely since time was required for the *in vivo* effect and *in vitro* addition of TPP to the assay media did not increase the specific activity A third possibility is that thiamine or TPP at these supraphysiological concentrations maintains a conformation of the multienzyme complex which is less susceptible to degradation than is the naturally occurring holoenzyme Such a mechanism has been postulated to explain the increase in hepatic pyridoxal-

5′-phosphate-dependent cystathionine synthase activity after prolonged administration of pyridoxine[9]

Fig. 1 Concentration dependency of ppGpp inhibition (results of experiments shown in Table 1) The percentage rRNA of total RNA has been calculated from the percentage ^{3}H-UMP in rRNA by multiplication with 1 25 to correct for the base composition of rRNA relative to total DNA–complementary RNA O, Total RNA, ●, percentage rRNA, ▲, total rRNA

Specific inhibition of ribosomal RNA synthesis *in vitro* by guanosine 3′ diphosphate, 5′ diphosphate

CONSIDERABLE evidence has accumulated that guanosine 3′-diphosphate, 5′-diphosphate (ppGpp)[1] is involved in the regulation of ribosomal RNA (rRNA) synthesis in *Escherichia coli in vivo* (see ref 2) The involvement of ppGpp is most convincingly indicated by results obtained under conditions of amino acid starvation A strong increase in ppGpp accumulation is always accompanied by a concomitant decrease in stable RNA accumulation[3] *In vitro*, a specific effect of ppGpp has not been found, neither in a purified[4], nor in a crude system[5] Travers *et al*[6,7] have proposed that ppGpp specifically affects rRNA synthesis by counteracting the effects of the protein elongation factor EF-Tu Here, we show that ppGpp can specifically inhibit rRNA synthesis *in vitro* using purified RNA polymerase with two templates—DNA prepared by phenol extraction, and nucleoids prepared using methods developed by Pettijohn *et al*[8]

Table 1 shows that our hybridisation competition system has a very high specificity for rRNA, a low background and a high hybridisation efficiency These characteristics together make it possible to detect clearly even small differences in rRNA synthesis

Using nucleoids as template we found that 3 9±0 3% (s d

mean) rRNA was made by added, purified RNA polymerase Reaction conditions were as described in Table 1, except for the about tenfold less DNA concentration ppGpp (0 6 mM) decreased total RNA synthesis by about 20% whereas rRNA was on the average 45% lower, resulting in a mean percentage rRNA synthesis of 2 7±0 4% In four different experiments, the percentage rRNA was always lower when ppGpp was added

The effect of ppGpp on total and rRNA synthesis was also assayed at various RNA polymerase–DNA ratios using phenol-extracted DNA At all ratios tested ppGpp specifically inhibited rRNA synthesis (Table 2), the inhibition seems to be less pronounced at high and low ratios The concentration dependency of ppGpp inhibition is shown in Fig 1 Both total and ribosomal RNA synthesis are progressively inhibited by higher concentrations of ppGpp Half maximal inhibition is obtained at about 0 15 mM which is the same as the apparent Ki for stable RNA accumulation *in vivo*[12] GDP (1 mM) did not decrease total or rRNA synthesis

As we found in all conditions studied a specific effect of ppGpp on rRNA synthesis, that is, a stronger inhibition than that of total RNA synthesis, it is remarkable that others did not find this effect Our hybridisation method is very sensitive and will allow detection of small differences, even at low rates of rRNA synthesis In our case, inhibition of total RNA synthesis by ppGpp was less than that found by others[4,5] If inhibition of total RNA synthesis is large it could have 'drowned' a differential

Table 1 Hybridisation competition analysis of [^{3}H] -RNA synthesised in vitro

ppGpp conc (mM)	Input ^{3}H-UMP (d p m) in RNA	^{3}H-UMP (d p m) in hybrid −rRNA	^{3}H-UMP (d p m) in hybrid +rRNA	Competed	^{32}P-rRNA (d p m) in hybrid −rRNA	^{32}P-rRNA (d p m) in hybrid +rRNA	^{3}H-UMP (d p m) in rRNA	^{3}H-UMP in rRNA (%)
0 0	321,595	16,107	4,031	12,076	2,848	176	18,069	5 6
0 14	294,338	11,031	3,193	7,838	2,781	150	11,888	4 1
0 28	281,434	8,997	3,001	5,996	2,861	125	8,748	3 2
0 69	250,021	7,576	2,808	4,768	2,846	112	6,985	3,0
1 38	230,846	6,943	3,236	3,707	2,771	93	5,531	2 5

An aliquot (50 μl) of *E coli* DNA (44 μg ml⁻¹) was added to 0 45 ml of a reaction mixture containing 40 mM Tris-HCl, pH 7 9 (25 °C), 0 4 mM potassium phosphate, 10 mM MgCl₂, 100 mM KCl, 0 3 mM each of ATP, CTP and GTP, 0 1 mM EDTA, 0 1 mM dithiothreitol and 0 07 mM ^{3}H-UTP 1 Ci mmol⁻¹ The solution was incubated at 38 °C for 10 min, and then 32 μg RNA polymerase was added ppGpp was added just before RNA polymerase After 30 min at 38 °C one-quarter volume of 1 5 M NaCl containing 0 15 M sodium citrate (pH 7) was added, and the solution was extracted once with the phenol mixture of Kirby[9] Total RNA synthesis was measured in a 10 μl sample to which 100 μg yeast RNA was added as carrier by precipitation with 6% TCA containing 10 mM pyrophosphate The remainder of the water layer was used directly in the hybridisation test Hybridisation competition analysis was essentially according to Haseltine (ref 4, Fig 6), except that we used *Proteus vulgaris* DNA enriched for ribosomal DNA on a methylated albumin kieselguhr column instead of *E coli* DNA Values are the average of two triplicate hybridisations in which 20 μl *in vitro* ^{3}H-RNA and 4,005 d p m ^{32}P-rRNA were used ppGpp was prepared by the method of Cashel[10] Further details of the experimental procedures were as described[11]

Table 2 Effect of ppGpp at various RNA polymerase to DNA ratios

Ratio of RNA polymerase to DNA (w/w)	Percentage rRNA		Percentage inhibition	
	−ppGpp	+ppGpp	total RNA	rRNA
1 7	3 4	2 4	7	34
14	8 5	4 4	16	56
28	5 5	2 5	12	60
43	4 3	2 4	16	53
57	2 4	1 5	12	45

The experiments were carried out as described in the legend to Table 1 The final concentration of DNA was 15 μg ml^{-1} at a ratio of 1 7, and 4 4 μg ml^{-1} at the other ratios ppGpp was added at a final concentration of 0 6 mM

effect on rRNA Why inhibition of total RNA synthesis is lower in our system is unclear, our ppGpp preparation was checked for purity using polyethyleneimine thin layer chromatography (more than 90% pure)

The question arises how ppGpp effects its specific inhibition of rRNA synthesis We have found that with the nucleoids packing of added RNA polymerase molecules on the ribosomal cistrons is maximal[11] Consequently, the elongation rate will determine the initiation frequency and it cannot be decided whether ppGpp acts specifically on elongation or initiation of rRNA Further experiments are needed to clarify this point

Whatever the mechanism, our results clearly show that ppGpp can specifically inhibit rRNA synthesis by purified RNA polymerase on a DNA template without the addition of other macromolecular components Although extrapolation to the *in vivo* situation must be carried out with great caution our data support the hypothesis of a direct involvement of ppGpp in the (negative) control of rRNA synthesis

Enhancement of interferon production by poly(rI)·poly(rC) in mouse cell cultures by ascorbic acid

We have reported[1] an increased response to interferon induction in mice fed a diet containing vitamin C, and have now found a similar phenomenon *in vitro* Addition of L-ascorbate to cultures of mouse cells (transformed L cells and normal embryonic fibroblasts) stimulated with polyinosinic acid polycytidylic acid (poly(rI) poly(rC)) resulted in increased synthesis of interferon

Mouse L cells (American Type Culture Collection, Rockville) were seeded in 2-oz prescription bottles (Brockway Glass Co , Brockway, Pennsylvania) at a concentration of 4×10^5 cells ml^{-1} in 25 mM HEPES-buffered Medium 199 (ref 2) with 10% decomplemented foetal calf serum Ascorbate was added to a final concentration of 10^{-4} M or 10^{-5} M and the cultures were incubated for 18 h at 37 °C A dose of 10^{-3} M ascorbate was also used initially, but it usually made cultures acidic, with subsequent toxic effects The medium was decanted, and the cell monolayer was exposed to synthetic poly(rI) poly(rC) (25 μg ml^{-1}, Miles) and diethylaminoethyl-dextran (100 μg ml^{-1}) for 1 h The cultures were washed three times with phosphate-buffered saline, refed with HEPES medium with included ascorbate and incubated at 37 °C for another 10 h The medium was then assayed by a colorimetric method[3] to quantify cytopathic effects in L cell monolayers with vesicular stomatitis virus (VSV) as the challenge virus Volumes of 1 ml of serial dilutions were used for assay, and the interferon titre, expressed in dye-uptake units (DU$_{50}$ ml^{-1}), was the reciprocal of the dilution which gave an absorbance reading at 540 nm midway between that of uninfected cell controls (100%) and the virus-infected controls (0%) Readings of duplicate dilutions generally agreed to within 10% A standard reference interferon preparation (NIH reference interferon G002-904-511) with an assigned activity of 12,000 U ml^{-1} was included with each assay, and these reference titres are presented along with the experimental results The NIH mouse reference interferon titres 22,500 U ml^{-1} as an average in repeated assays in our laboratory Since the assigned

Table 1 Effect of ascorbate on interferon induction by poly(rI) poly(rC) in mouse L cell cultures

Concentration of ascorbate (M)	Interferon titres*		
	Experiment 1	Experiment 2	Experiment 3

$1 0 \times 10^{-4}$	3,330	3,105	5,060
NIH reference	20,185	15,300	28,545

*Titres are expressed in DU$_{50}$ ml^{-1}
ND, not done

potency of the reference interferon is 12,000 U ml^{-1}, conversion to reference units can be made by dividing the experimental values in the tables by the factor 1 9 The viral inhibitor was inactivated by trypsin, was non-toxic to L cells, did not directly inactivate VSV, and showed no antiviral activity in normal chick embryo fibroblasts

The presence of ascorbate in cultures of L cells resulted in increased interferon production as demonstrated in three separate experiments Values for 10^{-5} M and 10^{-4} M ascorbate (Table 1) show a dose response effect Control cultures (no ascorbate added) produced a mean interferon titre of $1,405 \pm 285$ All three observations made with 10^{-4} M ascorbate exceeded this control value by more than three standard deviations and hence are considered significant

It is well known that cells maintained in culture lose their resemblance to normal cells In this connection, we have observed that primary and secondary cultures of mouse embryo fibroblasts are considerably less responsive to interferon induction by poly(rI) poly(rC) than are cells of the mouse L line Therefore, it seemed important to study the effects of ascorbate on cells newly established in culture The results of two experiments (Table 2) with secondary cultures of normal mouse embryo fibroblasts revealed that, as in the case of the L cell line, 10^{-4} M ascorbate substantially increased the production of interferon

Statistically, the interferon titres observed with 10^{-4} M ascorbate in both cases exceeded the mean value of $127 5 \pm 46$ for control titres by more than three standard deviations

The role of ascorbate in potentiating the production of

*Titres are expressed in DU_{50} U ml⁻¹

interferon is not clear Vitamin C may affect the interactions of poly(rI) poly(rC) at the cell surface or within the cell[4] Conceivably, ascorbate could function to increase the amount of interferon messenger RNA available for translation in cells stimulated with the polynucleotide by inhibition of a regulatory protein[5,6] and promotion of the stability of the interferon messenger RNA[7] There have been reports of stimulation of the antiviral activity of interferon by cyclic AMP[8] and, more recently, by cyclic AMP and certain of its synthetic derivatives[9] In this connection, preliminary experiments have suggested little difference in cyclic AMP levels between untreated and ascorbate-treated L cells as determined by radioimmunoassay[10] Cultures assayed after 4 h of exposure to ascorbate contained 60, 74 and 60 pmol mg⁻¹ nucleic acid, respectively, for cells untreated and treated with 10⁻⁵ and 10⁻⁴ M ascorbate In another experiment, cells assayed after 18 h of treatment presented cyclic AMP levels of 75, 77 and 72 pmol mg⁻¹ nucleic acid for the respective cultures The participation of ascorbate in enhancing interferon synthesis in mouse cells *in vitro*, as well as in the intact animal[1], remains to be elucidated

Possible cocarcinogenic effects of coffee constituents

ALTHOUGH the carcinogenic properties of secondary N-nitrosamines and related compounds are well established[1,2], their causal relationship to human cancer remains an open question because very little is known about the degree of human exposure to them Carcinogenic N-nitrosamines have been detected in some nitrite-preserved foodstuffs, but only at relatively low levels[3,4], so the major uncertainty comes from their formation *in vivo* from ingested nitrite and amino compounds Formation of N-nitrosamines in this way in the digestive tract of laboratory animals has been widely demonstrated (for typical examples, see refs 5–7) and has led to the induction of tumours characteristic of N-nitrosamines[8,9] We have suggested[10] that the interaction between nitrite and phenolic materials should also be considered, because the latter are major dietary constituents which usually react much more rapidly than most amino compounds with nitrous acid Certain natural phenols may therefore inhibit N-nitrosamine formation both in foodstuffs and in the digestive tract We report here, however, that readily oxidised phenolic compounds act as catalysts rather than inhibitors for

N-nitrosamine formation from nitrite salts and secondary amines at gastric pH This finding has important implications on the possible cocarcinogenic properties of several foodstuffs and beverages, including coffee

Oxidation of *o*- and *p*-dihydroxphenols (and of *o*- and *p*-aminophenols) to the corresponding quinones is well known[11] and may be anticipated for HNO_2, itself an oxidising agent (standard oxidation potential at 298 K, $E° = -0 98$ V)[12] Our experiments confirm this expectation Thus, treatment of 4-methylcatechol (I), for example, with dilute (10⁻²–10⁻³ M) HNO_2 at pH 2–4 and 25 °C gives rapid formation of the corresponding *o*-quinone (II) with evolution of nitric oxide (equation) Since the oxidation of 4-methylcatechol seems to be complete in about 8 min, it must be one of the best known scavengers for HNO_2, but its presence, however, catalyses concurrent N-nitrosamine formation

In the absence of added phenols, the more basic secondary aliphatic amines such as dimethylamine and piperidine react sluggishly with aqueous HNO_2, even at pH 3–3 4, where the maximum rate is observed[13] for example, $t_{\frac{1}{2}}$ is about 10h for dimethylamine with [HNO_2]=0 1 M and 25 °C (ref 13) N-nitrosamine formation is even slower at high pH and our finding for piperidine (Table 1), giving $t_{\frac{1}{2}}$ about 160 h at pH 4, [HNO_2]=0 1 M and 25 °C, is typical In the presence of readily oxidised phenols, however, formation of the N-nitrosamine is very much faster Thus, typical results summarised in Table 1 show that addition of even 10⁻³ M 4-methylcatechol increases the rate of N-nitrosopiperidine formation by a factor of at least 1,000 In practice, significant amounts (about 10%) of N-nitrosopiperidine are found within the brief period (3 min) required to effect the first sampling, and its concentration reaches a maximum (Table 1) after about 10 min at 25 °C Increasing the temperature to 39 3 °C has little effect on the amount of N-nitrosamine formed but its formation rate, as would be expected, is increased Without the addition of 4-methylcatechol the amount of piperidine converted to the N-nitroso derivative after a reaction time of 10 min would be less than 0 1 % even with the highest [HNO_2] examined

4-Methylcatechol bears a close structural resemblance to the phenolic component of chlorogenic acid (III), a very substantial (about 13% by weight), soluble constituent of coffee[14] This compound (III) is therefore present in both 'instant' and ground coffee extracts to the extent of about 260 mg per cup[14] Our experiments (Table 1) show that (I) and (III) exert very similar catalytic effects on N-nitrosamine formation Thus addition of 10⁻² M (III) leads to a maximum 56% N-nitrosopiperidine formation in about 10 min at pH 4 and 25 °C compared with 42% for 10⁻² M (I) Further, we have found in preliminary experiments that a proprietary brand of 'instant' coffee, itself, when added to the buffered HNO_2–piperidine reaction mixture at a realistic consumptive concentration of 2 g per 100 ml, also leads to rapid and substantial formation of N-nitrosamines

Table 1   Rates* of N-nitrosopiperidine formation in aqueous phthalate buffers at 25 °C

‡ Significant N-nitrosopiperidine formed almost immediately and reaches a maximum in about 10 min (see text) The amount given is the percentage of the initial [piperidine] (10^{-3} M)
§ At 39 3 °C, where the maximum percentage reaction shown is reached after 3 min

It is clear that both (I) and (III), under mildly acidic conditions, are very powerful catalysts for N-nitrosamine formation in aqueous media, and other readily oxidised phenols may be expected to act similarly The mechanism of their catalytic action is the subject of current investigation, but we believe that either nitric oxide or an aryl nitrite is the very reactive nitrosating species involved Significantly, oxidation of (I) and N-nitrosopiperidine formation both seem to be complete in about 8–10 min, and we have established that nitric oxide combines rapidly with piperidine under our experimental conditions.

The experimental conditions and reactant concentrations are not appreciably dissimilar from those expected for the human stomach following the ingestion of food containing 200 p p m $NaNO_2$ (about 3×10^{-3} M) and a single cup of coffee (about 7×10^{-3} M in chlorogenic acid) The clear implication is that coffee, and other foodstuffs containing readily oxidised phenolic materials, may significantly increase human exposure to carcinogenic N-nitrosamines by catalysing their formation in the digestive tract

Tumour antigen specificity of a DNA-binding protein from cells infected with adenovirus 2

Two new polypeptides of molecular weights 75,000 and 45,000 are found in KB cells infected with human adenovirus type 2 (Ad 2), (ref 1) They represent the major labelled protein components of a nuclear membrane fraction ('DNA replication complex') that is capable of synthesising adenovirus DNA *in vitro*[1-3] It has been proposed that these polypeptides are early viral gene products, for they are synthesised soon after infection in the presence of 1-β-D-arabinosylcytosine (Ara C), an inhibitor of DNA synthesis[1] Their association with the DNA replication

complex suggested that they may have an affinity for DNA and could play a role in the replication of adenovirus DNA It was subsequently shown that these two polypeptides bind strongly to single-stranded DNA–cellulose columns and that large amounts of these 'DNA-binding proteins' can be isolated from the cytoplasm of the infected cells[2]. Two polypeptides of similar molecular weights (72,000 and 48,000) were independently isolated from cell extracts of monkey kidney cells, abortively infected with Ad 5, by their ability to bind to single-stranded DNA–cellulose[4,24] The use of temperature-sensitive mutants of Ad 5 indicated that these polypeptides are viral-coded[4,24]. Comparison of tryptic maps suggested that the 48,000 component was a degradation product of the 72,000 polypeptide (A J Levine, unpublished) A polypeptide of molecular weight about 65,000–75,000 has also been detected by polyacrylamide gel analysis in KB cells soon after infection by Ad 2 and Ad 5 (refs 5–7) and in HeLa cells infected by Ad 2 (ref 8)

Ad 2 and Ad 5 (together with Ad 1 and Ad 6) comprise the group C human adenoviruses[9] Members of this group transform rat cells *in vitro*[10], and DNA fragments of subgenomic size isolated from Ad 2 and Ad 5 have been reported to transform hamster, rat and human cells *in vitro*[11] Most transformed rat cell lines derived by infection with Ad 2 contain DNA sequences representing about 14% of the viral genome and contain tumour (T) antigens[12]. T antigens are virus-specific early proteins that are synthesised during productive infection as well as in transformed and tumour cells[8] They are generally detected by two immunological methods, complement fixation (CF) of cell extracts and immunofluorescence of fixed cells, using sera from hamsters bearing adenovirus-induced tumours. T antigens induced by adenoviruses within the same group cross-react serologically[9] We describe below the results of three types of immunological measurements—CF analysis, radioimmune precipitation, and radioimmune precipitation-inhibition—which show that the DNA-binding protein of molecular weight 75,000 (75k protein) in cells infected with Ad 2 has T-antigen specificity.

The 75k protein was purified from the cytoplasm of infected cells by chromatography on a single-stranded DNA–cellulose column as described[2] The bulk of the 75k protein is present in the fraction eluting at 0 6 M NaCl from the DNA–cellulose column (0 6 M eluate) By modifying our published procedure[2] (Fig 1), we obtained preparations of 75k protein free of the 45,000 molecular weight protein Analysis of polypeptides labelled with ³H-leucine in the 0 6 M eluate by polyacrylamide gel electrophoresis revealed a single major polypeptide peak of a molecular weight of 75,000 with only minor amounts of contaminating labelled polypeptides (Fig 1) Unlabelled 0 6 M eluates were also electrophoresed and shown to contain 75k protein as the predominant constituent after staining with Coomassie brilliant blue

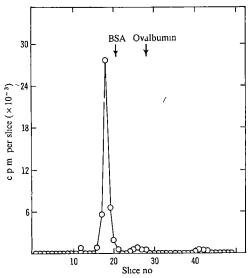
Unlabelled 0 6 M eluates were assayed by a CF microassay using hamster sera against several different T antigens (anti-T sera) The anti-Ad 1 and Ad 2 T sera and ascitic fluid were prepared in hamsters by injecting extracts of transplanted hamster tumours induced by Ad 1–SV40 or Ad 2–SV40 hybrid viruses Anti-Ad 12 (group A) and anti-SV40 T sera were


Fig 1 Gel electrophresis of DNA-binding proteins in the 0 6 M eluate from a single-stranded DNA–cellulose column KB cells were grown in suspension in Eagle's MEM containing 5% horse serum and were infected with Ad 2 at a multiplicity of 100 PFU per cell[2] At 2 h after infection, 25 µg ml⁻¹ of Ara C were added At 6 h, cells were centrifuged, washed with leucine-free MEM at 37 °C, and resuspended in leucine-free MEM with 5% horse serum Ara C (25 µg ml⁻¹) and ³H-leucine (2 µCi ml⁻¹, 41 Ci mmol⁻¹) were added and the cells were further incubated until 24 h after infection Cells were harvested by centrifugation, washed with phosphate-buffered saline, and resuspended in 0 01 M Tris, pH 7 4, 0 01 M NaCl, 0 0015 M MgCl₂ at a density of 10⁷ cells ml⁻¹ After standing in ice for 15 min, the swollen cells were disrupted by 15–20 strokes of a tight-fitting Dounce homogeniser and nuclei were removed by centrifugation at 2,000g for 10 min through a 5 ml cushion of 25% sucrose in 0 01 M Tris, pH 7 4, 0 01 M NaCl, 0 0015 m MgCl₂ The supernatant cytoplasmic fraction was treated with 20 µg ml⁻¹ of DNase I for 30 min at 22 °C in the presence of 0 05 M MgCl₂ and 0 001 M 2-mercaptoethanol The treated cytoplasm was dialysed overnight at 4 °C against at least 100 volumes of dialysis buffer containing 0 02 M Tris, pH 8 1, 10% glycerol, 0 05 M NaCl, 0 005 M EDTA and 0 001 M 2-mercaptoethanol A precipitate formed, which was removed by centrifugation before DNA–cellulose chromatography Single-stranded DNA–cellulose was prepared according to Litman[13] All DNA–cellulose column procedures were performed at room temperature Dried single-stranded DNA–cellulose (0 4 g) was suspended in dialysis buffer and used to pack a 1 8 cm³ column (0 8 × 3 0 cm) The column was washed with 10 ml of dialysis buffer and loaded with the cytoplasmic extract (approximately 24 mg protein) at a flow rate of 10 ml h⁻¹ The column was washed with 10 ml of dialysis buffer and eluted with 10 ml each of dialysis buffer containing 0 4 M NaCl and 0 6 M NaCl Bovine serum albumin (50 µg ml⁻¹) was added to the 0 6 M eluate to stabilise the DNA-binding proteins The 0 6 M eluate was concentrated by dialysis against 0 02 M Tris, pH 8 1, 0 05 M NaCl, 60% glycerol, 0 001 M EDTA and 0 001 M 2-mercaptoethanol overnight at 4 °C and was stored at −20 °C SDS gel electrophoresis was performed[14] with gels containing 6% polyacrylamide and 0 16% bis-acrylamide at 5 mA per gel for 30 min, then at 10 mA for an additional 6–8 h The gels were fractionated into 2 mm slices with a Gilson gel fractionator and counted in Aquasol (New England Nuclear) Marker bovine serum albumin and ovalbumin were electrophoresed in parallel gels and visualised by staining with Coomassie brilliant blue

obtained from hamsters bearing tumours induced by those viruses Typical results presented in Table 1 show positive fixation to a titre of 1 32 with anti-Ad 1 and Ad 2 T sera Anti-Ad 12 T serum, anti-SV40 T serum, and goat antiserum to purified Ad 2 virions were all negative Control preparations consisting of disrupted Ad 2 virions and a 0 6 M NaCl eluate from DNA cellulose chromatography of cytoplasm from mock-infected cells (Table 1, mock 0 6 M eluate) did not react with the anti-T sera These results indicate that the 75k protein is a non-virion, group C-specific T antigen found only in infected cells

CF titres of the 0 6 M eluate with anti-Ad 1 and Ad 2 T sera were relatively low and could perhaps reflect the assay of a minor contaminant rather than the 75k protein We therefore tested

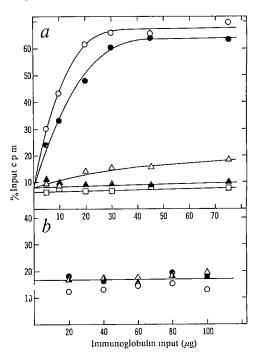
labelled 0 6 M eluates in an indirect radioimmune precipitation assay modified from Horwitz and Scharff[18] Immunoglobulins isolated from the hamster anti-T serum and ascitic fluid and goat anti-virion serum were used rather than whole sera to facilitate comparison between different sera Since over 90% of the radioactivity in the 0 6 M eluate is present in the 75k protein, immunoprecipitation of more than 10% of the radioactivity would mean that the 75k protein and not a minor contaminant is specifically measured Two different labelled 0 6 M eluates were assayed, and the results of a typical experiment are presented in Fig 2 A maximum of 63–66% of the input radioactivity in the 0 6 M eluate was specifically immunoprecipitated with anti-Ad 1 and anti-Ad 2 immunoglobulin, whereas only 7–10% (same value as the normal immunoglobulin control) was precipitated by the immunoglobulins from the anti-SV40 T or goat anti-virion sera The lack of quantitative precipitation could be caused by labelled contaminants in the 0 6 M eluate, or by a major second protein comigrating with the 75k protein (two early viral mRNA molecules of nearly identical size that could code for the 75k protein were recently reported[20]), or by the presence


Fig 2 Radioimmune precipitation assay of 0 6 M eluates from Ad 2-infected and mock-infected cells for Ad 2 T antigen Immunoglobulins were isolated from hamster anti-T sera and ascitic fluid and from goat antiserum to Ad 2 virions by DEAE-cellulose chromatography and concentrated by precipitation with 50% saturated (NH₄)₂SO₄ (ref 19) The immunoglobulins were dialysed against PBS–EDTA (0 01 sodium phosphate, pH 7 2, 0 1 M NaCl and 0 005 M EDTA) The 0 6 M eluates were diluted in PBS–EDTA containing 1% desoxycholate and 1% Triton X-100 and clarified at 12 000g for 15 min before assay Constant amounts of labelled eluate were added to increasing amounts of the hamster or goat immunoglobulin in 300 µl PBS–EDTA containing 1% desoxycholate and 1% Triton X-100 Immunoglobins from a pool of normal hamster sera or a normal goat serum were added to each tube to provide a total of 125 µg of protein to maintain a uniform precipitate in all tubes Control tubes containing only normal hamster or goat immunoglobulin were used to determine the background level of nonspecific precipitation The mixtures were incubated at 37 °C for 30 min in siliconised 2 ml centrifuge tubes (Kimax) and 50 µl goat anti-hamster IgG or 60 µl pig anti-goat IgG sera were added (optimal proportions were predetermined in precipitation assays) The tubes were further incubated for 2 h at 37 °C and the precipitated complexes were sedimented at 900g for 10 min The precipitates were dispersed by mixing (Vortex), washed twice in PBS–EDTA containing 1% of desoxycholate and 1% Triton X-100, dissolved in 0 25 M acetic acid, and counted in Aquasol *a*, 0 6 M eluate from infected cells Input, 8,522 c p m, 10,000 c p m µg⁻¹ *b*, Mock 0 6 M eluate Input 4,834 c p m 550 c p m µg⁻¹ ○, Anti-Ad 1 T, ●, anti-Ad 2 T, △, anti-Ad 12 T, ▲, anti-SV40 T, □, goat anti-Ad 2 virions

Table 1 Complement fixation assay of the Ad 2 75k DNA-binding protein

| Source of antigen | Hamster anti-T sera against | | | | Goat antiserum against Ad 2 virions | |

Disrupted Ad 2 virions	≤1 2	≤1 2	≤1 2	≤1 2	1 256	

The cytoplasm from cells infected with Ad 2 or mock-infected cells (treated in the same manner as infected cells but no virus was added) was fractionated on single-stranded DNA cellulose columns as described in Fig 1 Ad 2 virions purified as described[16] using CsCl for RbCl in the density gradient step were disrupted by the method of Prage et al[16] and sonicated before assay since the released cores tended to aggregate The 0 6 M eluates and the preparation of disrupted Ad 2 virions were assayed by the CF microassay[17] Pre-titred hamster and goat antisera were heated at 56 °C for 30 min and used at a dilution that gave five to ten units of antibody Assays were performed with 1 5 units of complement Similar results were obtained with a second preparation of 0 6 M eluate

* Ascitic fluid rather than serum was used
† Titre expressed as the highest dilution of antigen giving complete fixation
‡ The titre is 1 2 or lower, 1 2 is the anticomplementary titre of the antigens alone and represents the lower limit of the assay
ND, not done

of some denatured 75k protein that does not react with anti-T serum Some precipitation above background level was consistently observed with the anti-Ad 12 T immunoglobulin This could indicate that a low degree of cross-reactivity between T antigens of group A and group C is detected by the sensitive radioimmune precipitation assay A mock-infected 0 6 M eluate (labelled with a fivefold higher level of ³H-leucine since few host proteins are present in the 0 6 M eluate) was also assayed (Fig 2) This preparation did not react above the background level observed with normal immunoglobulin

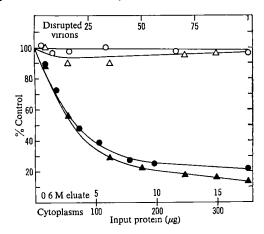
The specificity of the radioimmune assay for T-antigen activity was demonstrated by radioimmune-inhibition experi-


Fig. 3 Radioimmune-inhibition assay of Ad 2 T antigen activity In the inhibition reaction, aliquots of 125 μg of an immunoglobulin mixture from anti-Ad 2 T ascitic fluid (50 μg) and from a normal hamster serum pool (75 μg) were preincubated with increasing amounts of unlabelled 0 6 M eluate (infected cells), unlabelled cytoplasm from infected or mock-infected cells, or disrupted Ad 2 virions, prepared as described in Fig 1 Incubation was for 30 min at 37 °C in 400 μl of reaction mixture containing PBS-EDTA, 1% desoxycholate, and 1% Triton X-100 Control tubes consisting of the same mixture of immunoglobulins described above were preincubated with buffer alone ³H-eluate (13,049 c p m, 10,000 c p m μg⁻¹) was then added and the tubes were incubated for an additional 30 min Goat anti-hamster IgG serum (50 μl) was added and incubation was continued for an additional 2 h at 37 °C The precipitated complexes were then treated as described in Fig 2 and counted ○, Disrupted Ad 2 virions, ●, 0 6 M eluate (infected cells), △, cytoplasm from mock-infected cells, ▲, cytoplasm from infected cells The different protein inputs are given on the abscissae The degree of inhibition (% control) was calculated as follows after subtraction of background c p m (nonspecific precipitation with normal hamster immunoglobulin) from both inhibition and control reactions

$$\% \text{control} \quad \frac{\% \text{ input c p m precipitated in inhibition reaction}}{\% \text{ input c p m precipitated in control reaction}} \times 100$$

ments As shown in Fig 3, the precipitation of ³H-labelled protein from the 0 6 M eluate with a saturating level of anti-Ad 2 T immunoglobulin could be inhibited by 80% by preincubating the immunoglobulin with increasing amounts of unlabelled 0 6 M eluate or unlabelled cytoplasm from infected cells No inhibition was observed on preincubation with disrupted Ad 2 virions, or with the cytoplasm from mock-infected cells Note that a twentyfold higher input of infected cytoplasm was needed to obtain the same level of inhibition observed with the 0 6 M eluate This result indicates the feasibility of measuring 75k protein in unlabelled extracts of infected, transformed, or tumour cells by radioimmune-inhibition assay

No function has yet been assigned to the 75k protein A protein that binds to single-stranded DNA is required for the replication of bacteriophage T4 (ref 21) We have shown that the 75k DNA-binding protein fulfils the criteria for T antigen, as it reacts with antibody elicited to Ad 1 and Ad 2-transformed cells in hamsters It seems likely that there is more than one T antigen in Ad 2-transformed cells since several virus-specific RNA species have been detected[22] Carroll et al[23], have recently shown that a T antigen isolated from SV-40-transformed mouse cells binds to double, but not to single-stranded DNA It will be of interest to determine whether all Ad 2-transformed cell lines and tumours, as well as the rat line recently transformed by a 1 6×10⁶ molecular weight fragment of Ad 2 and Ad 5 DNA (ref 11), synthesise the 75k protein. This may indicate whether the 75k protein has an obligatory role in the induction and maintenance of the transformed state

Paramagnetic species in cataractous human lenses

KURZEL *et al*[1] studied the low temperature phosphorescence emission from normal and cataractous human lenses at 77 K After comparing their lens data with those obtained from tryptophan in a frozen ethanol–water glass, they concluded that the phosphorescence of the lens is caused by the tryptophan residues of lens proteins This was based on their finding in the lens a phosphorescence λ(max), phosophorescence excitation and phosphorescence quantum yield consistent with tryptophan and differing significantly from those of phenylalanine and tyrosine Here we present the results of an electron spin resonance (ESR) study which characterises the paramagnetic triplet state of normal and cataractous human lenses and provides proof that it stems from the tryptophan moiety and not tyrosine or phenylalanine This supplements previous observations that tryptophan is the dominant species in cataractous human lenses, giving rise to phosphorescent emission In addition, we have discovered that the lens excited triplet (phosphorescent) tryptophan is associated with the production of a free radical, we believe that this free radical may be the missing link between ultraviolet irradiation and lens photodamage leading to cataract formation[3,4]

ESR measurements were made with a Varian E-4 spectrometer The ultraviolet light source consisted of a Bausch and Lomb Model SP-200 mercury lamp which was focused by quartz optics on to the irradiation slits in the ESR cavity The microwave power was set at 10 mW or 100 mW for all ESR measurements and the microwave frequency ranged between 9 089 and 9 093 GHz

Cataractous lenses were obtained intact from surgery and noncataractous *post mortem* lenses were obtained intact at autopsy The lenses were frozen immediately in liquid nitrogen and stored at 77 K Before ESR measurements, the lenses were thawed, and each lens nucleus was removed and inserted into a quartz sample tube (3 mm inner diameter), the samples were then refrozen to 77 K

Aromatic amino acid samples (0 1 mM) were prepared by dissolving them in solvents consisting of equal volumes of 0 1 M phosphate buffer (pH 7 0) and glycerol The solutions were placed in quartz sample tubes (3 mm inner diameter) and frozen to 77 K For ESR measurements, the samples were placed in a liquid nitrogen-filled finger Dewar which was subsequently inserted into the microwave cavity

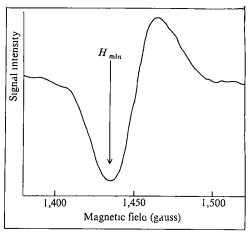
The triplet state ESR absorption derivative obtained in this study corresponds to the $\Delta M = 2$ transition The position of the peak, H_{min}, on the low field side of the spectrum is related to the zero-field-splitting parameter which characterises the spin–spin interaction between the two electrons which comprise the triplet H_{min} and the linewidth of the ESR signal are both sensitive to the electronic structure of excited molecules and can be used to identify the triplet species


Fig. 1 Triplet state of ESR spectrum for the $\Delta M = 2$ transition in the human lens Temperature=77 K Microwave frequency= 9 092 GHz Microwave power=10 mW
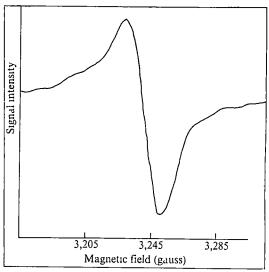

A typical triplet state ESR spectrum for the human lens is shown in Fig 1 For a microwave frequency of 9 091 GHz, H_{min} was 1,435±5 gauss and the peak-to-peak linewidth was 26±2 gauss No difference in either H_{min} or linewidth was observed between normal and cataractous lenses

For the frozen tryptophan, tyrosine and phenylalanine solutions at 77 K, we obtained H_{min} and linewidth values of 1,430±5 gauss, 1,240±5 gauss, 1,225±5 gauss and 25± 2 gauss, 30±2 gauss, 60±2 gauss, respectively We take the close agreement between the lens and tryptophan parameters as conclusive evidence that the lens protein phosphorescent state originates from the tryptophan residues, Shiga and Piette[5] reached a similar conclusion for ovalbumin and bovine serum albumin

The triplet state lifetime of both normal and cataractous lenses was then measured, a difference would be interpreted to reflect an alteration in the microenvironment of tryptophan between normal and cataractous lenses[6] The signal-to-noise ratio in the finger Dewar was not adequate to measure triplet state lifetimes, therefore, a Varian Model E257 variable temperature accessory was used At 133 K, the phosphorescent triplet state in both normal and cataractous lenses was found to have a lifetime of 4 0±0 1S

While making our ESR measurements, we observed that the intensity of the triplet state signal from both lenses and tryptophan solutions decreased after prolonged ultraviolet irradiation Along with the decrease in signal intensity, a gradual brunescent coloration developed in the samples which had previously

Fig 2 ESR spectrum of the ultraviolet induced free radical in the human lens Temperature=77 K Microwave frequency= 9 092 GHz Microwave power=100 mW The *g* factor=2 005

been uncoloured. We believe this coloration can be attributed to the presence of free radical products.

To test for the formation of free radicals, we irradiated a normal lens sample in the low temprature ESR finger dewar. We were able to follow the growth of the free radical species shown in Fig. 2. We have not been able to identify the radical species but assume that it results from the two photon ionisation of tryptophan. This has been demonstrated previously in frozen tryptophan solutions[7].

Human lenses are known to become more coloured with age and contain an increased quantity of insoluble protein, leading to loss of transparency. Current theories suggest that this coloration and decreased transparency may be related to photo-induced changes in aromatic amino acids[2,6,9]. Recently, photo-oxidation products of tryptophan have been identified in the human lens[10,11]. Our data suggest that a mechanism for photoinduced lens damage might be the production of free radicals. Roubal and Tappel[12] have shown that free radicals induce protein polymerisation and loss of solubility. Free radical reactions have also been implicated in ageing [13].There is reason to believe that ageing and cataractous lenses present the proper conditions for the stabilisation of free radicals. We have shown that ascorbic acid, which is a known free radical scavenger, is lost from the lens nucleus during cataract formation (unpublished data). The percentage of hydrophobic proteins also increases in the ageing lens[14], which may permit trapping of free radicals[15].

The possibility that ultraviolet light may be implicated in photodamage to the human lens is important, requiring further study. This is especially necessary in view of the widespread use of ultraviolet light today.

Electron diffraction studies of biological membranes and lipids

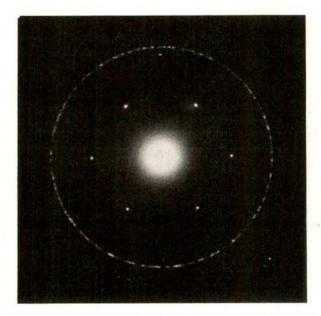
IN diffraction studies of biological membranes, X-ray diffraction has been used more frequently than electron diffraction in spite of certain advantages inherent in the latter technique. Electron diffraction enables the study of a small area (about 1 μm^2) of a very thin specimen, and the collection of experimental data within a short time. Moreover, the morphology and degree of purity of the specimen can often be investigated. It seems possible to overcome the main problems arising from the application of the electron diffraction technique to biological materials, namely the difficulty of studying hydrated materials and the damage caused to the specimen by the electron beam, and a study of wet biological membranes has been reported[1]. In this investigation dry specimens have been studied. Radiation damage was largely overcome by using


Fig. 1 Diffraction pattern of an unfixed and unstained A. laidlawii membrane. The two rings originate from the aluminium support film. The organisms were grown in a lipid-depleted basal medium supplemented with elaidic acid[2], and the membranes were isolated by osmotic lysis and washed[3]. After the last washing the membranes were resuspended in 10 mM ammonium acetate and deposited on copper grids covered with a 10 nm thick support film of aluminium. Membrane lipids were extracted with chloroform–methanol (2:1), freed from non-lipid contaminants[4] and fractionated into neutral, phospho- and glycolipids on a silicic acid column (BioSil HA). Lipid specimens for diffraction studies were prepared by spreading a lipid solution on a water surface and depositing the film obtained on grids, which were either bare or covered with an aluminium film. Stearic acid specimens were prepared in the same way.

minimum beam current, by maximally overfocusing the first condenser of the electron microscope, and by moderately overfocusing the second condenser. To minimise the temperature rise of the specimen, caused by inellastically scattered electrons, a cooled specimen holder was used. To facilitate heat transport, the specimen grids were covered with aluminium instead of carbon. A Philips 301 G electron microscope equipped with an anti-contamination device was used and the diffraction patterns were recorded at 100 kV on a highly sensitive X-ray film, Kodirex. All diffractograms were recorded at a specimen holder temperature of about −60 °C, which was regarded as a fair estimate of the temperature of the specimen itself.

Diffraction patterns of Acholeplasma laidlawii membranes (Fig. 1) showed the same pattern geometry as the stearic acid and the isolated lipids. The patterns were obtained only from small observation areas, about 1 μm^2. Nevertheless, superimposed, disoriented patterns could occasionally be seen. When larger areas were chosen, the observed patterns transformed into typical powder diagrams. The disoriented patterns might have derived from superimposed membranes or from a few domains within the same membrane possessing different orientations. The powder diagrams obviously originated from several membranes present in the observation area.

The diffraction patterns showed three spacings: 2.49, 3.67 and 4.15 Å, with an interplanar angle of 90° between the 2.49 and 3.67 reflections, and an angle of 68° between the 4.15 Å reflections. These data suggest an orthorhombic unit cell having an a axis of 7.37 Å and a b axis of 4.98 Å. Larger and slightly less reproducible spacings, about 2.6, 4.1 and 4.6 Å, were observed in preparations washed with buffers containing calcium or magnesium ions. It therefore

seems reasonable to assume that the presence of divalent cations caused the larger spacings in less exhaustively washed membranes. Interactions between these ions and the phospholipids would thus be the most feasible ones.

To investigate the influence of dehydration on the structure of the lipids in the *Acholeplasma* membranes, an X-ray powder diffractogram was taken, using a Guinier camera. The same spacings as in the diffractograms described above were obtained. This indicates that the water content of the membrane is of minor importance for the lipid structure below the thermal transition temperature.

The distances and angles characterising the diffractogram presented here are rather close to the parameters of the proposed hexagonal structure of biological membranes above the transition temperature[1,3,6]. The latter structure could be obtained by small changes in the 3.67 and 2.49 Å distances reported above. Thus our results show that diffraction studies of dry, single membranes in the static state prevailing below the thermal transition temperature are of importance for our understanding of the dynamic state characterising the membranes above this temperature. The finding that the 3.67 Å reflection is probably caused by lipids and not by proteins as proposed earlier[5] should also be mentioned in this connection.

We thank Dr S. Andersson for the use of the Philips EM 301 G microscope and for discussions, and Professor C. Weibull for reading the manuscript.

Primordial origins of chirality

THE origin of optical asymmetry in relation to the origin of life has been extensively discussed[1-4]. One suggestion is that there is a connection between molecular asymmetry and the asymmetry of elementary particles produced by weak interactions. Various mechanisms have been proposed whereby the choice of one optical isomer could be influenced by longitudinally polarised (left handed) electrons from β decay[5,6], but early experiments did not give any significant results[7]. Later, both positive[8,9] and negative[10-12] results have been obtained in a variety of experiments (differential decomposition of enantiomers bombarded by β⁻-rays, spin-polarised positron and muon annihilation in enantiomers).

In a new approach to this problem we carried out the crystallisation of DL-NaNH₄ tartrate in the presence and absence of chiral β^- particles from ^{32}P. Below 27 °C, DL-NaNH₄ tartrate crystallises in racemic conglomerates[13], that is, D and L crystallisation centres form independently and then grow. Any difference between the number of D and L centres will have a more marked effect on the optical activity of the conglomerates as crystallisation proceeds.

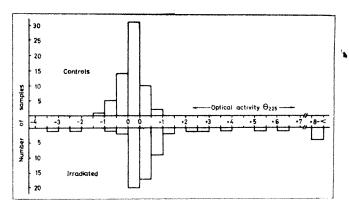
Pure DL-tartaric acid, free of mesotartaric acid, was con verted to the sodium ammonium salt. Its optical activity was checked by measuring α_{280} with a JASCO ORD/UV-5 spectropolarimeter, and θ_{225} with a JASCO 40c dichrograph. The sensitivity of the latter is ± 0.1 m°, and a 1×10^{-6} M excess of one isomer could have been detected. In the starting racemic material 2×10^{-5} M predominance of D (+) isomer was found.


Fig. 1 Distribution of levels of optical activity in NaNH₄-tartrate samples as crystallised in the absence (upper part of diagram) and in the presence (lower part) of chiral β^- particles (63 crystallisations in both cases). Positive CD signal at 225 nm (θ_{225}) corresponds to a negative rotation at the sodium D line, which is characteristic of the unnatural L (−) isomer.

For crystallisation, 8 ml 45% solutions of the tartrate were used. In six series (in all, 63 independent crystallisations) K₃^{32}PO₄ was added, the level of radioactivity being 20 μCi ml⁻¹; in the six control series, inactive K₂H^{31}PO₄ was added. The pH in all series was adjusted to 9.5 with NH₄OH. After equilibration at room temperature crystallisation was carried out over P₂O₅ in a desiccator at 1–4 °C. Precautions were taken in cleaning the glassware, excluding dust, and so on. When the crystallisation was about half complete (8–12 d), the crystals were filtered and weighted, and their optical activity measured in 2×10^{-2} M aqueous solution. As a check, the optical activity of the supernatant was also measured.

Figure 1 shows that in the presence of chiral electrons (^{32}P) the unnatural L (−) salt crystallised preferentially whereas an approximately symmetrical distribution is obtained in the control series, in the series with ^{32}P there is a markedly asymmetric distribution. It is clear, however, that β^- particles shifted the crystallisation towards L (−) isomer. The shift is significant at the 0.1% level (both χ^2 and Student's t test). The magnitude of the shift is indicated by the medians: 0.0 for control series, and 0.2 for irradiated samples. As would be expected, the small predominance of the D (+) isomer in starting material very slightly shifted the crystallisation of the control samples towards D (+) isomer.

The exact mechanism of the effect is not known. We think it unlikely that β rays would influence crystal growth, and suggest that the influence was to enhance the number of crystallisation centres of the L isomer. In this connection it should be mentioned that hydrated electrons have quite a long lifetime, particularly in alkaline solutions[14].

We thank Dr Cs. Fajszi, Dr. Soós and L. Kovács for their help.

reviews

To review one volume of Needham's great monument-in-the-making is like trying to make an architectural assessment of a single pillar of a temple. But one is encouraged in the attempt because a pillar is not a bad analogy. The superstructure of modern science is sustained on many singular supports; Greek atomism, mediaeval astronomy, Renaissance navigation, and so on. One of the pillars, alchemy, changes its appearance as one changes one's viewpoint.

There has been a lot of change in the historical assessment of alchemy. For a time it was viewed as the main forerunner of modern scientific chemistry; then as mere superstition and charlatanism; then as a lesser light to technological chemistry. Now we are beginning to re-assess it yet again as something respectable in its own right, a body of practice and belief that should be viewed not in terms of modern science and modern society, but as something of its own time. It is one of the outstanding merits of Needham's work that at the same time as he makes us look for the first time at a culture we did not pretend to know, he also makes us look afresh at the western science we thought we did know. This is true in general of his whole enterprise, but particularly clear in this volume.

It is at once chastening and stimulating to see Chinese alchemy studied with an eye to chemical detail which has not been applied so closely by any writer about western alchemy in the present generation of historians of western science.

Alchemy was concerned with many things, but the big thing was the distinctive character of gold. Gold was astonishing stuff to the ancient world. Familiarity with it never bred contempt, because one characteristic marked it off from all else; it was incorruptible. It survived all trials and could be recovered pure and undiminished from alloys and disguises by the process of cupellation. True: it was beautiful, but other things were beautiful. The imitation of its beauty was one thing: aurifiction, the production of the appearance of gold. But could gold be made: was true aurifaction a possibility? And if one form of matter could be incorruptible, could not Man be made incorruptible? So far, so simple. These are the familiar themes of western alchemy. The value

Science ancient and modern

Frank Greenaway

Science and Civilisation in China. Vol. 5: *Chemistry and Chemical Technology.* Part 2: *Spagyrical Discovery and Invention: Magisteries of Gold and Immortality.* By Joseph Needham with Lu Gwei-Djen. Pp. xxxii + 510. (Cambridge University Press: London, October 1974.) £12.00; $35.00.

of Needham's work lies in his expounding Chinese alchemy as a thing distinct in itself, having its own moral values, social relations and methods of enquiry. If some resemblances, some identities, are discovered which show Chinese and western alchemy to have a common basis and to have arrived at some common conclusions, this is for a good reason: "While we can easily see that artistic styles and expressions, religious ceremonies and doctrines, or different kinds of music, have tended to be incommensurable; for mathematics, science and technology the case is altered—man has always lived in an environment essentially constant in its properties, and his knowledge of it, if true, must therefor tend towards a constant structure".

Is the limited career of Chinese alchemy to be considered in Spenglerian terms, an aspect of a quasi-organic cultural growth and decay, or in Kuhnian terms, an aspect of the adoption of a compelling fashion of thought in a line of succession without progress? Needham respectfully rejects the Spenglerian pessimism but will not accept a naive Kuhnism. In fact, he will not accept entire any of the currently packaged philosophies of history, but insists that he is engaged in an enquiry which will lead to a new appreciation of the origins, development and internal and external relations of Chinese science when the work is done. His study of Chinese science leads him to remind us how provisional is our modern scientific 'knowledge'.

"It is neither independent of the accidents of Western European history, nor is it a final court of appeal for the eschatological judgment of the value of past scientific discoveries

either in West or East. It is a reliable measuring stick so long as we never forget its transitory nature."

One of the most difficult exercises for the historian of science is to relate the techniques of a historical period to modern scientific and technical knowledge. Needham's treatment of the metallurgical practices which the alchemists used for precious and base metals is exemplary. These pages can be recommended to any reader, whether he cares about Chinese alchemy or not, who wants a brief, logical (and so far as I can gauge, pretty complete) survey of all early metallurgical developments. There are some surprises, such as the widespread use of cupronickel, the as yet unexplained occurrence of some specimens of aluminium, and the extent of the trade in zinc.

When Needham has to deal with the derivative human theme of alchemy, the elixir of life, the drug of deathlessness, he does so by relating it most skilfully to the technical, metallurgical theme. He shows how the idea of physical immortality emerged almost imperceptibly out of the idea of longevity. There is, however, no one persistent view to be shown. There were many religions in China, influential successively or simultaneously, and each had its own philosophy of the nature of human life and its prolongation. In each, alchemical ideas could play a part. The descriptions of religious observance, incense burning in particular, are very well done, the accounts of unfamiliar liturgical and ritual customs never being obscured by the inevitably complex detail.

The excellence of the scholarly apparatus of these successive volumes is well known and needs no further praise. Nor does Needham's unfailing courtesy and generosity to his collaborators, whether they contributed to a whole chapter or a single line.

The value of this volume, only one of the four projected for the whole of Chinese chemistry, is likely to be as much in its stimulus to the reappraisal of western alchemy as in its original *raison-d'être*. A successful and convincing history of scientific chemistry as a whole has yet to be written. It would be strange, yet somehow satisfactory, if the stimulus to a new approach to a critique of modern chemical science should come from this splendid study of things "far away and long ago".

Biology of the gene

Gene Expression. Vol. 1 : *Bacterial Genomes.* Pp. xvii + 642. June 1974. £4.75. Vol. 2 : *Eucaryotic Chromosomes.* Pp. xiv + 467. September 1974. Benjamin Lewin. £8.00, cloth; £3.95, paper. (Wiley, London and New York.)

GENE EXPRESSION, originally intended as a revision of Benjamin Lewin's earlier successful treatise, *The Molecular Basis of Gene Expression,* reflects the growth of knowledge in the field and has expanded to become two major volumes.

Volume 1, *Bacterial Genomes,* reviews the extensive progress in the molecular genetics of prokaryotes over the past five years. The coverage is not limited strictly to gene expression, but includes the closely allied topics of recombination, DNA replication and cell division. The biochemically biased exposition, intended for advanced students and specialists, demands familiarity with both microbial genetics and nucleic acid biochemistry.

Lewin presents his subject through a critical appraisal of the key experiments, occasionally including carefully selected data. The clarity of the presentation is enhanced by the well designed diagrams. Original papers are abundantly cited; curiously though, references to the decisive experiments seem too often absent.

Volume 2, *Eucaryotic chromosomes,* contrasts strikingly with Volume 1 in the lack of precise information deriving, quite naturally, from the relative complexity of the subject. Lewin argues that sufficient advances have been made in our knowledge of eucaryotic gene expression to justify this attempt at proposing "a preliminary conceptual framework".

The first part of Volume 2 is devoted to the ultrastructure of eucaryotic chromosomes and its variation during the life cycle. The very lengthy discourse palls at times, but is alleviated by many excellent electronmicrographs. The analysis of DNA structure from the kinetics of renaturation and hybridisation is well explained, but the need for a sharper tool with which to approach sequence organisation in eucaryotic DNA is apparent between the lines.

The second part of the book is more directly concerned with the expression of eucaryotic genes. The processing of primary transcripts and models for the control of eucaryotic gene expression are prominent. The volume ends with an interesting discussion of the interaction between nucleus and cytoplasm, as studied by nuclear transplantation and somatic cell hybridisation.

Despite Lewin's apologies for his selectivity, in both volumes he could reasonably have been more selective and thereby more concise. Certain experiments described in great detail are superseded by subsequent reports. Even elegant experiments which have been conclusively refuted are best forgotten. In each volume, after such an array of experimental observations and conclusions, I would have welcomed an attempt to present a wider view, putting recent developments into perspective and discussing their implications for the future. I felt it a pity, too, that the concentration on mammalian cells in Volume 2 meant the omission of those eukaryotic systems most amenable to genetic analysis and, therefore, most likely to yield important information on gene structure and expression.

These minor criticisms should not be taken to detract seriously from the obvious merit of these volumes, the depth, scope and modernity of which will ensure their value to everyone interested in the biology of the gene.

W. J. Brammar

Watching volcanoes

Physical Volcanology. (*Developments in Solid Earth Geophysics,* vol. 6.) Edited by L. Civetta, P. Gasparini, G. Luongo and A. Rapolla. Pp. xvi + 333. (Elsvier Scientific: Amsterdam, Oxford and New York, 1974.) Dfl.90; $34.75.

THIS book represents the combined efforts of four editors and seventeen contributors to mark the occasion of the retirement in 1971 of Professor Giuseppe Imbò from the directorship of the Vesuvian Observatory.

Like all commemorative books it is very conservative; thus we see again the classic investigations of volcanic seismicity from Japan and of crustal deformation from Hawaii.

That wouldn't matter if the UNESCO book on the same subject had not been published in 1971, but this new book repeats (verbatim in some instances) some 30% of that material.

And the title seems to me to be wrong. The book deals mainly with the application of instrumental techniques in all but two of the fourteen chapters, and though that makes for an excellent reference book, it rather avoids consideration of the underlying physics.

I think that a more interesting volume could have been written under the title of 'Physical Volcanology' if some attention had been given to the physical processes of volcanic phenomena. The physics of lava flows, cone formation, and magma degassing are hardly mentioned, and the more avant garde subjects like the influences of earth tides and local tectonics on eruptions are not seen.

The book, however, contains some very useful reference material for anyone actively engaged in volcanic research. Most of the chapters describe in detail the application and limitations of one or other of the geophysical and chemical techniques that have been successfully used on volcanoes, in each case by one of the contributors, all of whom are acknowledged experts. It is to be hoped, though, that they are not led by the title of Chapter 9 into confusing ashes for gases; and I hope too that their efforts may help avert the great ions (p. 317) resulting from large lava flows. **James L. Brander**

Centenarian from a village near Sukhumi on the Black Sea coast. From *Biological Anthropology* (Readings from *Scientific American*). With Introductions by Solomon H. Katz. Pp. 494 + 340 illustrations. (Freeman: San Francisco, 1975.) $14.95, cloth; $6.95, paper.

More than most will remember

Collected Papers of Sir Harold Jeffreys on Geophysics and Other Sciences. Vol. 2: *Observational Seismology;* Pp. xxi + 697; £20.10. Vol. 3: *Gravity;* Pp. xviii + 661; £19.60. (Gordon and Breach, London, Paris and New York, 1975.)

HAROLD JEFFREYS is truly one of the giants of 20th century science, although he ploughed a fairly lonely furrow between the wars at a time when bright young men were expected to go into atomic and nuclear physics. But now geophysics is the most fashionable of subjects and many of its practitioners rely, consciously or unconsciously, on the foundations that Jeffreys built. His writings both on geophysics and beyond (even to an appraisal of the psychoanalytic significance of a label on a beer bottle) have been both prolific and a delight to read. The seven textbooks are easily accessible, but the rest is scattered around more than 40 different journals. So is there maybe a case for the publication of his collected papers?

For all that Jeffreys has published widely, four fifths of the papers in these volumes (of the six that will ultimately appear) come from the *Monthly Notices of the Royal Astronomical Society* and its *Geophysical Supplement* (later the *Geophysical Journal*). (There were times when Jeffreys practically kep.' the *Geophysical Supplement* going single-handedly!) Thus, if you have access to a complete run of these two journals you are paying a lot for the other one-fifth of his published papers. And the editing is relatively slight.

One of the fascinations of science is the way things age rapidly—particularly the interpretation of observations; it is, then, of interest to learn what, in retrospect, scientists would stand by, and what they think is no longer tenable. For instance, I should have liked to know how Jeffreys thought the J-B tables of 1940 stood now that there are newer tables by Herrin (at least, I do know, but I wish he'd put it in print). But where Jeffreys does add a modern footnote—and this is infrequently—it is brief and not very helpful. For example: "Some stations, mainly southern ones, received much higher reliabilities when the ellipticity of the Earth was allowed for", at the end of a 20 page paper.

One footnote, though, is pure Harold Jeffreys and touches on the question of the WKBJ approximation. In a 1969 note on a section in a 1915 paper, Jeffreys writes "This was my first discovery of what is best described as the Green–Liouville approximation. I

rediscovered it in 1923, having twice forgotten Green's equivalent treatment of tidal waves in a canal of slowly varying sections". He has forgotten more than most of us will remember.

Alas, the price of the complete set is such that the only geophysicists with that sort of money to spare are not those who will think of acquiring these volumes. And librarians can with justification say that all the papers are accessible somewhere—except perhaps the beer-bottle one.

David Davies

Marihuana

Marijuana: Effects on Human Behaviour. Edited by Loren L. Miller. Pp. xiv + 405. (Academic: New York and London, December 1974.) $29.50; £14.95.

The Use of Marihuana: A Psychological and Physiological Inquiry. Edited by Jack H. Mendelson, Michael Rossi and Roger E. Meyer. Pp. x + 202. (Plenum: New York and London, 1974.) £17.00; $44.00.

OVER the last few years, research on cannabis has burgeoned astonishingly. This has not come about by the slow process of natural evolution, but very obviously because grant money has flowed in that direction, particularly in the United States and Canada. For anyone with a really well developed eye for a bandwagon, the ultimate would now be to obtain grant money for a study of the social and political determinants of this granting. The story would provide a fascinating case-study.

When, for basically political reasons, a great deal of research money is suddenly pushed in a particular direction the prognosis is always uncertain—the result may be a lot of mediocre research or, alternatively, rather good things may happen. With research into the effects of cannabis the outcome has been of the latter and more fortunate kind. In several different scientific areas cannabis research is beginning to have about it a modest feeling of excitement.

The range of this research and something of the promise, is well conveyed in the volume on cannabis which is edited by Dr Loren Miller. Edited volumes on cannabis are now appearing thick and fast, but so far this is undoubtedly the most interesting and authoritative array of papers on this topic to have been put together in one book. The 14 chapters each either report the contributor's original research with adequate delineation of context, or review a particular sector. The laboratory dissection of the psychological aspects of cannabis is the theme

of several different chapters, and one feature of recent work is that experiment on the drug's interference with complex mental functions is providing a useful tool for basic study of those types of function. Chapters on the influence of cannabis on memory and on attention, nicely illustrate this development. Other contributions at the laboratory end of the spectrum deal with neurophysiological research and possible interference with neurotransmitter mechanisms; again these are not just 'drug studies' but use of a particular substance as an investigating tool. We have moved on from the days when study of CNS function was largely based on physical ablation of its parts, but the analogy is close.

This book also deals with some more social–medical questions. A chapter on the drug and psychiatric illness, gives a particularly sensible appraisal of issues which have not always attracted the coolest discussion. Progression to other drugs, cannabis and violence, and cannibis and car driving, provide the matter for further chapters. Too easy an acceptance of the inevitability of that approach to research which is always one removed from the social reality (drinking experiments, as it were, in the simulated laboratory bar rather than at the Pig and Whistle), receives a healthy jolt from an account of driving research in which experimental subjects drove round town in dual control cars after smoking, with careful real-life observation being backed by physiological measures made at the same time.

In *The Use of Marihuana* Professor Mendelson and his colleagues give an account of a project which yields a mass of data on a number of separate aspects of the drug's effect on the human subject. Even leaving aside the specialism of the content, this is a book which deserves notice as a superbly competent piece of scientific investigation. Some years ago Mendelson and his collaborators made an important contribution to alcoholism studies by observation of, and multiple measures on, alcoholics drinking in an experimental ward, which provided an operant-conditioning paradigm: the same type of design has now been applied to the influence of cannabis on man. In tolerant individuals, marihuana intoxication sustained over a period of 3 weeks and with dose on occasion going up to 200 mg THC a day, produced remarkably little disturbance. As the investigators themselves say, their work leads to no closure of the cannabis debate but only points to the necessity for "more sophisticated questions". Any assertion that cannabis is a drug which cannot produce tolerance, is after this study certainly no longer credible.   **Griffith Edwards**

Prosimians and evolution

Prosimian Biology. (Proceedings of a Meeting of the Research Seminar in Archaeology and Related Subjects.) Edited by R. D. Martin, G. A. Doyle and A. C. Walker. Pp. xxi+983. (Duckworth: London, November 1974.) £30.00.

"THIS collection of papers" the late W. C. Osman Hill wrote in the foreword, "can be seen to cover an extremely broad spectrum". He was far from wrong. Fifty four chapters by authors from many countries and several disciplines describe the behaviour, ecology, physiology, anatomy, neurophysiology, cytology, biochemistry and evolution of prosimians.

The book represents more than an addition to current knowledge of another group of little known mammals. As Doyle and Martin point out in their introductory chapter, the morphology of contemporary prosimians is broadly similar to that of the array of Eocene primates from which the Anthropoidea developed. Living species may thus provide an approximate blueprint of the behaviour and ecology of the common ancestors of prosimians and anthropoids. Moreover, the many examples of convergence between prosimian and anthropoid species occupying similar niches strengthen arguments relating behavioural and morphological differences to variation in ecology. For both reasons, the study of prosimians may help us to understand the evolution of the higher primates.

The book's most important contribution lies in the first section. This reports the results of field studies covering 15 different species. Until recently, the behaviour and ecology of prosimians was poorly documented, partly because most species are nocturnal and almost all live in habitats where observation is difficult. This group of papers represents a major advance in the field and bears witness as much of the authors' endurance as to their perspicacity. The extensive sections on anatomy, biochemistry and evolution provide many insights into the functional significance of particular structures, ranging from teeth to toenails, and into the phylogenetic status of a wide variety of species. A general weakness, considering the stated justification for studying prosimians, is the authors' reluctance to discuss the relevance of their findings to the evolution of the higher primates and man.

The book is well produced and carefully edited. It contains fewer makeweight chapters than most published collections of conference papers. And

Lesser bushbabies (*Galago senegalensis moholi*)

it is likely to represent a milestone in its field for many years. Nevertheless, it should make contributors, editors and publishers think carefully about the wisdom of producing similar volumes. At £30.00 it is beyond the reach of private buyers. All except the most affluent libraries are likely to look askance at highly specialised sympo-

sium proceedings which cost as much as a year's subscription to the average journal. If the size and cost of symposia proceedings continue to escalate at this rate, it is inevitable that they will only be available in the largest libraries. That will benefit neither readers nor authors.

T. H. Clutton-Brock

Most theories according to others

Transport Phenomena in Aqueous Solutions. By Tibor Erdey-Gruz. Pp. 512. (Adam Hilger: London; Akademiai Kiado: Budapest, December 1974.) £12.00.

THE transport properties covered in this book are the traditional ones of shear viscosity, concentration diffusion and electrical conductivity. There is only passing mention of bulk viscosity, thermal diffusion, dielectric relaxation, and so on. The three properties covered form the subjects of chapters 2, 3 and 4. The first chapter discusses the molecular structure of liquid water and the fifth, which should perhaps more logically have been the second, covers the equilibrium properties of aqueous solutions.

The author has an encyclopaedic knowledge of what has been said and done, but shows little discrimination. Every experiment and, what is worse, every theory is referred to, but he rarely tries to judge between them. Thus, sections 1.3.3.2 to 1.3.3.9 describe briefly eight different classes of theories of the structure of water and are followed, as if in despair, by 1.3.3.10 which is called simply "Further Theories". His classification is impeccable but he does not tell the reader which of these mutually inconsistent theories he

believes to be correct; nor does he marshall well the evidence on which the reader could judge for himself. The same is true of the treatment in later chapters on theories of transport. Moreover, even his references become perfunctory when he touches on modern theories which require for their understanding a knowledge of non-equilibrium statistical mechanics.

Perhaps he sees it as the duty of the author of a monograph simply to summarise the views of others (the commonest phrase in the book is "according to X"), and not to inflict his own views on his readers, but it makes for a dull book. The only point at which it comes alive is in the section (p. 351–390) on the effect of non-electrolytes on electrolytic conductivity. There, the author has himself contributed experimentally to the subject and his discussion is much more cogent than elsewhere.

The book can be recommended, however, to those who want access to the voluminous experimental literature, and to the mechanically more simple theories of the last 40 years. The references and indexes are, on the whole, accurate, comprehensive and organised in a way which makes it easy to recover the information in the literature.

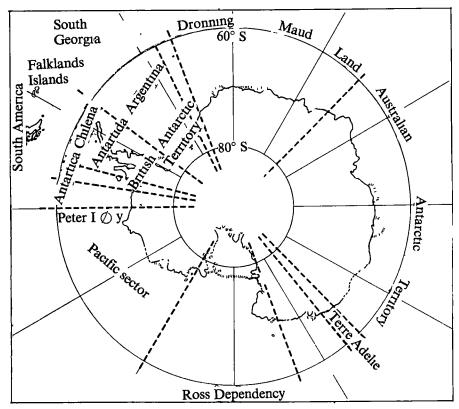
Please, SIPRI, stay on the fence

As commentators never tire of pointing out, the presence of the word 'peace' in the title of any organisation immediately renders the intentions of that body suspect, such has been the misuse of one of the most beautiful as well as one of the most significant words of the English language But the same commentators generally make that point in order to draw attention to the one glowing exception—the Stockholm International Peace Research Institute (SIPRI)—an organisation which in nine years has built up for itself a major reputation as a purveyor of accurate unvarnished information on armament and disarmament provided by an international team whose commitment has been to objectivity in assessment rather than to politically motivated public statements

Scientists have had particular cause to be grateful to SIPRI Much of the present debate on arms control and disarmament centres on technological feasibility, prospects held by military research and development and methods of verification In these fields, in which no national military organisation exactly invites the participation of outsiders, SIPRI has fought bravely to keep abreast and to provide hard fact The SIPRI Yearbook has become necessary reading for all who profess an interest in defence, of whatever political hue

Since SIPRI s inception, *Nature* has been both an admirer of the institute and a regular user of its data (This partly stems from the concerns of both the present and the immediate-past editor in nuclear matters The present editor (declaring an interest) also worked for a time at SIPRI) We shall, no doubt, continue to depend heavily on SIPRI for many things, but it is necessary to note a gradual shift in the institute's policy which could jeopardise its future effectiveness, at least if it conceives of its future function as similar to the one it has discharged with distinction in the past nine years


When SIPRI was founded by the Swedish government and guaranteed its independence, there were those who saw it simply as a private research department of Mrs Alva Myrdal, the Swedish delegate to the Eighteen-nation Disarmament Conference Certainly Mrs Myrdal has used SIPRI's work more than most, but any fears that the institute would become subservient to a particular philosophy were soon allayed As well as eschewing external alignments, SIPRI has had to watch its internal scene rather carefully Of necessity staff who are prepared to uproot their lives elsewhere in order to spend two or three years in Stockholm are going to be of more than average commitment The institute has never made any secret of this—indeed in the first yearbook the then director, Robert Neild, acknowledged that his staff were of one mind that the arms race was dangerous and that efforts to slow it down had been incommensurate with the danger SIPRI's skill has been in converting this conviction into objective analysis

In the past few years there have been signs of growing impatience—not with objective analysis but with political systems which stoke up the arms race and treat arms control with such little respect Until recently this impatience has hardly manifested itself in very extreme forms, the pages of SIPRI reports don't exactly drip with blood There has just been the odd paragraph or two in a preface or a summary indicating despair, particularly with the pursuits of partial arms control measures to the exclusion of more general disarmament Small beer, maybe, compared with the sort of editorialising that everyone else does—and why shouldn't they use their own results more positively? And yet the surprise one feels at encountering even such inoffensive (though controversial) comment is akin to the shock that would be created if the Registrar-General were to preface his annual statistics by a comment that he was getting tired of recording increases in population, people must cut down on copulation

The most recent publications from Stockholm suggest that the trend towards a more committed viewpoint continues Two booklets by Frank Barnaby, the present director, (*Preventing nuclear-weapon proliferation* and *Nuclear disarmament or nuclear war?*) are fairly obviously aimed at a new and much wider audience The emotional temperature has gone up a fair bit, to the extent of a few half-page pictures, not all strictly relevant (such as a napalm victim) and some ringing phrases about nuclear strategy being "inhumane, immoral even genocidal" and so on

Well, who are we to snipe about emotional writing and irrelevant pictures? The point is simply this If SIPRI is to become more polemical it will undoubtedly gain in popular acclaim and will always find a ready audience and willing supporters But it will forfeit its status as an organisation that can work within the system and command respect and help from insiders There are far too few bodies of this sort in arms control for this to be seen as anything but a matter of great concern

It is quite likely that much of this change of attitude at SIPRI springs from a feeling of impotence in the face of so much military expenditure This is to adopt too pessimistic view of the benefits of reliable factual reporting, for which the dividends are always less tangible but ultimately more profound And SIPRI has had real successes, particularly in its reporting on the world arms trade and its long term study in chemical and biological warfare These very successes have sprung from the institute's ability to seek opinions and deal directly and honestly with many individuals deeply involved in questions of defence and armament Come down off the fence on the other side from them and they will neither give advice nor read what is written □

Antarctica: the end of an era?

THE problems of mineral exploration in Antarctica will almost certainly be discussed when signatories of the Antarctic Treaty meet in Oslo in June Largely concerned with the potentially vast reserves of oil and other fossil fuels, the discussions will ensure that old issues of territorial sovereignty will once again be raised But fears that each of 12 signatory states intend to grant themselves exclusive rights of exploitation may be unnecessarily pessimistic, writes Alan Piper

There is still a considerable amount of doubt about the full extent and location of fossil fuel resources in Antarctica, though consideration of the pre-drift, Gondwana continental arrangements suggests that the Ross Sea and Weddel Sea areas may prove productive Even vague possibilities, however, lend an added significance to the debate about possible mineral exploitation in Antarctica and it is unlikely that the tacitly acknowledged, underlying political rationale behind the maintainence of expensive scientific bases in Antarctica can remain suppressed for very much longer

At the time that the Antarctic

The Antarctic Treaty, applying to the entire area of the globe south of 60°S, was signed in Washington DC on December 1, 1959 by Argentina, Australia, Belgium, Chile, France, Japan, New Zealand, Norway, South Africa, the Soviet Union, and the United States After ratification by all 12 signatory states the treaty entered into force on June 23, 1961, since when it has been acceded to by Czechoslovakia, Denmark, the Netherlands, Poland, and Rumania

Recognising that "it is in the interests of all mankind that Antarctica shall continue for ever to be used exclusively for peaceful purposes and shall not become the scene or object of international discord" the treaty
● suspends previously existing disputes over territorial sovereignty in Antarctica

● prohibits the establishment of military bases, the explosion of nuclear devices and the disposal of radioactive waste within the treaty area
● invests contracting parties with the right to inspect the full scope of another nation's scientific and logistic operations to encourage open scientific cooperation in Antarctica
● calls for regular consultative meetings between the signatory states for the purpose of "exchanging information, consulting together on matters of common interest pertaining to the Antarctic, and formulating and considering measures in furtherance of the principles and objectives of the treaty"

In 1991, after the treaty has been in force for 30 years the contracting parties will be required to review its operation

---

Treaty (see box) was signed five of the contracting nations — Australia, the UK, France, New Zealand, and Norway—had previously asserted recog nised claims to about 80% of the Antarctic landmass and adjoining con tinental shelf in sectors radiating out wards from the pole Of the remainin signatories, Argentina and Chile ha advanced conflicting claims to most c the British sector, while the goverr ments of the Soviet Union and th United States had refused at any tim to recognise any territorial claims o the continent and have asserted non themselves, Japan had renounced he former territorial claims under th terms of the 1951 peace treaty

The treaty is justifiably held in hig regard as a considerable politic achievement It not only froze th legal *status quo* regarding claims t territorial sovereignty but, significantl: was the first multinational treaty c substance to involve the Soviet Unioi The demilitarisation of the Antarct continent and the provision for sciei tific cooperation has provided a coi tinuing zone of contact between th super powers

The treaty has worked well in assurance of exclusively peaceful oper tions And though each of the si natories can inspect "the full scope another nation's scientific and logisti operations", a right regularly exercis by several countries, no evidence h yet been produced to suggest that tl spirit of the treaty has been contr vened by any party

Regular consultative meetings of si natories are called for by the treat and at the last meeting, held in We lington in 1972, the representativ recommended to their governmen that "the subject 'Antarctic Resourc Effects of Mineral Exploration' 1 carefully studied and included on tl Agenda of the Eighth Consultati Meeting" The issue will certain figure prominently in the Os discussions

To date, there have been no sig that the UK has finalised a policy the issue of economic exploitation, b some decisions will have to be reach soon The obvious need is for a regin within which mineral exploitatio would be available to any state oper ing under licence, whether or not party to the present treaty Th approach to the problem, howeve would presuppose that the over-ridii issue of territorial jurisdiction had be settled As long as uncertainties ov sovereignty continue, it is doubtf whether signatories would agree to 1 cognise the legal rights of any outsid to operate within a claimed sector

It is to be hoped, at the least, that system of licensing under the contr of the present signatories will

adopted. Some of the signatories will arrive in Oslo with no definitive policy in mind. That is almost certainly true in the case of the United States. The likelihood of unilateral action, which has always remained a possibility with that country, cannot as yet be ruled out but the Americans will probably adopt a wait-and-see attitude: "On paper, the United States has a policy; in reality, it does not", says a recent article in *Science*. Whatever policies or

non-policies the signatories take to Oslo, however, there is little hope that they will be published in advance. When preparatory discussions, called especially to consider the problem of mineral exploration, ended in Oslo recently no formal statement was issued.

It would be unrealistic to expect that a settlement will be reached during the Oslo talks. (Discussions on the conservation of the Antarctic seals continued for 10 years before the final proposals

were adopted in 1972. Recommendations on measures for the conservation of Antarctic flora and fauna, first proposed in Brussels in 1964, have still not met with final approval.) But most of the parties to the treaty are unwilling to roll an already snowballing problem further into the future, and many will feel that further prevarication on their part will lead outside countries to question the capability of the signatories to handle the matter satisfactorily.   ☐

Limits to oncology

Dr Michael Stoker, Director of the Imperial Cancer Research Fund Laboratories, Lincoln's Inn Fields, London, thinks that a levy on money for cancer research should be used to ensure that sufficient 'strategic research', as opposed to 'tactical research', is carried out. (From a lecture given at the dedication of the Seeley G. Mudd Building, M.I.T., on March 6.)

EVEN in these hard times, the support available for cancer research is relatively large by comparison with other biomedical fields, especially in the USA. But, in spite of clear enough aims in terms of alleviation of suffering caused by cancer, the course to be followed is uncharted and the weighting to be put on the various alternatives is largely guesswork. Indeed, the modest progress in prevention and cure of cancer has so far been based almost entirely on empirical judgements and serendipity, followed by well organised development, but it has given no guide to formulation of the principles to be followed for any major and general advance. Close monitoring and direction by the sponsors is, therefore, scarcely possible or at any rate useful. This results in a dilemma concerning the limits of cancer research supported by earmarked funds, particularly for those tackling the more

fundamental aspects of cancer biology.

I shall first consider, as background, some pressure which tend to broaden the limits of cancer research. At an extreme would be the socioeconomic viewpoint, which would consider cancer as a minor problem compared with poverty, population control, pollution and so on. This radical view could consider it justified, and not at all dishonest, to divert cancer funds to the greater good, or to choose research topics, which, though related to oncology, also contribute to the solution of greater social ills. But this almost certainly neglects the wishes of the donors. These may be based on emotion and irrational fears about the implacability of cancer, but it is surely the worst and most dangerous sort of scientific conceit to decide that you know better than the customer what he really wants, at any rate in terms of final objectives.

Then there are those who accept the objective of cancer alleviation, but for whom the modest progress so far, and the lack of a rational approach, means that a better understanding of biological systems as a whole is a necessary prerequisite for any real advance in cancer research. Cancer funds at this stage, therefore, should go predominantly to general biology. This viewpoint is no less strong through its reinforcement by the more personal motives and ambitions of scientists. Most of us would like to do something about cancer, but we are also strongly attracted to the great unsolved problems of wider generality, where advances will bring us the acclaim of our peers.

It is against this background, and the opposing forces of accountability, cost benefit and so on, that the question of relevance, and also responsibility to the sponsor or donor, must be considered. If you gave your money to cancer research, how would you like it spent? At one extreme almost any science, or at any rate biological science, would be relevant, whereas, at the other, cancer research funds should be restricted to programmes with at least conceptual links to practical applications in a finite time.

In some fields of research this dilemma can be acute, for example,

those relating to the molecular and supramolecular organisation of eukaryotic cells. Two main classes of research can be identified in relationship to oncology, and it is helpful to distinguish them.

The first would include any research programme which might have a bearing on cancer, but which is just as likely to lead to benefits in other fields of medicine, agriculture and so on. In other words there is no *a priori* reason to suppose that the resulting advances in knowledge will benefit cancer over and above any other human good. Clearly this research includes the general understanding of living systems and is very long term in its objectives. It is still applied research in that the goal is human health rather than satisfaction of curiosity, but it is multipurpose, with oncology included.

The second class covers research likely to be more relevant to cancer than anything else. Though other benefits may come, the reason for the research is the special likelihood of increasing the understanding and finally the alleviation of cancer, and not of other human ills. It may still be very much concerned with fundamental aspects of living processes, but those thought to be especially important in cancer.

I shall refer to the former approach as strategic research and the latter as tactical research. They can be distinguished by applying the following questions. Is the research programme under consideration more likely to benefit cancer than other ills? If so, it is tactical. Or does the research include cancer among other possible benefits? It would then be strategic. This requires judgement of outcome and not intent.

In the light of these criteria, I shall mention briefly three research fields which are at present believed to be of high priority and which compete for cancer research funds.

The first is the cell surface, which is at present a subject of such intensive study, much of it with cancer funds. But is the elucidation of the mysteries of the cell surface more likely to benefit cancer than for example the vascular diseases or the primary immunological disorders? Of course there are a num-

ber of changes to the cell surface which are considered to be characteristic of cancer cells, or at least of transformed cells; on closer examination, however, many, even of these, have been found to be manifestations of rapid growth and are almost certainly secondary rather than causal phenomena. This has led to an increasing concentration on the role of the surface in normal cell functions, in relation to both growth and differentiation. It does not diminish the possibility that a change in the cell surface is a primary event in a cancer cell, nor should one forget the particular importance of the tumour-specific surface antigens, but the main thrust of cell membrane research seems now to be much more concerned with normal cell biology; although it is of the utmost importance and one of the most fruitful of all present fields I would nevertheless class a good deal of it as strategic research rather than tactical in its relationship to cancer.

Second, tumour virology is clearly concerned more directly with cancer than anything else and is therefore tactical research. This is not only because such viruses are carcinogens but because of their quite exceptional additional values as models of eukaryotic genetic material containing cancer genes. Nonetheless, it may turn out that the ubiquitous endogenous viruses are as relevant to normal development as to cancer. RNA-directed DNA synthesis, which is now used for all sorts of problems, could carry wide implications over and above its special role in certain tumour viruses, and it does not necessarily follow that all reverse transcription is oncology.

Finally, consider differentiation, a diverse and popular field of research which is particularly difficult to assess in relation to cancer. Differentiation involves changes in gene expression and since cancer also is now widely believed to be a manifestation of gene regulation, strong claims are made for cancer funds for support of differentiation, morphogenesis and so on in a variety of prokaryotic as well as eukaryotic systems. Indeed, there is now an additional justification for cancer funds, with the use of the teratoma as a model system. But it does not follow that even a full understanding of gene expression, for example, in embryogenesis, will necessarily lead to a solution of that other change in cell regulation which leads to cancer. In fact, many would hazard a guess that there is a fundamental difference: namely, that cancer involves a change in the genome and differentiation does not.

Most studies on development and differentiation must surely be classed as strategic research, with possible relevance to cancer as well as to many other practical problems.

Other examples, such as chromosome structure, protein synthesis and so on, would show that there is really a continuous gradient of research in terms of relevance to cancer. Nonetheless, I would maintain that a position on the gradient can usefully be identified at which cancer changes from one of many potential beneficiaries to the primary potential beneficiary. There will naturally be sharp differences of opinion as to where this point lies in relation to specific research programmes and many will disagree with the examples given. But that does not diminish the general value of distinguishing strategic and tactical research when considering allocation of cancer funds.

It would obviously be simple and administratively tidy to restrict cancer funds to tactical research alone, and to leave the support of strategic reseach to other sources. It would also be an evasion of responsibility and, in my view, a serious mistake. The vast accumulation of knowledge about cancer and cancer cells is matched only by our abysmal lack of understanding, which simply reflects our inability to solve the complexities of eukaryotic cells. So cancer research funds must surely contribute in some way to strategic research dealing with these fundamental issues. But the method of funding should not encourage deceit and need not necessarily be the same as for the more straightforward tactical aspects of oncology.

There have been many studies of the relationship between fundamental research and useful application, mostly in the physical sciences and engineering, and it is generally agreed that a simple causal chain between a curiosity-oriented discovery in a university laboratory and the emergence of a useful product or other advance is, to say the least, extremely rare. The relationship is complex, and there is much to be said for Harry G. Johnson's concept of basic research contributing to a general pool of knowledge in which the applied scientist or developer fishes and takes samples as he needs them (*Minerva*, **XI**, 17; January 1972). The result is a lack of temporal correlation between the acquisition of the elements of knowledge and their subsequent appearance in useful application.

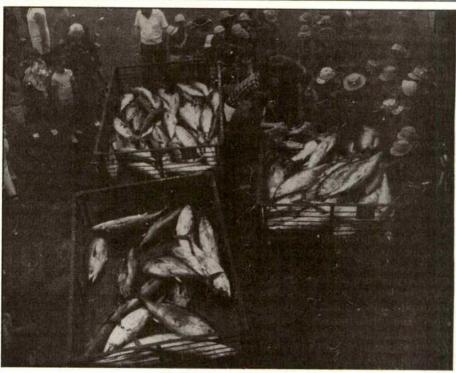
My plea therefore is that some mechanism should be found so that cancer funds can be used for the maintenance and expansion of this pool of general knowledge. What I am proposing, in effect, is a sort of levy or tax on cancer money to help pay for its dependence on strategic biology. It was Rothschild who included, in a controversial report a few years ago, an enlightened and more widely applicable proposal along these lines: namely, that most government laboratories, whatever their objectives, be allowed about 10% of their overall budget for allocation to more basic research, not strictly accountable in terms of relevance. The levy from cancer funds might perhaps be higher but we should not forget the sucesses of the past decade or so, in Hodgkin's disease for example, chorioncarcinoma and some leukaemias, and in at least the avoidance of lung cancer. These advances have not depended, so far as I can see, on any deep understanding of the molecular basis of livng processes, and so long as there is a prospect of continued progress the tactical research responsible must surely receive a substantial share of available funds. Nevertheless cancer research has so far had little effect on the outlook for patients suffering from most of the more common cancers, and it is this which calls, in addition, for the long term strategic approach and appropriate investment.

Leaving aside the actual scale, how might a levy system for strategic research work in practice? Within a single centre devoted to cancer research and dependent on grants and contracts it may be decided internally to allocate a certain share of facilities to strategic research of wider relevance. The proportion may vary considerably between centres. At grant level, applications for a predetermined share of cancer funds could be reserved and judged by a special agency, solely on the basis of scientific merit and without concern for the primary relevance to cancer. For government funding it is important that the contribution, however it is organised, should be deliberately set aside from any earmarked cancer budget and for that matter from other earmarked budgets, for cardiovascular disease and arthritis, for example. The levy, even if small, should be quantified and announced, and it should not be regarded as covered by the existing public expenditure on such things as university research.

The decisions about the strategic or tactical aspects of individual research proposals, and their inclusive or exclusive relevance to human cancer, will still have to be made, no doubt by committees of temporarily faceless peers. But I come back in the end to a rather idealistic view that a great deal of responsibility lies at the grass roots, namely with the individual conscience of the scientist who initiates a programme and the collective conscience of the group who constitute the centre or institute. And for those dependent on cancer funds, the framework of reference for this conscience should be the donor, be it the reluctant taxpayer, the major benefactor or the sad widow who subscribes her pound or dollar. ● □

'international news

Mediterranean poison fish forecast

from Alexander Dorozynski


IF mercury contamination of Mediterranean fish continues at the present rate, it will take an average fisherman some 375 weeks, or 7 years, to absorb enough mercury for the first symptoms of poisoning to appear, and 1,000 weeks, or about 20 years, for poisoning to become lethal.

This startling forecast is made in a report prepared after the most extensive study of mercury absorption by the biomass yet carried out in the Mediterranean. Maurice Aubert, a medical doctor and director of the Centre d'Etudes et de Recherches de Biologie et d'Oceanographie Médicale (CERBOM) in Nice, has found that average mercury levels in 17 out of 31 species of fish studied exceed the maximum level considered as acceptable in France (0.5 p.p.m.). In nine species (including tuna, swordfish, crab, shrimp and red mullet) the average mercury levels exceed 1 p.p.m.

Dr Aubert points out that previous toxicological and epidemiological studies, notably in Japan and Norway, have shown that a total load of 80 mg of mercury absorbed by the organism of an average adult is lethal, and that the first neurological symptoms appear at about 30 mg. Fishermen along the Mediterranean are known to consume much more fish than other people—a weekly average of 2 kg of fish being a common figure.

Since it has been found that only 4 to 5% of mercury absorbed is fixed in the organism, a weekly absorption of food containing 2 mg of mercury will result in a fixation of 80 μg. At this rate, the lethal dose is reached in about 20 years.

In his report, prepared for the French Institut National de la Santé et de la Recherche Médicale (INSERM), Dr Aubert notes that his estimate is in agreement with pathological studies carried out in Japan among victims of 'Minamata disease'. Among the first victims were children, for whom the lethal dose was 25 μg of mercury. The fish in Minamata Bay contained about 10 p.p.m. of mercury, and the average

Mediterranean fish market : mercury at dangerous level?

diet of children included no more than 350 g of fish every week from the age of two until death at the age of five. This means that the total amount of mercury consumed was 3.5 mg a week, or a total of 525 mg during the three years. The accumulated lethal dose of 25 mg corresponds to a fixation rate of 5%.

Statistics concerning adult Japanese fishermen also support his estimates, he writes. From the moment a Minamata fisherman started eating fish containing 10 p.p.m. of mercury, it took about 300 days for the neurological symptoms to appear, and another 500 for the disease to reach the lethal stage. Given an equivalent consumption (and 10 times less contamination of Mediterranean fish), the process would take 10 times longer—somewhat more than seven years for the appearance of first symptoms, and twenty for the fatal outcome.

Dr Aubert, who is senior researcher at INSERM and whose studies are supported by the Ministry of Health, does not want to sound alarmist. A man of the sea and a well-above-average fish eater, he makes it a point to add that there is no reason to panic, to stop eating fish or to deprive fishermen of their livelihood. But there are good reasons for taking stock of the problem and finding ways of reducing mercury seepage into the sea.

Five years ago, Dr Aubert carried out an analysis of hair samples of four regular fish eaters in Nice; two of them were fishermen, one was Dr Aubert himself, and the other was his wife. In one fisherman, he found a total organic mercury concentration of 7.39 p.p.m. In Japan, first symptoms of Minamata disease were found to appear in people having accumulated in hair as little as twice this amount. Another fisherman had 1.58 p.p.m. and Mme Aubert, who is also a medical doctor and works with her husband, 2.88 p.p.m. As to Dr Aubert himself, his hair indicated a non-negligible level of 3.66 p.p.m.

It appears that this is the only study of mercury contamination of man that has been made along the Mediterranean. In Rome, several experts of the UN Food and Agriculture Organisation concerned with the Mediterranean were queried, and none was aware of any other similar study. Yet, the test is neither very difficult to carry out, nor costly.

It is known that the Mediterranean is particularly vulnerable to pollution. Warm and saline, almost tideless, with a limited continental shelf (an extended shelf favours a mixing effect) and communicating with the ocean only by a narrow strait, it is a relatively motionless sea. Most of its shores are densely

populated by people of different nations, some concerned with maintaining their rapid industrial expansion, others with achieving as rapidly as possible a degree of industrialisation equivalent to that of their neighbours.

Anti-pollution measures are not encouraged by energy shortage and economic crisis, and it is not unreasonable to believe that some aspects of pollution are ignored to avoid worrying consumers or restricting producers.

Mercury may be a case in point. Analysis of the mercury content of water is difficult and unreliable, but it is known that even if undetected amounts of this metal are present in water, it can be accumulated along the food chain, reaching particularly large concentrations in long lived and carnivorous fish, such as tuna.

Sources of mercury contamination are numerous and only a thorough investigation can identify them and attribute to each its share. From Barcelona to Genoa, some 50,000 industrial plants, large and small, add metals and chemicals to the sea. It has been estimated that the chemical industry alone is responsible for the rejection of 65 tons of mercury a year. Paper mills, electronic and pharmaceutical plants, and factories making explosives, add their share; so does agriculture, in countries where mercury-based fungicides are not banned. (In France alone, 4.5 tons of mercury are used in agriculture every year.)

Methyl mercury is the compound most readily absorbed by marine organisms. In Minamata Bay, methyl mercury was discharged by an acetaldehyde factory, but Dr Aubert notes that mercury salts can be methylated in the sea under favourable conditions, particularly in an acid environment. Thus other forms of pollution which contribute to a lowering of the *p*H of sea water catalyse mercury pollution.

The most typical example of this, he points out, is the result of the dumping at sea of huge amounts of residue by ships of the Montedison factory in Scarlino, on the Italian coast facing the island of Elba. The factory produces titanium dioxide, rejecting among other chemicals and metals, sulphuric acid compounds with a *p*H of 0.2, causing the lowering of the *p*H of sea water over large areas. The rejection of these "red muds" (so called because of the colouring action of iron) started "on an experimental basis" in 1972 and went on for two years before the president of Montedison and four administrators were condemned to suspended prison terms.

By then, more than 1 million tons of noxious residues had been dumped north of Cap Corse, disrupting the ecology of an area where some fish were found with almost incredibly high mercury contents (one dolphin had a level of 74 p.p.m. in its liver, 51 p.p.m. in its lungs and 14.6 p.p.m. in its muscles.)

Natural mercury contamination also takes place in the Mediterranean, where deposits are known to exist along the shores. Natural conditions can also contribute to the formation of methyl mercury; sediments, where the *p*H is lowered by metabolic activity of micro-organisms, can be conducive to the transformation of mercury salts into methyl mercury (this phenomenon was reproduced *in vitro* in CERBOM's aquaria.)

Undoubtedly many other mechanisms are involved, and they are far from being entirely understood; researchers wonder, for example, why is it that in some parts of the sea, where the mercury content is high, the amount of mercury accumulated in the biomass is relatively lower than in other areas, where mercury is hardly detectable.

André Jarrot, Minister of the Quality of Life, points out that the actual mercury levels in fish represent no danger whatever for the average French or European consumer, but announces nevertheless that some measures are being taken.

Already, there is a directive that can ban the setting up in sensitive areas of industrial plants producing chlorine by electrolysis using mercury electrodes. Fungicides containing methyl mercury are no longer authorised and, in the paper industry, the use of fungicides and biocides containing mercury in any form is forbidden. Mr Jarrot points out that a plan is already under way to reduce mercury pollution by 50% in two years and by 90% in five years.

If this is carried out, the French may be as successful in controlling mercury pollution as they seem to have been in controlling bacterial pollution along the beaches, which had reached an unsafe level a few years ago.

Since then, Dr Aubert and other researchers have intensively studied the behaviour of earth bacteria in water; Dr Aubert has identified antibiotic secretions in water and also shown that some marine micro-organisms secrete nucleoproteins that act as "telemediators" (which are inter-specific, but otherwise comparable to pheromones secreted by insects and animals) to trigger or interrupt antibiotic secretion in other micro-organisms. His studies of the antibiotic properties of the sea have led him to develop, in collaboration with Professor N. Desirotte, a mathematical formula to determine the point of discharge at sea of domestic sewage, whether treated or not. The equation is

$$\log C = \log (C_0/h) - (\beta\gamma/1.1)t$$

where C_0 is the bacterial concentration in the sewage before discharge and C the concentration at time t (h) after discharge from an outlet at a depth h (m); β is a coefficient which depends on flow and is unity for a discharge of $1 \text{ m}^3 \text{ s}^{-1}$; γ is a coefficient of the bactericidal action of sea water and is unity for the Mediterranean (comparative measurements in other seas show that γ can vary, so that it is important for it to be included in the mathematical model).

This formula has been used to determine the optimal position of sewage outfalls from large cities, sometimes requiring an outfall several hundred

---

If contamination by mercury is successfully coped with, another serious problem is nevertheless likely to emerge in the years to come: thermal pollution, notably from nuclear power plants, which are particular wasteful of heat.

So far there is only one nuclear plant on the Mediterranean, at Vandellos, about 30 km south of Tarragona on the Spanish Costa Dorada.

The plant uses the French graphite-gas system, and was built with French technical assistance three years ago. It is cooled with sea water pumped from a depth of 13 m at the rate of $33,000 \text{ l s}^{-1}$ and rejected directly into the sea. As it enters the plant, the water is chlorinated to prevent shell incrustations in the pipes, and more than 300 tons of chlorine are thus emptied into the sea every year.

The temperature of the water as it leaves the plant is increased by 6 or 7 °C; the temperature of the surface water is raised by 3 °C over approximately 10 hectares and by 1 °C over several tens of hectares. In the summer, water leaving the plant has a temperature of more than 30 °C—too high for any known Mediterranean life form.

In August 1972, the American ERTS satellite took a photograph showing a large dark area covering several hundred hectares off Vandellos and believed to correspond to an impoverishment of plankton life. But surprisingly enough and in spite of protests of fishermen who have complained that surface fish have disappeared from within a radius of several kilometres from the plant, no serious study has been made of the ecological effects of this thermal and chemical pollution. Such a study could have served as a model for future nuclear plants that are planned along the Spanish coast and in Séte, Martigues and Port-la-Nouvelle on the French side of the Mediterranean.

metres and even several kilometres from the shore so that, whatever the meteorological conditions, the bacterial pollutants do not reach the shore alive.

Thus pollution on the beaches of the Côte d'Azur, which had reached an unpleasantly high level a few years ago, has considerably decreased. Similar improvements are being undertaken in other Mediterranean countries. ☐

New deal in French research?

from the staff of La Recherche

FOR the first time since he came to power, M Giscard d'Estaing has invited a select committee on scientific research to the Elysée Palace. The report at the conclusion of this meeting set out in detail the government's scientific policy; in particular, it stressed that "the development and stabilisation of the French research efforts is becoming increasingly important, and France should rate among the leading countries with comparable resources in both the volume and quality of its research . . .". For the first time for many years, the government has thus confirmed its intention to give scientific research some degree of priority.

This political assurance is important insofar as the financing of research has been growing more and more difficult, because recent increases in research budgets have usually been lower than the average rates of growth for general equipment, and barely compensated for inflation. Although the GNP criterion may not necessarily be adequate in determining the research effort of a country, it is nevertheless significant that the portion of the GNP devoted to research in France has been consistently decreasing since 1967, falling from 2.3% to 1.7% in the past even years. This continuous diminution of the intensity of the research effort, along with serious problems of employment in science, has worried a large section of the scientific community, and the problem was brought to the public eye by two candidates for the presidency of the Republic in May 1974. M Giscard d'Estaing is now attempting to set matters straight in the projected budget, and so to turn away from the policy which he initiated when he was Minister of Finance.

The involvement of the Elysée is without doubt important politically, since it will give a major trump card to those responsible for scientific policy when the next budget discussions are being held—especially to the Minister or Industry and Research, M d'Ornano.

A meeting of ministers at the end of April will decide the main points of the 1976 budget and it will then become clear whether research is really to be recognised as a priority, and whether the increase in the finance available next year will permit real growth. And now, after the political assurances as to the principle of increased research efforts, and the speculation on the growth of the research budget, it remains to be seen whether French scientific policy will have new life breathed into it.

The first decisions announced after the meeting with the President already provide some useful indicators. On the level of the organisation and construction of research policy, important decisions are of three types. First, provision is made for the formation of executive groups to activate research in certain ministries. Their function would essentially be to coordinate and initiate scientific projects in ministerial departments. On the financial level, the *enveloppe recherche* which includes a large portion of non-scientific research, would be redefined. It will no doubt be extended in the future so as to cover certain other projects, such as the big civil aviation programmes and telecommunications research. This would allow better coordination of scientific policy. Provision is also made for the creation of a basis for intervention in the programme of the Délégation Générale à la Recherche Scientifique et Technique (DGRST). This measure could no doubt be most important for it would, in particular, allow the DGRST to instigate interdisciplinary research projects on various subjects of great general interest.

The second series of measures announced concerns research personnel. It is first stated that science posts will be created "regularly and continuously". Measures will be taken to reabsorb the jobs of researchers without contracts, and to facilitate the mobility of staff, especially concentrating on better coherence of contracts and the devising of appropriate incentives.

The third type of decision aims to involve the scientist more in the responsibilities of scientific policy. It seems that there are divergent views on this. The government has in effect announced, on the one hand, that a committee presided over by M P. Aigrain (and including two academicians) would study reform of the Acadamy of Sciences and, on the other, that the role and composition of the Consultative Committee would be redefined. This choice can be interpreted as follows. A new, rejuvenated academy, would give the scientific community a forum where ideas could be aired, and a framework within which committees of experts could be formed to report on scientific problems. The Aigrain committee has already set to work to this end.

The Consultative Committee would be required to translate the wider socioeconomic needs of the whole country into the language of the practical objectives and means of scientific policy. On one matter the meeting with the President gave few precise details, that is, on policies relating to industrial research. Certainly, there is mention of the "economic assessment of the research effort" and of the importance of research to aid export growth, but it stays on the level of good intentions. Economic assessment of research was already on the cards in 1966, when the bill was passed creating the Agence Nationale de la Valorisation de la Recherche (ANVAR) on the model of the MRDC; it would be an exaggeration to say that no progress has been made on this problem in the past 10 years, but people have realised that the relation between science and innovation is far from being as simple as they thought.

It is on this problem of policy towards industrial research that the government document probably says least. A special committee under M R. Poignant will be handing in a report very soon on this question to the Minister for Industry and Research. ☐

Oceanography in Korea

THE government of South Korea has recently been expanding its interest in science and technology, and nowhere is the interest more visible than in oceanography. Two years ago the Korean Ocean Research and Development Institute (KORDI) was established to coordinate the development of the country's marine resources and collaborate on an international scale. By 1977 the new Science City in Daejon will be housing KORDI and 16 other institutes in the process of being established; for the present KORDI is based in Seoul.

The growth of the institute depends much on international goodwill. The United Nations Development Programme has agreed to provide $800,000 over three years, and bilateral assistance is being sought from Japan, European countries and the United States.

A staff of 63 is envisaged by 1977 and recruitment will be a major problem. Since many Koreans with the appropriate experience are living abroad, an extra effort has had to be made to attract them back; salaries are higher than those in comparable government departments, and modern housing is also being made available. ☐

Congress to vet NSF grants?

by Colin Norman, Washington

IN a move which is sending shivers of apprehension through the scientific community in the United States, the House of Representatives has decided that Congress should vet every research grant that the National Science Foundation (NSF) wants to award, and that it should have a chance to veto those considered to be a waste of taxpayers' money. A little-noted amendment designed to do just that was attached to an otherwise routine budget bill last week, in spite of an urgent plea by one Congressman that to pass the measure would constitute "an act of public and scientific irresponsibility".

Even if the amendment does not survive passage through the rest of the Congressional mill—it must be approved by the Senate before it becomes law, and its prospects there are far from certain—the fact that the House passed it provides ominous signs of growing political disenchantment with expenditures on some kinds of basic research. Put more bluntly, it is clear that some Congressmen have discovered that many research projects provide plump targets through which they can show the folks back home that they are doing their bit to hold down public expenditure.

The amendment simply states that the NSF must supply Congress each month with details of all the research projects it wants to support, and that Congress should have 30 days in which to exercise a veto over any grant that it considers unworthy. A resolution passed by either the House or the Senate would be sufficient to kill any such project.

Although the amendment does not suggest any criteria by which Congress should judge the scientific worth of research projects, it asks the NSF to provide "all facts, circumstances and considerations relating to or bearing upon the decision of the National Science Foundation to approve said grants, including to the maximum extent practicable the manner in which the national interest will be fostered by the approval of such grants". Since the NSF awards about 14,000 grants each year, the measure would clearly be an administrative nightmare if it ever reached the law books.

Why has the House suddenly turned sour on the NSF? Part of the reason is the widespread publicity accorded to some broadsides recently delivered by Senator William Proxmire against a handful of the NSF's research programmes, and another factor is that the NSF has been caught up in a bitter controversy over school textbooks. The whole business, in fact, provides an excellent example of the irrational manner in which many policy decisions are taken in the United States.

The NSF's troubles began a few weeks ago when Proxmire, an influential and entertaining man who is closely watched by the press, launched an attack on a few NSF social science programmes by the time-honoured tactic of firing off press releases holding up the research to ridicule. In the space of a couple of weeks, he poured scorn on a study on romantic love, a project entitled "Hitchhiking, a Viable Addition to a Multimodal Transportation System", a study of the "Social Behaviour of Alaskan Brown Bears", and a "Preliminary Investigation of a Special Impact of Television on Blacks".

Even without Proxmire's stamp, the press releases would have been guaranteed newspaper space, for the study on romantic love—which Proxmire termed the "boondoggle of the month"—was so juicy that it was carried by virtually every newspaper in the country, from the *New York Times* downwards. No matter that the study was designed to investigate why so many marriages end in divorce, which is not an irrelevant factor in family life in the United States, the attacks precipitated a spate of reports of supposedly trivial or useless research projects being supported by government funds. Particularly prominent was a list of projects with funny-sounding names which was broadcast by Paul Harvey, a radio commentator whose utterances are carried by scores of local stations.

Although many of the projects on Harvey's list date back to the early 1960s and have long since been terminated, the upshot of all the publicity was that members of Congress have been deluged with letters from their constituents complaining about wastage of government funds. Since constituents' mail provides an indication of voter sympathies, which few Congressmen can afford to ignore, the NSF suddenly found itself on the receiving end of a good deal of flak.

One example of a trivial research project, which was mentioned during the debate and which has attracted a good deal of publicity, is a $70,000 study of perspiration in Aborigines. Though that study has attracted much ridicule, it was in fact designed by the Department of Defense in the hope of finding a way to prevent soldiers from becoming dehydrated in tropical climates after many hours without water —a problem which does not seem to be encountered by Aborigines.

Such ill-informed attacks on the NSF's research programmes are by no means new, and they would probably have had little impact this year had it not been for another dispute about the foundation's activities. That dispute concerns a school science course developed in the 1960s by the Educational Development Centre in Cambridge Massachusetts, with NSF funding. Called "Man: a Course of Study" (MACOS), it is a collection of films

---

IT is now a year since the European Space Agency (ESA) was to have subsumed the role of ESRO (the European Space Research Organisation) and what was left of that of the European Launcher Development Organisation (ELDO). It was then that ESRO's Director-General Dr Hocker, completed his term of office, making way for an appointment to the new post of Director-General of the ESA. In the event the two got inextricably twisted together and the situation become further confused by the French government's overall review of its science budget and the future of the Ariane launch rocket development which had been accepted as part of the 'European' package.

At last the situation is clarifying. The appointment of a permanent Director-General has been at the root of the whole impasse and it is now clear that the compromise candidate Roy Gibson has been accepted by the two rivals in sponsorship, the French and Germans. They have agreed to drop their respective national candidates and accept the Englishman, who has been doing the job on an acting basis and under considerable difficulties for the past year.

A specially summoned meeting of the space ministers of the 10 member countries, the European Space Conference, is convening in Brussels this week to confirm the appointment. Seven directors to complete the ESA top management will be announced at the same time. The organisation has been running with three directors short since last year.

It is expected that the same ministerial meeting will decide one way or another on the formula now put forward by the French for ESA participation in the operating costs of the French launch range of Kurou in Guiana from which the Ariane launching rocket is to fly. The switch to the French-designed rocket has also involved a charge of launch range. The previous Europa launcher based on the British Blue Streak was launched from Woomera, Australia where at one time the Australians were offering to pay all the operating costs. *Angela Croome*

booklets and exercises designed for use in teaching anthropology to 11-13 year olds. It includes studies of herring gulls, salmon and Netsilik Eskimos—a primitive and near-extinct Eskimo tribe living in North-western Canada. The course is now fully developed, and the NSF has been actively promoting its use in schools.

Like a good many other school courses and textbooks, MACOS has, however, generated a good deal of controversy, as a result of which John B. Conlan, a conservative Republican from Arizona, has been trying to persuade Congress to stop the NSF promoting it. Conlan objects particularly to the studies of the Netsilik Ekimos because, he says, "communal living, elimination of the weak and elderly in society, sexual permissiveness and promiscuity, violence and other revolting behaviour" are recurring themes in the studies. About 1,700 schools throughout the United States have, however, decided that MACOS is acceptable and are using the course.

Conlan tried to delete funds from the NSF's budget for promoting MACOS when the matter was being considered by the Science and Technology Committee, but the move failed. The Director of the NSF, Guyford Stever, subsequently announced, however, that he would defer all funding for MACOS pending a complete review of all the NSF's policies for promoting educational courses.

Not satisfied with that, Conlan took his grievances to the floor of the House last week, but failed narrowly—by a vote of 196 to 215—to delete the funds from the NSF's budget. During the course of the debate, Richard Ottinger, a Democrat from New York, suggested that the course simply describes the Netsilik culture in non-offensive terms.

Nevertheless, several members of Congress indicated that they had received many letters from constituents about MACOS, following press accounts of the dispute, and that factor clearly added to the NSF's troubles in the House. Together with the widespread publicity surrounding attacks on supposedly trivial programmes supported by the NSF, the dispute about MACOS indicated to some Congressmen that the NSF should be brought under more intensive scrutiny, and Bauman's amendment seemed to provide a means for doing just that. Consequently, the a m e n d m e n t was approved by 212 votes to 199.

Exactly how Congress should decide which of the NSF's programmes are in the national interest, what criteria should be applied to censorship of educational programmes, and which research could be dropped without hurting the progress of science, is, however, another matter. □

THIS footprint may be 250,000 years old: one of the oldest recorded prints of man. Pressed into volcanic ash, it was uncovered with some others in 1970 during the construction of a dam near Demirköprü in Turkey. It is now on display at the Museum of National history in Stockholm, as part of an exhibition about the origins and future of man.

The Museum acquired the print from Mr Thomas Barton, one of the engineers working on the project in Turkey when the print was uncovered. He did not, however, actually see it extracted as he was working some miles away at the time. He was given it later by men at the discovery site, who told him of its possible interest, and when he returned to Stockholm he brought it with him.

The placard explaining the exhibit states that the Turkish Metal Research Institute in Ankara determined the age of the ash and that the National Laboratory of Forensic Science in Stockholm has examined the print and agrees with the Turkish institute's findings. The forensic laboratory however, denies having tested the ash. According to a spokesman there, two members of staff were only asked to determine whether the imprint was actually of a foot or not. In their opinion it was. Neither has the Natural History Museum itself carried out any tests on the ash, as the equipment at its disposal cannot cope with the supposed youth of the sample. In the opinion of Professor Welin, of the museum's research department, any tests he could do would yield only a very approximate indication of the age of the ash. And there is no equipment elsewhere in Stockholm which could make a more accurate determination.

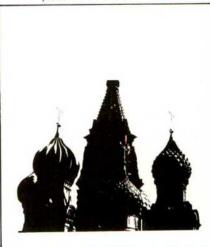
Apart from the Turkish test, then,

where has the 250,000 year old estimate come from?

The impression of the heel is deeper than that of the instep and the whole print is slightly blurred, suggesting it was made by someone running in the ash. The foot was pointing in the direction of the River Gediz. The theory advanced to fit these facts is that a man was caught in the midst of a volcanic eruption and ran for his life towards the river, imprinting the ash which, because of rain and heat, was baked into that form and shortly afterwards covered with lava. And Mr Barton says that there was volcanic activity in Turkey 250,000 years ago.

If this theory is correct, the print would belong to the Quaternary period. The Museum states that the print predates Cro-Magnon man, who came to Europe at the end of the last ice age. If this is true the runner would have lived during the Pleistocene period—possibly at the same time as Neanderthal man.

As the dating of the print—and even the circumstances of its discovery—have been based largely on hearsay, it would be a good idea to confirm the results of the Turkish test. There are, however, no plans to do this. Only the Turkish Embassy in Stockholm is showing interest on the grounds that Mr Barton did not obtain the necessary official permission to export an antiquity from the country. (Mr Barton insists that he acted within the law in bringing the print back.) During the course of its enquiries into this aspect of the affair the Turkish Foreign Ministry may of course discover whether the print is in fact an antiquity or not. But that seems a rather back-handed way of finding out the truth about what could be an important anthropological discovery.   *Wendy Barnaby*

THE problems of higher and specialist education have always been particularly difficult for Soviet educationalists, who must seek the best means of using potential talents for the good of the state, while not departing from the theoretical tenets of equal opportunity. During the half century of Soviet rule, a number of solutions have been proposed. At one stage the exceptionally gifted were expected to develop their talents in extracurricular time (traces of this remain in the mathematical "o l y m p i a d s" for schoolchildren), whereas under Khrushchev, the policy was one of what may broadly be called 'sandwich courses for all'—a coordination of education and work which led to considerable interruption of production and the exasperation of supervisors and managers. During the past few years, the Khrushchev policy has been quietly modified, adapted and legislated out of existence, and a return to more conventional policies introduced.


The new approach includes a certain amount of streaming, or rather creaming, of the highly gifted into specialist schools at a fairly early age. (One interesting facet of Soviet educational psychology is that, although it denies the existence of educational subnormality—except in the case of actual brain damage—it does admit the existence of above-average mentalities—although hedging its bets to the extent of claiming that the intelligence of a "lively" average child can be improved by educating him or her together with the highly gifted). Whatever the theoretical justification for creaming, current Soviet policy seems to have as its pragmatic aim the production of the vast work force of the intelligentsia needed for the expansion of the Soviet economy.

A recent *Pravda* article by the Minister of Higher and Specialist Secondary Education, V. Elyutin, outlines the plans for the 1980s and 1990s, and stresses the need for a new strategy in scientific and technological training for the next 10 years. Present plans include means of "making the training of specialists more flexible, and ensuring the organic connection of education and life, science and industrial activity". One defect of the Khrushchev system was that, for logistical reasons, young people were assigned to factory training that was unrelated to their talents or future professions. Another fault was the difficulty secondary school children had relating their school studies to the specialist technique of industry, in which they were supposed to participate. Minister Elyutin's stress on the cooperation of higher educational institutions (from Moscow Uni-versity downwards) with industry—a policy which is to be "extended further" in the immediate future—indicates that the emphasis will now be on such industrial training at a later age, when it can be more meaningful to the student and less disruptive to the factory. He notes, however, that such cooperation between institutes, or groups of institutes, and industrial enterprises may take "the most diverse" forms. The new plans are still production-orientated ("changes in specialities and specialisations" will be introduced

Russia today

from Vera Rich, London

"in accordance with the needs of the national economy as they arise"), yet underlying the whole statement one senses a realisation that such a policy can only be fruitful if it is implemented in accordance with the special circumstances of each institute.

● The failure of the latest Soyuz to complete its link-up with the orbiting Salyut space station will not, repeat not, have any effect on the joint Soyuz-Apollo mission planned for July 1975. So we are told quite firmly by both parties to the project. Commander Richard Truly, the back-up capsule commander of the US team, said at a press conference in London, on his way to Moscow for a joint training mission, that the Americans still have every confidence in the joint mission and are satisfied with the safety aspects of the flight. The Russians, for their part, were eager to explain that this Soyuz was not the model which will be used for the joint mission, but an earlier version that had been "less diligently" checked than the system planned for the link-up. International goodwill and cooperation continues unaffected.

Yet in spite of the mutual reassurances, one wonders why the Soviet planners chose to announce the failure at all. It had not risen above the horizon of foreign tracking stations and need therefore never have been mentioned. Presumably it was the forthcoming joint mission which prompted the Soviet planners to make the announcement—but was their motivation one of cooperation, or fear of further setbacks? In the latter case, an aborted flight with the safe recovery of the cosmonauts might serve as a reassurance: even if the rocket fails, the men are safe. The old rumours of Vladimir Ilyushin, Gagarin's alleged predecessor on the launch pad, have never been entirely squashed in either East or West, and the Soyuz failure does offer a certain "substantiation", in that a crew-carrying rocket can be launched and fail without being tracked by foreign stations. The latest Soyuz venture is, at all events, a success for Russian safety procedures, and this fact may well have motivated the decision to release the news.

● Intimations that increasing pressure was to be exerted on participants in the illicit Sunday seminar for "refusnik" scientists have, unhappily, been justified by recent events. A letter to western "Academies of Science, Scientific Societies and Individual Scientists", signed by 45 participants of the seminar, states that increasing pressure is being exerted on individual participants "in order to interfere with the seminar's work." Methods mentioned include the issue of call-up papers for retraining in the Soviet Army (which could later be interpreted as access to classified information, a *prima facie* reason for refusing a visa), prosecution for "parasitism" (being without employment, although the scientists concerned have been deprived of their jobs as a result of applications for exit visas) and, in the case of Mark Azbel, the physicist, a kind of *de facto* exile. Professor Azbel, formerly Head of the Department of Electron Theory at the Landau Institute of Theoretical Physics of the Soviet Academy of Sciences, had been visiting relatives in Chernovtsy, and was about to return home to Moscow when he was stopped at the railway station and told not to go there for several months "or he would find himself further east" (in Siberia). Azbel is now stranded in Odessa without friends or money. It seems that, since the seminar continues to meet, in various venues, the authorities are now trying to erode it by pressure on the individual participants. They still seem unwilling to take the simple step, suggested by the seminar's founder, Aleksandr Voronel, of granting the whole group exit visas and thus letting them transfer their vexing activities to Jerusalem or Tel-Aviv.

Topography of ribosomal proteins

from a Correspondent

THE bacterial ribosome is the only cellular organelle for which a thorough understanding of both structure and function at the molecular level can be expected in the not too distant future. A central part of the structure–function correlation is obviously elucidation of the spatial arrangement of proteins within the ribosome; current interest in this aspect of ribosomes alone has produced a flood of well over a hundred papers in the last twelve months. Here I shall summarise briefly the present state of this problem of 'protein topography' with reference to the *Escherichia coli* ribosome.

In considering the three-dimensional arrangement of the proteins, a number of points must be borne in mind. First, the ribosomal proteins not only vary considerably in size, but, more important in this context, they may also have very irregular or elongated shapes within the ribosomal particle. Second, the proteins are not all present in equimolar amounts at all stages of the protein synthetic cycle; although this question of which proteins are 'unit' and which are 'fractional' still requires some clarification, it is certain that the ribosome cannot be considered a homogeneous entity. It remains to be seen whether the removal or addition of a fractional protein can seriously distort the arrangement of the other proteins. Third, conformational changes can occur as a result of interaction between the ribosomal sub-particles, or as a result of interaction with the various components of protein synthesis (tRNA, factors, and so on) and again it remains to be seen whether such changes are accompanied by a radical change in the protein arrangement within the particle. Fourth, only a small proportion of ribosomes are active in protein synthesis in *in vitro* systems, which raises the possibility that distortions of the protein arrangement may occur as a result of the isolation procedures used, or of course is a result of the procedures used to make the structural investigations. But since several techniques have been used during the last few years to examine the spatial arrangement of the ribosomal proteins, their success may be

judged by the measure of agreement between their various results.

The use of bifunctional protein cross-linking reagents is the most direct way of determining which pairs of proteins are neighbours within the ribosome. The chief problem here is in identifying the proteins contained in the cross-linked complexes; this identification can be made directly with antibodies specific to the individual proteins (for example Lutter, Bode, Kurland and Stöffler, *Molec. gen. Genet.*, **129**, 167; 1974). Most attention however has been given to the development of cleavable reagents, which enable the proteins in the cross-linked complex to be identified by gel electrophoresis, after chemical cleavage of the cross-link. The most widely used reagents for this purpose have been the *bis*-imido esters, and of these, *bis*-methyl suberimidate proved in earlier work to have the most useful properties (Bickle, Hershey and Traut, *Proc. natn. Acad. Sci. U.S.A.*, **69**, 1327; 1972). The reagent attaches to the ε-amino groups of lysine residues, and the cross-link is cleavable by ammonolysis.

Some authors, however, finding that the cleavage reaction did not proceed very satisfactorily, developed other reagents. The most noteworthy new reagents are methyl 4-mercaptobutyrimidate (Traut, Bollen, Sun, Hershey, Sundberg and Pierce, *Biochemistry*, **12**, 3266; 1973), and *bis*-azide compounds derived from tartaric acid (Lutter, Ortandel and Fasold, *FEBS Lett.*, **48**, 288; 1974). Both of these react with amino groups, but the former does not of itself introduce a protein–protein cross-link. Instead, the mercaptobutyrimidate effectively adds an SH group to the protein, and these SH groups can subsequently be cross-linked by mild oxidation. Cleavage of the isolated protein complexes is accomplished in the mercaptobutyrimidate case by reduction, and in the tartryl diazide case by periodate oxidation of the vicinal OH groups. Using this approach, many 30S protein pairs have been cross-linked, as have a smaller number of 50S protein pairs (Clegg and Hayes, *Eur. J. Biochem.*, **42**, 21; 1974). The possibility that some of the reagents

can themselves distort the protein arrangement remains, but the consistency of the results obtained with the different reagents argues against this. Further, in one case, a cross-linked protein pair (S5–S8) was incorporated back into a reconstituted 30S particle, without impairment of protein synthetic activity (Lutter and Kurland, *Nature new Biol.*, **243**, 15; 1973).

If the 30S ribosome is treated with nucleases under suitably mild conditions, it can be broken down into fragments of ribonucleoprotein which can be analysed for their protein and RNA content. Those proteins which are found together in such fragments are presumably neighbours in the intact particle, since it is unlikely that a ribonucleoprotein complex consisting of widely separated groups of proteins joined by an unprotected RNA strand could survive the nuclease treatment. Using this approach, the 30S particle can be readily split into two fragments of unequal size, the one containing eight to ten proteins and the other five or six (for example Morgan and Brimacombe, *Eur. J. Biochem.*, **37**, 472; 1973). Various smaller fragments have been isolated, containing sub-sets of these two groups of proteins, the smallest consisting of only two proteins.

A similar division of the 30S proteins into groups has been made from hydrolysates of a protein-deficient reconstitution intermediate (RI) particle (Zimmermann, Muto and Mackie, *J. molec. Biol.*, **86**, 433; 1974). In this type of approach, the proteins are of course not covalently attached to the RNA, and therefore special care must be taken to ensure that the observed results are genuinely specific. The importance of this point has been underlined by the finding that under conditions which promote 'unfolding' of the ribosomal sub-particles, the proteins lose their specific sites of attachment to the RNA (Newton, Rinke and Brimacombe, *FEBS Lett.*, **51**, 215; 1975). This almost certainly invalidates a number of previous fragmentation studies, particularly in the case of the 50S particle, although more recently some specific 50S fragments have been

described (for example Roth and Nierhaus, *J. molec. Biol.*, in the press). But in contrast to the 30S particle, the 50S cannot be split into two well-defined halves, despite the fact that the 23S RNA is readily cleavable into an 18S and a 13S RNA (for example Allet and Spahr, *Eur. J. Biochem.*, **19**, 250; 1971). The finding by neutron scattering that the centres of mass of protein and RNA are widely separated in the 50S particle as opposed to the 30S could explain this difference (Moore, Engelman and Schoenborn, *Proc. natn. Acad. Sci. U.S.A.*, **71**, 172; 1974).

It has been known for some time that the 30S proteins interact with one another during *in vitro* reconstitution from protein and RNA in a very specific manner. These interactions have been incorporated into an 'assembly map' (see Held, Mizushima and Nomura, *J. biol. Chem.*, **248**, 5720; 1974, for the latest version). Although these interactions need not necessarily be a direct reflection of the protein neighbourhoods within the 30S particle, there has been striking agreement between those proteins which are found together in cross-linked pairs or ribonucleoprotein fragments and those which are related in the assembly map. It seems reasonable therefore to conclude that most if not all of the assembly interactions are indeed direct reflections of the ribosomal topography. The question of whether all the proteins in the complete particle have substantial contact with the RNA has yet to be settled, and it has been suggested that it may be more appropriate to think of the assembly interactions as being between regions of ribonucleoprotein as opposed to simply interactions between proteins (Kurland, *J. supramolec. Struct.*, **2**, 178; 1974).

There is of course as yet no corresponding assembly map of the 50S particle, since a successful total reconstitution of the *E. coli* 50S particle has only recently been achieved (Nierhaus and Dohme, *Proc. natn. Acad. Sci. U.S.A.*, **71**, 4713; 1974). Some assembly interactions have however been determined, using protein-deficient core particles as the starting point (Highland and Howard, *J. biol. Chem.*, **250**, 831; 1975).

Differential reactivity to chemical reagents has been used by many workers as a probe of ribosomal topography, the assumption being that those proteins which are most exposed on the ribosome surface will react most strongly with a particular protein reagent. Among the methods used have been digestion with trypsin, or reaction with kethoxal, various aldehydes and N-ethyl maleimide. Interpretation of the results of such experiments is however rather complex, since exposure or lack of exposure of a particular re-

active group is not necessarily a reflection of the protein topography in the wider sense. A reactive group on a protein could be shielded by RNA, or by the tertiary structure of the protein itself. Further, it is not easy to predict how far a chemical reagent can penetrate into the ribosome, and it is therefore not surprising that the degree of agreement between the various results is not very high. A good summary of the recent data can be found in a paper by Benkov and Delihas (*Biochem. biophys. Res. Commun.*, **60**, 901; 1974). At present, data from reactivity towards very large reagents are more easy to interpret, and two methods are noteworthy in this context. The first of these is measurement of the accessibilty to protein-specific antibodies (for example Stöffler *et al.*, *Molec. gen. Genet.*, **127**, 89; 1973), and the second is the iodination of ribosomal proteins catalysed by lactoperoxidase, of which a recent example is the work of Litman and Cantor (*Biochemistry*, **13**, 512; 1974). The general conclusion from all these methods is that all 30S proteins have some accessible groups on the ribosome surface, whereas the 50S proteins are not so readily accessible.

Several groups have attempted to coordinate the available data into three-dimensional models of the protein arrangement of the 30S particle. In all these models, the proteins have been represented as spheres, and the authors have been careful to point out that the arrangements are only schematic, and serve mainly as a means of testing the self-consistency of the various data. A technique has, however, recently been developed which casts doubt on the whole validity of even this crude type of model building: the direct visualisation of the proteins by electron microscopy of complexes formed between

ribosomal sub-particles and protein-specific immunoglobulins. This technique has become possible since both sub-particles have a readily recognisable shape in the electron microscope. Thus, if the ribosome is treated with a single protein-specific antibody, a ribosome–antibody–ribosome complex is formed, with the Fab arm of the antibody attached to a point on the ribosome surface. Several proteins have been localised on the surface of both sub-particles by this method (for example Tischendorf, Zeichhardt and Stöffler, *Molec. gen. Genet.*, **134**, 187; 1974), but the most important feature of the results is that while some proteins show a single surface binding site for their cognate antibodies, others seem to have multiple binding sites over a wide area of the surface, for example protein S4 (Lake, Pendergast, Kahan and Nomura, *Proc. natn. Acad. Sci. U.S.A.*, **71**, 4688; 1974). This indicates that the conformation of the proteins within the ribosomal particle is variable, and can be highly extended, which, as implied at the beginning of this article, alters the whole conception of the ribosomal topography, and rather changes the interpretation which must be made of many other data (such as the protein cross-linking results). In this context it should, however, be borne in mind that the overall dimensions of the 30S particle as measured by electron microscopy differ significantly from those estimated by low angle X-ray scattering in solution (Hill and Fessenden, *J. molec. Biol.*, **90**, 719; 1974).

In conclusion, the topography problem is still obviously some way from complete solution, but it is encouraging that the techniques in current use are by no means exhausted; further rapid progress can therefore be expected.

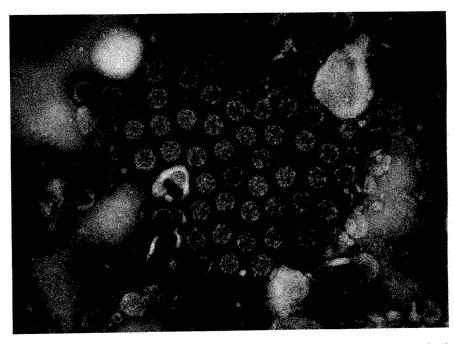
Devonian arthrodires

from B. G. Gardiner

A. RITCHIE'S article (see this issue of *Nature*, page 569) on Devonian arthrodires is a painstakingly compiled record of the distribution of the genus *Groenlandaspis*. He has shown that—like some other arthrodires (including *Bothriolepis, Holonema*) — *Groenlandaspis* is found in Devonian deposits all over the world and pleasingly has confirmed that the poorly known *Coccosteus disjectus* from Ireland and Bristol is yet another species of *Groenlandaspis*.

The distribution of *Groenlandaspis* will certainly excite palaeogeographic interest, but it is dangerous to jump to hasty conclusions about continental drift from such evidence

and Ritchie's caution is amply justified. As yet there is no articulated theory to enable us to deal with the zoogeography of Devonian fishes and so the significance of their distribution, which has been a puzzle for many years, remains an enigma. For most groups of fishes this will only be resolved when we have a clear picture of the configuration of the continents in the Devonian. But in the case of arthrodires, an entirely fossil group, an even more critical component is missing. For them we lack an acceptable phylogeny, a vital factor because palaeozoogeography can only make sense as the evolution of organisms in space and time.

The virus of acute diarrhoea


*from Anthea Thornton
and Arie J. Zuckerman*

ACUTE infectious gastroenteritis has long been one of the commonest causes of childhood illness throughout the world. In England and Wales (1961) acute diarrhoea accounted for 6% of deaths in the first year of childhood. But in technically underdeveloped countries, where malnutrition and other debilitating diseases are undoubtedly important contributing factors, deaths from acute diarrhoeal disease in early life are of such magnitude as to be a leading cause of mortality. Probably no more than an eighth of the infants and children of the world are free from appreciable risk of a lethal diarrhoea. Some episodes of gastroenteritis are clearly associated with certain bacterial pathogens; in at least 65% of cases, however, such agents cannot be isolated. Viruses of various type have occasionally been isolated but in most cases their pathogenic role has remained unestablished.

Recently a new candidate virus, originally classified as a member of the orbivirus group, was seen in epithelial cells of duodenal mucosa from children with acute non-bacterial gastroenteritis (Bishop *et al.*, *Lancet*, **ii**, 1281–1283; 1973) and subsequently in negatively stained faecal extracts from such children (Flewett *et al.*, *Lancet*, **ii**, 1497; 1973). Morphologically similar particles have since been detected in duodenal fluids and faecal extracts by numerous other workers. Throughout the world, these viruses have now been reported in 396 out of a total of 827 (48%) of children with acute enteritis, and in only two of 357 children without infection. They have rarely been detected in children over the age of six, and are more often encountered in winter. There is now convincing evidence that the new virus is an aetiological agent in acute childhood gastroenteritis. The virus infects epithelial cells only during the symptomatic stage of the illness and its presence coincides with histological abnormalities and depressed duodenal mucosa disaccharidase levels. Seroconversion has been demonstrated in some children and oral transmission of infection has been achieved with one adult volunteer.

The virus differs from both the reovirus and orbivirus group in serology, morphology and polypeptide composition. The virions consist of a core about 38 nm in diameter, bounded by a membrane from which short cylindrical capsomeres radiate outwards like the spokes of a wheel. An outer layer of capsid subunits seems to be attached to the tops of the inner ones; they are

The characteristic morphological appearances of the 'rotavirus' in negatively stained faecal extract of an infant with acute gastroenteritis. × 126,000.

continuous at the periphery of the virions giving the impression of a continuous membrane surrounding the virus (intact diameter 60–65 nm). The wheel-like appearance of these viruses (see figure) prompted the suggestion that they be called 'rotaviruses' (Flewett *et al.*, *Lancet*, **ii**, 61–63; 1974), though Davidson *et al.* (*Lancet*, **i**, 242–246; 1975) now suggest that 'duoviruses' may be more appropriate.

Any new genus eventually proposed would probably also include the morphologically identical viruses that cause epidemic diarrhoea of infant mice (EDIM) and some outbreaks of neonatal calf and pig diarrhoea, the simian SA11 virus and the O agent isolated from gut washings in sheep and cattle. Complement fixation and immunofluorescent tests show that the human virus, the EDIM virus, and the Nebraska calf diarrhoea virus are also related antigenically. Immune electron microscopy revealed that human convalescent sera reacted with the human and calf viruses, both the intact particles and those which had lost their outer capsid layer, whereas calf antibody reacted only with the inner capsid layer of the human particles. Thus it seems that the inner capsid antigens are the common group antigens detected by complement fixation and immunofluorescent tests and the outer capsid antigens are probably type-specific. This view is reinforced by the finding that the human viruses do not infect calves.

The calf, pig and EDIM virus have been grown in tissue culture and lately the human virus has been shown to replicate in foetal intestine organ culture. Moreover immunofluorescent

studies showed that the virus-specific antigen was localised in the epithelial lining of the villi (Wyatt *et al.*, *J. infect. Dis.*, **130**, 523–528; 1974) which supports the earlier duodenal biopsy findings of Bishop *et al.* (1973). In the future the development of techniques by which human rotaviruses may be propagated to high titres in all cultures may eventually lead to development of a vaccine. An orally administered attenuated vaccine effective against the calf diarrhoea virus has already been prepared.

No other viruses have conclusively been shown to cause gastroenteritis in older children and adults. Parvoviruses (22 nm, DNA viruses) may cause bovine enteritis and similar viruses have been found by immune electron microscopy in stools from patients with gastroenteritis. They seem, however, to be found as easily in patients without gastroenteritis. Slightly larger (27 nm) picorna-like viruses have been detected in faecal extracts from an outbreak of gastroenteritis in Norwalk, Ohio. Transmission of infection and the detection of antibody to the Norwalk agent in infected people by immune electron microscopy have also been achieved. But the similarity of such small isometric particles to bacteriophages necessitates extreme caution in the interpretation of the findings in the electron microscope, and the specificity of virus-agglutinating reactions in immune electron microscopy studies has yet to be confirmed. In pigs and calves coronaviruses are also an important cause of enteritis though no cases have yet been reported implicating this group with human gastroenteritis.

Overall, existing evidence points to rotaviruses as a most important cause

of infantile gastroenteritis throughout the world. It is important to note, however, that to date few specimens have been examined from regions where gastroenteritis mortality rates are particularly high. The use of the electron microscope for rapid and reliable detection of rotaviruses in clinical specimens and the development of serological methods of identification will greatly facilitate further studies.

Does Hex A depend on Hex B?

from a Correspondent

THE question of the relationship of the N-acetyl hexosaminidases is still in dispute. It has been known for six years or so that two major electrophoretic forms of hexosaminidase (A and B) occur in human tissues and also that one of these (Hex A) is deficient in patients with Tay-Sachs disease, a fatal recessive disorder of infants characterised by the accumulation of a complex lipid, the ganglioside GM_2, the *in vivo* substrate of the enzyme, in the brain. The deficiency of both enzymes is also found in some patients —a variant which is often called Sandhoff's disease. It has generally been thought to be unlikely that two separate and independent gene loci code for the hexosaminidases, as the deficiency of both A and B in Sandhoff's disease would presumably require two separate mutations (at the locus for A and for B). The deficiency of Hex B alone has never been reported and Tay-Sachs disease is extremely rare—thus the coincidence of the two homozygous mutant genes in the same individuals would be expected to be very rare indeed. But twenty or so cases have in fact already been reported.

Biochemical and immunological evidence suggests that the enzymes are closely related, and two types of model have been proposed for their relationship. One is that Hex A and B possess similar and dissimilar subunits (for example $A = \alpha\beta$; $B = \beta\beta$). The other is that A and B are essentially the same protein, one enzyme being a secondarily (possibly enzymatically) modified form of the other.

In theory one might expect to learn something from the study of somatic cell hybrids. Human–rodent hybrid cells progressively lose their human chromosomes. By analysing the hybrids in a search for the coincident presence or absence of human enzymes and chromosomes genes can be assigned to particular chromosomes. When more than one gene (situated on more than one chromosome) is required to code for a particular protein or proteins the

number of independently located genes involved can be determined.

Information of this kind has been obtained for hexosaminidase but the results from different laboratories are conflicting (van Someren *et al., Humangenetik,* **18,** 171, 1974; Lalley *et al., Proc. natn. Acad. Sci. U.S.A.,* **71,** 1569, 1974; Nguyen Van Cong *et al., C.r. Acad. Sci. Paris.,* **278,** 1761, 1974; Gilbert *et al., Proc. natn. Acad. Sci. U.S.A.,* **72,** 263, 1975). In the most recent paper on the subject Gilbert *et al.* claim that there are indeed two independent gene loci that code for the hexosaminidases. The gene for Hex B is assigned to chromosome 5 and the gene for Hex A (in agreement with the other groups) is shown to be on the same chromosome as mannose phosphate isomerase(MPI), which has now been assigned to chromosome 15 (van Heyningen *et al., Ann. Hum. Genet.,* **38,** 295; 1975). This result differs from that obtained previously by Lalley *et al.* and Nguyen Van Cong *et al.* These authors never observed the retention of human Hex A in the absence of Hex B in the hybrid cells and suggested that Hex A requires the presence of two human genes for its expression and B requires only one of the two genes (which now seems to be on chromosome 5). These findings were consistent with both the favoured models for Hex A/Hex B relationship. The lack of observation of one particular combination is not however in itself very convincing evidence for a dependence model. The best supporting evidence would come from clones which have MPI but neither Hex A nor Hex B, predicted from this model for those clones which have chromosome 15 but not 5. Very few definite clones of this type have so far been reported. Gilbert *et al.* on the other hand claim to have clones of all the possible types (including Hex A+, Hex B−), which are consistent with their model. There are, however, some major problems that cast doubt on the interpretation of their results.

In order to avoid implicating two mutations in Sandhoff's disease, Gilbert *et al.* have suggested that the defect may be a mutation in a locus which controls the expression of both A and B or makes an activator. The first problem is that there is some evidence that certain Sandhoff patients at least make non-active antigenically cross reactive 'hexosaminidase' proteins (Srivastava and Beutler, *J. biol. Chem.,* **249,** 2054, 1974; Carroll and Robinson, *Biochem. J.,* **137,** 217, 1974). If the control model were right then no such protein should be synthesised. Second, another informative hexosaminidase variant has been reported in a healthy parent of a patient with Sandhoff's disease (Dreyfus *et al., New Eng. J. Med.,* **292,** 61,

1975). This individual has a deficiency of both Hex A and Hex B, as detected using an artificial substrate, and is probably heterozygous for the Sandhoff allele and one which produces kinetically abnormal A and B enzymes (which seem to hydrolyse the natural but not the artificial substrates for the enzyme). This variant strongly suggests that the enzymes must have polypeptides in common.

From the technical point of view, other workers have commented on difficulties involved in identification of the human hexosaminidase components in hybrid cells, and it may be that a problem of this kind is leading to misclassification of the enzymes.

So, the argument goes on . . .

Genes, enzymes and behaviour

from T. J. Crow

THAT heredity is a powerful determinant of behaviour was first cogently argued in Lange's book *Crime as Destiny* (Allen and Unwin, London, 1931). The controversy about the genetic contribution to intelligence has recently had a lively renaissance; H. J. Eysenck, a protagonist of the innate factor school, has also championed the view that there are important hereditary influences on the personality variables neuroticism and extraversion. In the more limited field of overt psychiatric disease the contribution of genetic factors to the major psychoses, schizophrenia and manic depressive illness, is now generally accepted and has recently been re emphasised by studies on adopted off spring of schizophrenic patients (for example Heston, *Science,* **167,** 249 1970; Kety, *Am. J. Psychiat.,* **131,** 957 1974). Evidence for genetic factors in neurotic illness (for example Shields *Monozygotic Twins;* Oxford Universit Press, 1962) is less well-known, but per haps equally significant.

Attempts to study the links betwee genes and behaviour have led to th development of animal models. I selective breeding experiments in rat Broadhurst (*Nature,* **184,** 1517; 195! was able to demonstrate a genetic in fluence determining 'emotionality', a defined by increased defaecation rate in an open field apparatus, and a independent factor of 'extroversio introversion' (*J. exp. Psychol.,* **56,** 34 1958).

Bovet and his colleagues (*Scienc* **163,** 139; 1969) demonstrated ve striking differences between strains, a consistencies within strain, in the rate and temporal patterns, of aquisition a conditioned avoidance response mice. Such experiments invite specul

tion concerning the neurochemical basis of the differences, and, in view of evidence for an important role for central monoamine neurones in behavioural control, focus interest on genetic variations in mechanisms regulating monoamine turnover

Recently Ciaranello, Lipsky and Axelrod (*Proc natn Acad Sci U S A*, **71**, 3006, 1974) have reported that the concentrations of three adrenal catecholamine synthesising enzymes, tyrosine hydroxylase, dopamine-β-hydroxylase and phenylethanolamine N-methyl transferase, are twice as high in the adrenals of Balb/cJ mice as in those of the related inbred strain Balb/cN, and that heterozygous progeny are intermediate between their parents in the concentrations of these enzymes Ciaranello *et al* (*J biol Chem*, **249**, 4528, 1974) examined the F_1, F_2 and backcross progeny of the mating between these sublines and concluded that single gene loci control the steady state concentrations of each enzyme The correlation between the activities of these enzymes suggested either that the loci were linked structural genes or that a single regulatory gene locus controls the phenotypic expression of the three enzymes Ciaranello *et al* (*Proc natn Acad Sci U S A*, **71**, 3006, 1974) also draw attention to differences between the two strains in fighting behaviour after a 2-week isolation period In this case analysis of the F_2 mice suggested the behavioural differences were determined by a single gene with fighting recessive

Such genetically determined behavioural differences could be coincidental, a cause, or a consequence, of the altered enzyme levels, but evidence for a relationship between aggressive behaviour and central catecholamines (Scheel-Kruger, Randrup, *Life Sci*, **6**, 1389, 1967, Welch and Welch, *Comnun Behav Biol*, **3**, 125, 1969) may be relevant to the association On the other hand much recent evidence supports the hypothesis that there is an association between central catecholamine-containing neurones and the mechanisms of reward (Crow, *Psychol Med*, **2**, 414, 1972, Ritter and Stein, *comp Physiol Psychol*, **85**, 443, 973) The question of whether unitary neurochemical mechanisms are associated with single dimensions in behaviour is one which increasingly will have to be approached

On the opposite side of the coin is an accumulation of evidence for environmental influences on central catecholamine turnover (Thierry, Javoy, Glownski and Kety, *J Pharmac exp Ther*, **63**, 163, 1968, Lewy and Seiden, *Science*, **175**, 454, 1972) Such findings may illuminate how genetic and environmental influences interact in the pathogenesis of the psychoses

A plasmid dissected

from David Sherratt

A NUMBER of features has made the bacterial plasmid Col E1 an increasingly attractive DNA molecule for studies of genetic organisation, DNA replication and gene expression Its small size of $4\,2 \times 10^6$ daltons, sufficient to code for about seven average-sized proteins, makes it easy to isolate and handle in analytical studies and its replication can conveniently be studied both *in vivo* and in a soluble *in vitro* system In addition, the Col E1 molecule has a single unique site for double strand cleavage by the sequence specific restriction endonuclease *eco*R1 This provides an invaluable positional reference for structural and replication studies of Col E1 and also provides an ideal tool for *in vitro* construction of hybrid DNA molecules containing DNA from either pro- or eukaryotes covalently linked to Col E1 (see for example Herschfield *et al*, *Proc natn Acad Sci U S A*, **71**, 3455–3459, 1974)

Localisation and analysis of specific regions of DNA (such as replication origins, strand interruptions, specific protein binding sites) by electron microscopy or other techniques requires some reference point In linear molecules with unique ends such as bacteriophage T7, the ends provide reference points (with ambiguity unless the ends are distinguishable) But Col E1 and many other DNA molecules of interest are either circular or like phage T4 have non-unique ends Various approaches have been used to provide visual markers in such molecules Inman (*J molec Biol*, **18**, 464–476, 1966) used mild denaturing conditions to visualise the AT-rich regions of phage lambda as 'loops' which occurred at fixed unique positions This technique has been widely used, though it is inapplicable for many molecules as small as Col E1 Another approach has been to construct heteroduplexes *in vitro* between molecules differing by a deletion or addition of genetic material (see Sharp *et al*, *J molec Biol*, **71**, 471–497, 1972), though this technique is not easily applicable to analysis of replicating molecules The use of sequence specific restriction nucleases such as *eco*R1 to introduce double strand breaks at specific sites in DNA is a relatively simple technique and is being extensively used in the physical mapping of small DNA molecules

Replicating Col E1 molecules have been isolated from exponentially growing *E coli* cells, by Lovett, Katz and Helinski (*Nature*, **251**, 337–340, 1974), from *E coli* minicells by Inselberg (*Proc natn Acad Sci U S A*, **71**, 2256–2259, 1974) and from a soluble *in*

vitro system which allows Col E1 initiation, semiconservative replication, termination and ligation to give complete closed circular duplexes (Tomizawa *et al*, *Proc natn Acad Sci U S A*, **71**, 802–806, 1403–1407, 2260–2264, 4935–4939, 1974) In each of these systems, the majority of replicating molecules when examined by electron microscopy are seen to be circular with two branch points, such *theta* structures are characteristic replicative intermediates of many circular replicons The positions of the branch points with respect to the *eco*R1 cleavage site were determined independ-

THE FATAL BALLOON ASCENT

THE readers of NATURE are no doubt aware of the fatal result of the recent ascent of the balloon *Zenith*, the following authentic details at first hand will no doubt be of interest —

CIRON (Indre), April 17

The *Zenith* was sent up on the 15th of April in order to determine the quantity of carbonic acid contained in the atmosphere at an altitude of 24,000 feet The "let go" was given at twenty-five minutes to twelve A M The captain was M Sivel, and there were only two passengers, M Gaston Tissandier and M Crocé-Spinelli The ascent took place gradually in a slight E N E wind, the sky being blue but vaporous The rate of ascent was calculated to be nine feet per second, but diminished gradually Shortly after one o'clock the altitude obtained was 22,800, and the passengers were quite well, although feeling weak The inhalation of oxygen produced good restorative effects when tried Then a consultation took place, and the *Zenith* being in equilibrium, a quantity of ballast was thrown over board M Tissandier then fainted, and is ignorant of what was felt by his friends

At eighteen minutes past two he was awakened by M Crocé-Spinelli warning him to throw over ballast as the balloon was fast descending He obeyed mechanically, and at the same time Crocé-Spinelli threw overboard the aspirator, weighing eighty pounds Tissandier then wrote in his book a few disconnected words, and again fell asleep for about an hour When he awoke, the balloon was descending at a terrific rate, no more ballast was left to be thrown away, and his two friends were suffocated Their faces had turned black, and the blood was flowing from their mouth and nose They were evidently dead It was a terrible situation

from *Nature*, **11**, 495, April 22, 1875

ently by each of the above groups of workers In each case, the distance from the cleavage site to the nearest branch (for molecules less than 60% replicated) was shown to be about 18% of the genome length, while the length from the other branch was variable and inversely proportional to the extent of replication of the molecule These results show that replication is initiated about 18% of a genome length from the *ecoRl* cleavage site and proceeds unidirectionally away from that site Whereas molecules in all stages of replication were observed *in vivo* and *in vitro*, molecules isolated from the *in vitro* system in the presence of glycerol (10%) and spermidine (2 mM) were nearly all about 7% replicated, indicating that there is a potential rate-limiting step at this stage of replication (*Proc natn Acad Sci USA*, **71**, 2260–2264, 1974)

Two other structural features of Col E1 molecules have also been examined with respect to the *ecoRl* cleavage site Col E1 molecules can be isolated as supercoiled 'DNA–protein relaxation complexes' which undergo a strand-specific single-strand cleavage after treatment with protein denaturing agents Helinski and co-workers (*Nature*, **251**, 337–340, 1974) first showed that the break in such molecules is located about 18% of the genome length from the *ecoRl* restriction site, that is, either at the origin/terminus of replication or at an equal distance the other side of the restriction site To distinguish between these possibilities Tomizawa *et al* (*Nature*, **253**, 652–654, 1975) tested the ability of pulse-labelled newly initiated Col E1 DNA to hybridise with Col E1 molecules in which the DNA in the region of the break in 'relaxation complex' had been removed but which still contained the sequences present in the symmetrical position 18% of a genome's length the other side of the *ecoRl* site The newly initiated DNA failed to hybridise to such molecules, showing that the break in 'relaxation complex' is coincident with the origin/terminus of replication and reinforcing the suggestion that relaxation complex is involved in Col E1 replication Col E1 supercoils containing a single stretch of RNA in either strand can be isolated after extensive replication in chloramphenicol (Blair *et al*, *Proc natn Acad Sci USA*, **69**, 2518–2522, 1972) Tomizawa and co-workers then went on to analyse the position of the gap created by removal of the RNA with respect to the *ecoRl* cleavage site and showed the RNA to be located at random, indicating that it is not a unique piece of RNA involved in initiation of DNA synthesis at the origin, though it could be involved in priming of 'Okazaki fragment' synthesis or

merely an artefact introduced during chloramphenicol replication

This type of experiment can be extended to analyse the organisation and control of Col E1 genes For example, the polarity of the 'nicked' strand in 'relaxation complex' with respect to the *ecoRl* site has been determined by Tomizawa (*Nature*, **253**, 652–654, 1975) and it is also known that Col E1 hybrid molecules with other DNA inserted at the *ecoRl* site fail to synthesise colicin yet remain immune to colicin killing (*Proc natn Acad Sci USA*, **71**, 3455–3459, 1974), suggesting that the immunity gene does not cross the *ecoRl* site, yet the colicin gene or one required for its synthesis does Using other restriction enzymes and an *in vitro* protein synthesising system it should be possible to map the Col E1 genes, isolate the gene products and study their regulation and functions

Quantising gravity?

from John Taylor

RECENT developments in unifying the forces of nature have been proving successful but so far have not involved gravity The quantum mechanical nature of the other three forces has up to the present prevented gravity from being treated alongside them due to great difficulties in setting up a sensible quantum theory of gravity Yet the problem of quantising gravity is a pressing one if a unified theory of all the forces of nature is to be obtained There is also the need for a quantised theory of gravity to describe the first 10^{-43} seconds of the big bang and to prevent the annihilation of matter at the centre of a black hole

These and other reasons have still left a great deal to be desired in the earlier programme of quantising gravity In the last three years great strides have finally been made by using techniques developed to handle the unified theories of weak and electromagnetic interactions This has proved possible since both unified models and gravity are invariant under gauge groups, these being internal symmetries in the former case and the space–time coordinate transformations in the latter The perturbation rules for calculating scattering matrix elements so as to be unitary at each order were developed in the 1960s for theories invariant under quite general gauge groups Unphysical modes of the gauge fields were found to be required to preserve unitarity, though these modes could never be created so never caused embarrassment

The recent advances have stemmed from attempts to obtain sensible answers for the resulting perturbation

calculations in the gravitational (The outstanding question has bee the removal of the ultraviolet di gences (arising from particles of a trary high energies in internal sta which plague any realistic quant field theory In the unified weak electromagnetic models these u violet divergences can be remo completely by absorption into and definition of the masses and charge the particles present the renorm ation programme Quantised gravil not explicitly renormalisable in sense that the ultraviolet diverge cannot automatically be removed redefinition of particle masses recent progress in quantum gravit in evaluation of some of these ul violet divergences and their remova additional terms (counter terms) in action function of the fields

The first step in this programme taken by 't Hooft and Veltman (*A Inst Henri Poincaré*, **20**, 69–94, 19 following the pioneering work of Witt (*Phys Rev*, **162**, 1195, 1239, 19 who evaluated for pure gravity counter terms that eliminate the ul violet divergences of all Feynman grams with a single loop of inter particles (in this case only gravito They showed that S-matrix eleme from such single-loop diagrams w finite after suitable field renorma ations had been performed, no infin counter terms were needed But such tricks were discovered wh eliminated single-loop diagram dive ences in the case of gravitation int acting with a scalar field, so that su terms were needed to be added to t action in such a way as to change considerably

This programme of investigating infinite counter terms are needed make single-loop S-matrix eleme finite has been extended to mo realistic forms of quantised matt fields interacting with quantised gravi Deser and Van Nieuwenhuizen (*Ph Rev*, **D10**, 401–420, 1974) have sho that extra counter terms are needed the case of otherwise free photons fermions, and a similar situation hol for charged mesons in self-interacti as well as gravitation, as it does photons are also involved (Nou Moghadam and Taylor, *Proc R So* in the press) This latter situation particularly appropriate since it allo for some of the subtleties of the unifi weak and electromagnetic interacti models

It could well be that the contributi of diagrams with higher numbers closed loops of internal particles cou cancel the infinities of the single lo ones However using the modifi action function, with single lo counter terms included, generates t new particles One of these is a scal

particle which can be made so massive as to put it beyond observation, the other, of spin two, destroys the theory since it is a ghost particle with a negative norm As such it violates unitarity, and certainly in particle physics ghosts should frighten one if they can be seen If this spin-two ghost particle could be decoupled from all other fields then it would have been rendered harmless, though recently it has been realised that such decoupling is very difficult for gravity in the presence of photons or scalar or spin-$\frac{1}{2}$ particles

If such is the case there are two ways forward in quantising gravity One is to start afresh from an alternative beginning to that of Einstein, this is also very difficult since there are almost unavoidable arguments which lead to Einstein's theory of gravity (Deser, *J gen Rel Grav*, **1**, 9–18, 1970) The other alternative is to investigate more carefully the forms of matter for which there is cancellation of the ultraviolet divergences from single loop diagrams This is a difficult but not impossible problem Its solution, if there is one, will give a hint as to the form of quantised matter–gravity interaction which is infinity free at all orders, it is to be hoped that there is only one such solution If there is no such form of theory then gravity will be different indeed from the other forces of nature

Alpha emission in fast pion reactions

from P E Hodgson

MANY researchers in recent years have provided evidence that nucleons in the region of the nuclear surface tend to condense into alpha particles This naturally affects the cross sections of reactions involving the transfer of a cluster to or from a nucleus, and it is by analysis of data on such reactions that an estimate of the alpha-clustering probability can be obtained

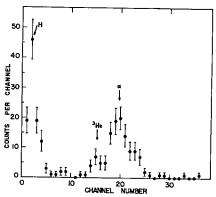
One of the most direct ways of demonstrating the existence of alpha particles on the nuclear surface is to knock them out with a suitable projectile Unfortunately the cross sections of these reactions are quite low so that thick targets must be used, and this stops most of the alpha particles from emerging Instead of trying to detect the alpha particles directly, the residual nuclei after the reaction had taken place were identified from their characteristic gamma-ray spectra It was then found that a substantial proportion of these nuclei were just the target nucleus less one, two or three alpha particles This strongly suggested that alpha particles were ejected from the nuclei by


Fig. 1 Particle spectrum showing alpha particles and helions

the projectiles, though of course the possibility that the nucleons were ejected individually could not be excluded

This result was found in many experiments using fast and slow kaons and pions as projectiles (*Nature*, **249**, 616, 1974)

Some doubt was thrown on the interpretation of these results by an alpha particle knockout process when it was found by statistical model calculations that the observed distribution of final nuclei is what might be expected on purely energetic grounds It therefore became of great importance to demonstrate the reality of the alpha knockout process by detecting the emitted alpha particles directly

This has recently been done by a group at Saclay and Tel Aviv (*Phys Rev Lett*, **34**, 485, 1975) They bombarded ^{27}Al with 70 MeV negative pions and found a significant cross section for the emission of He ions, predominantly alpha particles They were able to overcome the problem of low yield by using the intense electron beam from the Saclay linear accelerator that produces a pion beam of intensity 10^6 pions per second This made it possible to produce a significant number of alpha particles in a target thin enough for most of them to escape

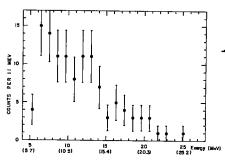
The observed particle spectrum at 90° to the beam is shown in Fig 1 and has a significant alpha peak and possibly a smaller peak due to helions The energy spectrum of the He ions in Fig


Fig 2 Energy spectrum of the He ions emitted from the bombardment of ^{27}Al by 70 MeV negative pions

2 shows that their intensity has a maximum at about 10 MeV, and falls to zero around 25 MeV The differential cross section for alpha-particle emission is 6 2 mbarn sr^{-1} in the energy range 5 5–30 MeV

Calculations within the framework of a cascade evaporation model indicate that such a yield of alpha particles can be explained by simple evaporation following the excitation of the nucleus by a series of pion–nucleon interactions Further work is now needed, particularly measurements in the forward direction to see if any of them can be attributed to a direct knockout of pre-existing alpha particles on the nuclear surface

Electric seaweed eggs

from Julian Lewis

MANY non-spherical embryos develop from spherical eggs What then is the origin of their asymmetry? In most cases the fertilised egg, despite its spherical shape, does not have spherical symmetry in its chemical constitution from the outset there is some local specialisation of the membrane or cortex, or an uneven distribution of material in the cytoplasm But there is no need in principle for an egg to start life lopsided It may have at first true spherical symmetry, and lose this through the development of an instability as it matures Its internal dynamics may be such as to magnify the slightest departure from symmetry into a full-blown polarisation The egg would thus spontaneously become polarised, but the direction of its polar axis would be subject to control by almost any sort of weak environmental vector

Jaffe and his colleagues have studied the eggs of the closely related seaweeds *Fucus* and *Pelvetia* (*Advances in Morphogenesis*, **7**, 295, 1968) These eggs, about 100 μm in diameter, are at first spherical Within a few hours after fertilisation they glue themselves to the sea bed, and then germinate they develop a bulge and become pear-shaped as the future rhizoid begins to grow out Practically anything, from a beam of light to a gradient of pH or a mechanical deformation, can govern the direction in which the rhizoid emerges This is strongly symptomatic of a symmetry-breaking instability, some other conceivable interpretations can be ruled out experimentally (Jaffe, *Science*, **123**, 1081, 1956)

Thus interest centres on the positive-feedback mechanism in the egg which amplifies and maintains whatever asymmetry happens to arise Jaffe suggests that a sort of self-electrophoresis

may occur if one part of the cell membrane transports ions at a different rate from the rest, a steady electric current may be driven through the cell, carrying towards the specialised patch of membrane just those charged molecules which support its specialisation This speculation has some experimental backing

In the first place, Jaffe (*Proc natn Acad Sci U S A*, **56**, 1102, 1966) aligned about 200 eggs, similarly polarised, in seawater in a loose-fitting capillary tube He found a potential difference of about 40 μV between its ends, and argued persuasively that this must arise from a flow of current, with an estimated density of 6 μA cm^{-2} at each rhizoid tip This might plausibly be driven by a cellular e m f of the order of millivolts

More recently, Nuccitelli and Jaffe have described in detail (*J Cell Biol*, **63**, 614, 1974) a probe small and sensitive enough to measure the electric fields and hence the current densities within 50 μm of a single egg (*Proc natn Acad Sci U S A*, **71**, 4855, 1974) The tip of the probe vibrates (at about 200 Hz), and picks up the minute change of potential (10^{-7} to 10^{-8}V) between the extreme points of its path, typically 30 μm apart The findings roughly match the results of the earlier work A striking phenomenon is the occurrence of large irregular spikes, lasting about a minute, during which the signal from the probe increases by a factor of ten or a hundred These spikes may well mark the insertion of fresh vesicles of membrane at the growing rhizoid tip, though sceptics might say they could be artefacts—transient diffusion potentials, perhaps, due to polyelectrolytes released from the egg and turbulently stirred about by the vibrating probe

Before the rhizoid axis becomes irreversibly determined at germination, there is an impressionable phase when environmental cues, such as light, can impose on the eggs a tentative and still reversible polarity Robinson and Jaffe (*Science,* **187**, 70, 1974) took a sieve with small round holes, plugged each hole with a *Pelvetia* egg at the impressionable stage, shone a light from one side, and measured the rates of entry and exit of radioactive calcium ions through the dark (prospective rhizoid) and light (prospective thallus) ends of the eggs The rate of entry on the dark side was at first about three times greater than on the light side, and the rate of exit about three times less The eggs, therefore, must pump calcium through themselves This pumping of calcium peters out towards the time of germinating, just as the flow of electricity begins.

One still does not know how strongly the ionic currents affect the cytoplasm,

or whether the cells are in fact polarised by self-electrophoresis But the evidence for persistent currents through fucoid eggs is important, if only in drawing attention to a factor in cell organisation which tends to be neglected, more because it is hard to measure than because it is insignificant, rare, or peculiar to seaweeds One might here perceive a distant echo of the finding, for instance, that the localisation of acetylcholine sensitivity in muscle cell membranes depends on electrical activity (Lømo and Rosenthal, *J Physiol, Lond*, **221**, 493, 1972)

Between Earth and Sun

from L J C Woolliscroft

A MIST (Magnetosphere, Ionosphere and Solar–Terrestrial Relations) Meeting, arranged by the Royal Astronomical Society, was held at the University of Exeter on March 25 and 26

THE significant role of atomic oxygen was stressed in a session on the lower ionosphere M R Bowman and L Thomas (Appleton Laboratory, Slough) gave two reasons for studying the density of oxygen first, it breaks the chain of reactions which starts with electrons and ends with negative ions, and thus it tends to prevent the loss of free electrons Second, it also breaks another chain by which positive ions such as N$_2^+$ react to form the series of water cluster ions, H$^+$ (H$_2$O)$_n$ where n can be at least as high as seven These cluster ions dominate the ion spectrum below about 85 km and it was encouraging to see that the model of Bowman and Thomas predicts an increase in atomic oxygen above this height with a diurnal variation below it P H G Dickenson (also Appleton Laboratory) presented new rocket measurements of atomic oxygen using the resonant fluorescence and absorption techniques These methods give better results than measuring the resistivity of thin silver films (oxidised by the atomic oxygen) because the response is faster His results seem broadly to agree with the Bowman and Thomas model but as yet the whole diurnal variation has not been studied

F N Byrne (Queen's University, Belfast) showed some preliminary data on the ionised and neutral concentrations of magnesium, aluminum and iron The ionised form of the metals has been shown to be important at altitudes above those characteristic of the cluster ions (typically 90–110 km) but the ratios of the ionised to neutral concentration is uncertain The reaction

of neutral metal atoms with nitric oxide ions to give metal ions should be very efficient and so some reverse mechanism is needed to explain Byrne's finding that significant densities of neutral atoms remain He suggested this was another role for atomic oxygen

The solar magnetic field and its effects are now felt to be more complicated W M Glencross (University College, London) challenged the conventional theory for the heating of the solar corona by shock waves He suggested that magnetic fields also play a part and showed Skylab and X-ray photographs to illustrate that the intersecting loop field configurations he proposes can in fact exist G M Simnett (Birmingham University) invokes the magnetic field at a few solar radii to account for the delays (at least 20 minutes) in the propagation of energetic protons and electrons from solar flares This process also accounts for modification of the energy spectrum of the particles during their passage through the corona which can be inferred from measurements near the Earth

The yields of turnips and other crops were discussed, together with the whole relationship between solar phenomena and the weather on Earth, by J W King (Appleton Laboratory) The correlation between various climatic and related phenomena, such as rainfall, surface pressure and temperature with the 11-year sunspot cycle is interesting enough, but what is much harder to envisage is why some properties correlate with the 22-year solar cycle of field reversals Perhaps the most striking of these are the periods of drought in the United States which at least in part led to the depression in the 1930s, and the mini-depression of the 1950s On a much shorter time scale the weather is altered by magnetic storms and after reversals of the magnetic field of the solar wind at the magnetosphere

These results were greeted with scepticism by a meteorologist in the audience who wanted details of a mechanism rather than King's qualitative suggestions of various possibilities including variations in the solar constant (the power emitted by the Sun), solar protons leading to water molecules in the atmosphere, and perturbations of the atmosphere at, say, 100 km causing a resonance in the lower atmosphere

D M Willis (Appleton Laboratory) presented results of how the magnetosphere might be involved in some form of coupling between the solar wind and the weather On the basis of the energy available it does not seem that the magnetosphere can provide the mechanism unless it is by some trigger-ing or resonance phenomenon ●

review article

Computer programming as a cognitive paradigm

P. J. Hayes*

As work on artificial intelligence has made increasingly clear, intelligent behaviour depends more on an organised knowledge of the real world than on problem-solving mechanisms This has led in artificial intelligence research to an increasing preoccupation with techniques for representing such knowledge, and recently to a view of programming as itself a form of knowledge representation.

As an essential part of the methodology of artificial intelligence research, the art and science of writing computer programs has inevitably been a central concern It has been suggested that artificial intelligence should be regarded as a science of which experiments are programs In the past few years, however, programming has become a focus of attention in its own right, and researchers have begun to look at the activity of writing programs as itself a problem area to which artificial intelligence might be applied, as it has already been applied to chess playing, recognising speech, or designing a bathroom Systems are now being designed and implemented to write programs to solve a given problem, which 'debug' programs[1], and which reason about the properties of programs Moreover, the development of the field since 1969 has been marked by a rash of new programming languages which represent a distinct break with the main computing tradition At the same time, both in Britain and in the USA, the main funding agencies (the Science Research Council and the Advanced Research Projects Agency), have noted the emergence of "automatic programming" as an important growth area in artificial intelligence

This apparently narcissistic concern with programming reflects a fundamental change in our view of what sort of knowledge has to be stored and used by an intelligent program, and how it can be represented The advance has emerged, characteristically, from a series of acrimonious debates, starting with a methodological dispute and finishing with a technical synthesis in which both sides can participate without losing face In this article I want to sort out a little of what is now agreed and what is not, and what consequences the new ideas have, both for our view of intelligence and for the development of programming To begin, however, we must be quite clear what we mean by 'a program'

Meaning and procedure

Asked to define 'program', most people would probably come up with something like 'sequence of instructions for a computer' This corresponds to the usual layman's view of the computer an electronic device which obeys long sequences of simple unambiguous instructions, very quickly, without errors But this definition would be adequate only for programs written in machine codes, which bear a direct relationship to the electronics which implement the instructions Most programs are written in much 'higher level', programming languages, such as ALGOL Programs in these languages are not simply sequences of instructions, but can have a complex syntactic structure More importantly, the meaning of a programming language is not

* Address Computing Centre, University of Essex, Wivenhoe Park, Colchester CO4 3SQ, UK

directly related to the structure of any particular physical computer

The use of the term 'level' here refers to a fundamental computing idea An ALGOL programmer, for example, can ask for, say, a two-dimensional array of numbers When his program is run, complicated machine-code instructions will be generated which simulate this structure There are many ways of doing this which way is used is completely invisible to the ALGOL programmer It is a decision at a lower level than that of the ALGOL program A primitive operation (creating or using an array) at the higher level corresponds to an elaborate mechanism at the lower, the workings of which are invisible from above The ALGOL programmer may himself have in mind that his array represents the floor plan of a cathedral this, again, is an idea at a still higher level For, he could have used a wide variety of different data structures, (each probably with several ways of being implemented in code) to represent his conceptual structure Much of the art of computing consists in this use of complexity at one level to provide clean structures at a higher level, the meaning of which is independent of the encoding The development of large programs would be impossible without it

The meanings of high level programming languages have to be defined in terms of a 'conceptual machine' corresponding to the language This device may be quite unlike any physical machine for example, the 'ALGOL machine' is capable of directly evaluating arithmetic expressions, automatically maintains an internal dictionary of symbols in the program, and has a memory arranged as a stack (like a pile of plates) rather than as a sequence of boxes No physical computer was ever built with any of these characteristics It is important to realise that ALGOL programs are not merely abbreviations of machine code instruction sequences they have an existence quite independent of any physical machine The same ALGOL program can be implemented and run on a variety of quite different actual computers operating on totally dissimilar physical principles (for example, electronic, electromagnetic, fluidic) and yet the program retains its unique identity and meaning through these different incarnations It has been suggested[2] that a facility be incorporated in a high level language to allow a program to query the hardware of the machine about its input–output peripherals, so that it [the program] can organise its files appropriately for the machines it [the program] happens to find itself in from time to time

In some cases, the conceptual device underlying a programming language is not much like a machine at all The language SIMULA, for example, is designed to aid the writing of programs to simulate complicated system of activities, such as a dockyard To understand a SIMULA program one has to think of a collection of processes being created, running in parallel,

communicating with one another and altering their behaviour

The 'machine code' picture breaks down also, when we consider the relationship between high level programming languages and their meanings These languages do not consist of simple imperatives they also contain, for example, expressions which require to be evaluated, and declarations which define the meanings of names Some high level languages, indeed, contain no imperatives at all, although they un-ambiguously specify computations LISP, a language widely used in artificial intelligence work, is such a one In LISP, one defines functions (possibly recursively), and asks for them to be evaluated the language consists entirely of expressions

A program, then, need not be in any sense a sequence of instructions for a machine What all programming languages do have in common however, is a concern with activity, in the sense that they describe processes in some sort of device We will take this, then, as the definition of 'program' a program is a description of a process Any organised and constructive way of describing processes can be regarded as a programming language

Representing knowledge at the right level

Ever since the beginning of AI work, a central idea has been that in order to behave appropriately in some given situation, a program must have available, or be based on, knowledge of the situation and the circumstances To play chess, one needs to know a lot about chess-playing, to see a scene, one needs to know a lot about the sorts of object in the scene, about perspective, and about chiaroscuro

If this seems like a platitude, it is one It amounts to saying that there is no magic key to intelligence the science-fiction idea of the great mechanical brain suddenly becoming a super-intelligence when the last connection is soldered together, is a nonsense Paradoxically, the central theme of AI work diminishes the role of machinery, emphasising rather the importance of knowledge and inference (Platitude or not, however, this approach to understanding intelligence differs profoundly from that which would have us first understand how the brain works, in a neurophysiological sense)

Not surprisingly, then, many AI workers have been concerned with general ways of representing knowledge, with, we could say, general representational schemes For example, many people including myself have tried to adapt formal logical notations as vehicles for representing 'common-sense' knowledge of the everyday world others have emphasised, rather, the importance of such non-deductive modes of inference as the use of analogy and inductive generalisation For example, Newell has worked on a notation[3] for expressing observations of 'analogical similarity' such as "If you think of a nose as a snout, and feet as trotters, then a man can be thought of as a pig"

Merely having a notation to express knowledge is of no use, of course, unless the system can use the knowledge in some way Each scheme comes equipped with some processing rules which sanction certain inferences to be made using the notation Logical calculi have such rules of inference corresponding to logically valid deductions, schemes involving networks use, typically, a form of graph-matching to discover whether one network can be imbedded in another, Newell's analogy system uses an elaborate symbol-substitution mechanism to infer new, more complex, analogies from old ones, and so on

The information encoded in such a general scheme is at a higher level (in the sense described earlier) than that at which the actual program using the information is written (although such a program will almost certainly be written in a high-level language remember, there can be many levels) For example, the semantics of the knowledge encoded in the schemes—what it is about—is usually nothing whatever to do with the internal workings of any device, but rather concerns facts about some external environment chess for a chess-playing program, chiaroscuro for a vision program, mathematics for a theorem-proving program, actions and their effect on a world for a robot's planning program Moreover, one of these schemes

can be implemented differently in different programming languages without altering its meaning (such as by using different data structures to represent a network of relationships)

There have been, and still are, heated debates between different AI schools as to which are the most appropriate vehicles for expressing information about various task domains It is noticeable, however, that, in practice, no program which has actually achieved an interesting level of performance has ever used any of these methods to represent all the knowledge on which its performance depends

Many successful programs are simply one-off pieces of code in which the 'knowledge' is embodied directly in the way the details of the program are written For example (one of many), Kelley[4] wrote a program to find the outline of a person's head in a head-and-shoulders photograph (a police 'mug shot') This ingenious and successful program was based on a number of facts about heads and their appearance for example, that heads do not have long narrow projections, that they are more or less symmetrical, that they sit on shoulders, and so on But these facts were nowhere explicitly represented rather, the actual program was written in a way which was based on them For example, the no-projections fact was embodied in a heuristic rule by which the edge-following algorithm refused to follow such contours The knowledge was encoded at a lower level than that of an explicit representational scheme for expressing such facts

Even in programs which do use some such general scheme, one often finds that certain kinds of information, crucial to the success of the overall system, are embodied in the lower-level programming details An early example was Raphael's SIR[5], a program for answering simple English questions about a data base I will not describe its linguistic powers, which were rudimentary Its way of storing information and making inferences, however, was interesting as a pioneer attempt to represent relationships using a network

The fact "Hands have five fingers" was encoded by having an arc, from a node called HAND, to a node called FINGER, labelled with the relation HASASPART, and a note to the effect that there are 5 of them That people have two hands was encoded similarly If asked how many fingers people have, SIR could make the inference and reply, 'TEN' it did this by using a collection of little programs (written in LISP) which traced along arcs of the network This sounds quite elegant but notice that the inference requires also a general fact roughly, that if an X has N Ys as parts, and a Y has M Zs as parts, then an X has (M times N) Zs as parts And this fact is not in the network it is embodied in one of the little LISP programs

Another more recent example is provided by a much more sophisticated language-understanding system, Schank's MAR-GIE[6,7] Schank uses an intriguing graphical notation for expressing concepts and facts, which he calls 'conceptual dependency' notation Many claims are made for the generality of this notational scheme and yet, when one looks at the details of the system, one finds that the actual inferences are performed by specially-built LISP programs ("inference molecules" see ref 8) which directly encode most of the general facts which are needed

Special versus general

Now, what is wrong with having 'real-world' knowledge embodied directly in lower-level code in this way? If the program works satisfactorily, is that not enough? What more objective test could one have of a program's abilities? AI workers can be placed into two camps by the answers they give to such questions We could call these the specialists and the generalists

The former would tend to say there was nothing wrong with such encoding, that a program should be judged by its behaviour They have traditionally been concerned to get programs to perform well in limited task areas, using whatever means come to hand Joel Moses, author of a very successful program for symbolic integration, makes spirited defence

of this point of view[9] Generalists (of whom I am one), would argue, on the other hand, that having general schemes for representing knowledge is an essential step in capturing the adaptability of intelligent behaviour Purely on engineering grounds, it is very hard to alter information encoded at too low a level SIR, for example, had to be almost entirely rewritten in order to extend its repetoire of conceptual relationships by just one addition, and was indeed abandoned for precisely that reason Kelley makes similar remarks about his head-finding program

More profoundly, since learning would seem to consist largely, in the addition to, or alteration of, a program's knowledge-store, it is vital that this knowledge be represented in a form in which it can be easily altered and added to, if meaningful learning by programs is to take place Winston's concept-learning program, for example[10], which can be taught descriptions of simple assemblies of bricks (arches, towers, piles), by showing it examples and counterexamples, depends for its abilities on having a very clean representation of concepts (in a network, in fact, although that is not essential) which can be progressively altered by local increments

More fundamentally still, it seems to me that we should query whether knowledge encoded at such a low level is really present in the program at all That a certain mechanism succeeds in a task is not adequate evidence alone that it in any sense knows what it is doing A cabbage leaf channels rain to the root of the plant very efficiently but we would not say that the cabbage knew about rain

For several years in the mid-1960s, the 'generalist' and 'specialist' themes in AI research developed almost independently Some people worked on both sides of the methodological gulf at once but even then, there seemed to be very little generality visible in the *ad-hoc* specialist performance programs, and even those of the generalist persuasion were forced to the use of *ad-hoc* coding in order to get adequate efficiency in actual working systems Many attempts were made to combine a general scheme for representing knowledge with a general-purpose heuristic mechanism controlling the application of the processing rules But these always resulted in systems which, when applied to realistically difficult tasks, got lost in uncontrollably large search spaces This is the now famous 'combinatorial explosion' For several years, this uncomfortable situation was blamed on the 'weakness' of the general-purpose problem solvers It was generally considered that when these became more 'powerful', as a result of identifying ingenious general heuristic mechanisms, the situation would improve Great hopes were attached especially to the development of logical theorem-proving programs

Internal and external information

As is now, in retrospect, clear, this diagnosis was mistaken The fault lies not in the general heuristic mechanisms, but in the interface between those mechanisms and the knowledge represented in the formalisms The latter, consisting solely of information about the external task environment, gave no direct guidance to the mechanisms which processed the information And without such guidance, no mechanism could possibly be 'powerful' enough to make appropriate inferences

Consider, for example all the facts which an adult knows about people One of them is probably that people bleed if you cut them, another, that they can walk If you want to get somebody across a room, the second might be relevant, the first not but that fact is not about the world, but about how to think about the world

The point is similar to the platitude with which we began the magic mechanism must be replaced by appropriate knowledge But in this case, information is required not about the external task environment, but rather about the internal 'environment' of the scheme's processing rules In a word, the system must represent, and use, information about its own thought processes

And as we have seen, a description of a process can be

regarded as a program It is not surprising, therefore, that the first expressions of this insight took the form of advocating the use of a suitable programming language as a way of representing knowledge of the external environment This is the content of the term 'procedural representation of knowledge'[11-13]

It is important to emphasise at this point that we have not simply moved full circle, back to the specialist programs with their 'knowledge' rigidly encoded in conventional programs Rather, the proposal was to lift some programming ideas to the same level as that of the general representational schemes, in the hope of retaining much of the plasticity and clarity of the schemes already in use, but allowing the expression of information which controls the inferential activity These programming languages are very high level

The first programming language of this kind to be developed was MICROPLANNER[14], and a brief example will show how such control information can be encoded in it Consider the statement if a black cat crosses your path, you will be lucky Expressed in a logical notation, this would be something like

((Exists X) Black(X) and Cat(X) and Crosses(X,path(you)))
$$= > Lucky(you)$$

In MICROPLANNER, it can be expressed in many ways, depending on what you want to do with it For example

```
(CONSE (LUCKY? YOU)?)
  (PROG(X) (GOAL (BLACK?X))
          (GOAL (CAT?X))
          (GOAL (CROSSES?X PATH?YOU))
```

The brackets are an inheritance from LISP, but what this means is, if you want to prove that YOU are lucky, try proving that there is a thing which is black and a cat and crosses your path— in that order Now, in fact, this is probably a very inefficient way to establish this, as there are a lot more black things than things which cross your path A better version might be

```
(PROG (X) (GOAL (CROSSES? X PATH? YOU))
         (GOAL (CAT?X))
         (GOAL (BLACK?X))
```

More dramatically, it can also be expressed

```
(ANTE (CROSSES?X PATH?YOU)
  (IF (AND (GOAL (BLACK?X))
           (GOAL (CAT?X))
  (ASSERT (LUCKY? YOU)))
```

which means, whenever it is asserted that anything crosses your path, see if it is a black cat if so, assert that you are lucky This is quite a different way of using the same fact Notice, though that the level of these programs is similar to that of the logic the MICROPLANNER system can clearly be seen to be performing inferences MICROPLANNER is as different from LISP, as LISP is from machine code

Facilities of this sort were first used, to powerful effect, in Winograd's now well known program[11] which held an English conversation with a human user The demonstration was very dramatic, and since then this and other, similarly high level, programming languages have come into widespread use in AI work

A high level programming language is based, we have said, on a conceptual device whose activity it describes Now, MICROPLANNER's device is not much like a machine at all it is, rather, an idealised 'thinker' States of the device contain structured collections of assertions—the thinker's beliefs—and rules for manipulating them Transitions between states correspond to inferences Winograd's program used this directly to model its beliefs Successors to MICROPLANNER retain these essential outlines, usually with more highly structured states This gives a new view of computation as controlled inference, and of machines as essentially devices for storing assertions[15]

This differs radically from the conventional semantics of programming languages It is too soon to tell how far-reaching an effect it will have on our view of computing in general, but it seems to be unlikely to be negligible Hewitt, who designed MICROPLANNER, has developed, for example, a very general theory of computing based on the idea of an 'actor'[16]

The now widespread conception of a programming language

as a representation of knowledge explains the interest in programming as an activity, with which we began For, now, programming is expressing knowledge, debugging is learning, and reasoning about programs is thinking about knowledge —one could say, introspection Sussman's work[10] on automatic debugging of programs is a good example his system analyses, classifies and corrects various kinds of programming error in simplified MICROPLANNER programs, such as the achievement of one goal being undone by a later action (this is a 'protection violation bug') He regards this debugging as a model of a theory-formation process start with a simple theory and enrich it by looking closely at the places it does not work The program is the theory

There is by no means universal agreement on the best way of expressing process-control information It is no longer fashionable, indeed, to argue that a programming-language notation is essentially the best way to convey this information I am myself working on a more direct notation for expressing such knowledge But what is accepted now, by almost all AI workers, is that much of the information stored in an AI program has to be about what to think, as well as about what is true This distinction cuts across the arguments about deductive or analogical assertions mentioned earlier and it represents, I believe, a real advance in our understanding of thinking

In AI, a program might be said to be aware of a thing when it has a sufficient amount of knowledge of that thing explicitly

represented and available for making inferences In these terms, the 'procedural representation of knowledge' is a step towards the construction of programs which are aware of their own thought processes One could think of a worse definition of consciousness

Tectonic implications of Precambrian shear belts in western Greenland

J. Bak & K. Sørensen

Geologisk Institut, Aarhus Universitet, 8000 Aarhus C, Denmark

J. Grocott, J. A. Korstgård, D. Nash & J. Watterson

Department of Geology, University of Liverpool, Liverpool 3, UK

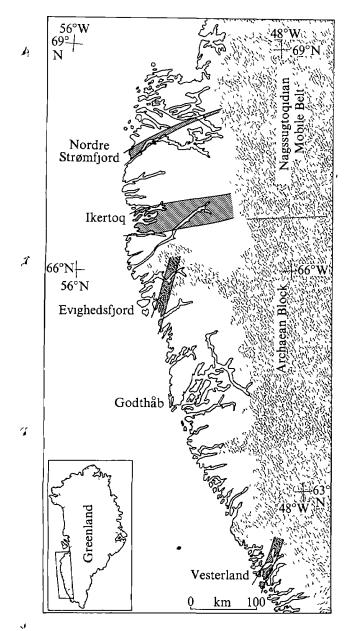
The occurrence of four Precambrian shear zones in western Greenland may point to the existence of a lithospheric plate during Proterozoic times The large scale, ductile, transcurrent movements can be interpreted as tectonically deeper expressions of major transcurrent faults and may represent the internal distortion of a Precambrian continental block

WHETHER the plate tectonic regime which characterised at least the later part of the Phanerozoic was of equal significance during Precambrian times is one of the outstanding geological problems of the present time One approach to this problem is to examine the nature and distribution of large scale Precambrian displacements, to establish whether they are compatible with the neotectonic plate model (or with a modified version of this model, such as that requiring extensive internal distortion of lithospheric plates[1]), or whether they represent an entirely different tectonic system The occurrence of four major shear belts, up to 40 km wide, in the Precambrian of western Greenland (Fig 1) suggests that intracontinental displacements were significant in late Archaean–early Proterozoic times The shear belts represent zones of mainly ductile, simple shear strain with dominantly transcurrent displacements of possibly

up to 200 km At higher tectonic levels and at the surface these shear belts would have been expressed as major transcurrent faults The characteristics of ductile zones of simple shear have already been described[2-4]

Nordre Strømfjord Shear Belt

This belt is situated in the central part of the Nagssugtoqidian mobile belt (Fig 1) and can be traced for about 150 km between the coast and the icecap The coastal half of the belt, which is the only part so far investigated in detail[5], consists of strongly deformed granulite facies gneisses for which a shear strain (γ) of 6 has been calculated The belt is 15 km wide in the coastal section and so this shear strain implies a displacement of at least 100 km across the belt, including the transitional zones on either side The shear strain has been calculated from the reorientation of earlier planar structures, the rotation of which shows the displacement to have been subhorizontal and sinistral, with a subvertical shear plane The orientation of planar structures across the belt varies in a manner consistent with a wedge-shaped profile for the belt, narrowing upwards, with a wedge angle close to 40°

Towards the north-east the shear belt is crossed by an amphibolite facies–granulite facies boundary which postdates the shear deformation The decrease in metamorphic grade


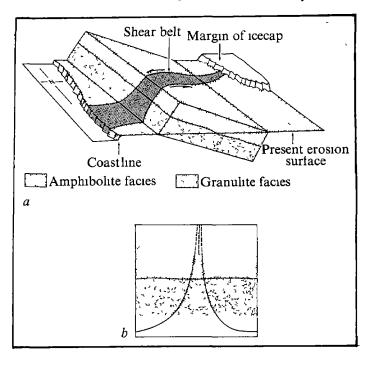
from the coast towards the icecap is accompanied by a decrease in width of the shear belt from 15 km to approximately 7 km, which is compensated for by an increase in shear strain, so that displacement across the belt remains almost constant regardless of width The eastward decrease in both width and metamorphic grade can be interpreted as the result of the differential uplift, by about 10 km, of the coastal region relative to the inland region (Fig 2) Numerous occurrences of pseudotachylite have been recorded in the Nordre Strømfjord region[6,7], but not within the shear belt

Ikertôq Shear Belt

This belt is 40 km wide, striking ENE with an exposed length of 150 km, and consists of highly deformed amphibolite facies gneisses bounded on both the northern and southern sides by granulite facies gneisses unaffected or only slightly affected by the shear movements[8,9] An elongate block of granulite facies gneiss with maximum width of 12 km occurs within the shear belt and is characterised by weak or absent shear deformation, we regard this block as a large augen structure A simplified map of the facies distribution in the coastal region is shown in Fig 3 The structural history of the shear belt is complicated in many places by later ductile overthrusting, but where these later effects are absent, as in Itivdleq Fjord, the original

characteristics of the shear belt are preserved In Itivdleq the intense L-S tectonite fabrics are consistent with a sub-vertical shear plane, with low angle stretching directions (x axis) corresponding to dextral transcurrent movements Estimates of the shear strain indicate values greater than $\gamma = 6$ which, if extrapolated to the full width of the Ikertôq Shear Belt, would correspond to a minimum displacement of over 150 km when allowance is made for the Kingaq and other smaller augen

The granulite facies rocks bounding the shear belt, and within the Kingaq augen, are structurally distinct from the amphibolite facies rocks of the shear belt in as much as tectonite fabrics related to the shear movements are either weak or absent, and large scale, open, fold interference patterns are present Discrete ductile shear zones, up to 50 m wide do occur within the granulite facies areas, however, and are characterised by retrogressive amphibolite facies assemblages These small shear zones are either subparallel or oblique to the regional shear direction, and have variable movement directions

Brittle movement zones, with pseudotachylite and pseudotachylite breccias, occur throughout the Ikertôq Shear Belt, but are most abundant within 5 km of both the northern and southern boundaries The strike directions of the zones of brittle movement are usually parallel to those of the gneiss fabrics although the directions of movement are mostly unknown The brittle movements extended over a long period of time, the earliest occurrences alternated with ductile movements while the rocks were still at metamorphic temperatures The latest pseudotachylites postdate dykes of Cambrian age


An important difference between the Ikertôq and Nordre Strømfjord shear belts is that in the Ikertôq Belt the mineral facies boundaries are very nearly coincident with deformation boundaries, whereas the mineral assemblage of the Nordre Strømfjord belt postdates the deformation, and metamorphic and deformation boundaries are apparently unrelated to one another

Evighedsfjord Shear Belt

This belt[10] has not yet been investigated in detail and its south-westerly continuation (Fig 1) is conjectural

In Evighedsfjord it is expressed as steep zones of highly

deformed, amphibolite facies gneisses retrogressively metamorphosed from surrounding, undeformed, granulite facies rocks The western margin is about 10 km wide granulite and amphibolite facies alternate in linear strips on a scale of tens or hundreds of metres The amount and direction of displacement have not been established, but smaller shear zones with similar trend and attitude are the result of sinistral transcurrent movement Pseudotachylite veins and breccias are abundant, and are concordant with the steep fabric of the highly deformed amphibolite facies rocks, although individual veins are transgressive Although they occur mostly in the amphibolite facies gneisses, there are some pseudotachylite breccias in granulite facies rocks otherwise unaffected by the shear movements The pseudotachylites postdate the ductile deformation but all of those seen predate the Kangâmiut dyke swarm[10], the emplacement of which can be shown to closely follow the ductile deformation

Vesterland Shear Belt

Although the Frederikshåb district in which this shear belt occurs has been systematically mapped on a scale of 1 20000 (ref 11) the shear belt is not known in detail as it was not recognised as such until the later stages of the mapping programme The belt has a NNE trend and can be traced over a distance of 60 km from Vesterland on the coast[12] to the icecap in amphibolite facies gneiss terrain[13] It is about 10 km wide and the marked tectonite fabric—and its orientation—are consistent with a subhorizontal shear direction Two domains of extremely high shear-strain occur at the margins of the belt Detailed analysis of the northern part of the shear[14] belt has shown the strain to be very variable, from $\gamma < 1$ to $\gamma \geqslant 6$, and, consequently, it has not yet been possible to integrate the strain across the belt to determine the amount of displacement, although it is clearly dextral

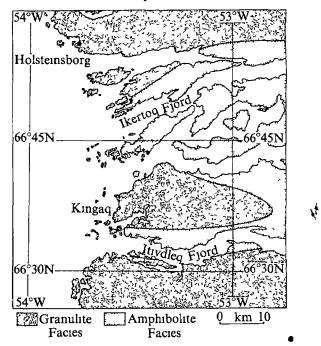
It is likely that other shear belts will be recognised in western Greenland in the future The possibility that a major shear belt exists in Godthåbsfjord has been suggested[14]

Age and seismicity of the shear belts

The limited radiometric data on rocks within and bordering the shear belts, and the ages of displacements relative to dyke swarms, show that movement on all four shear belts is likely to have been initiated 2,000–3,000 Myr ago, although there is no reason to suppose that all were initiated at the same time Movement along the northern margin of the Ikertôq Belt occurred as recently as the Mesozoic[15], and faulting of Jurassic dykes along NNE fractures close to, and within, the Vesterland Belt has been recognised[16,17]

The abundant occurrence of pseudotachylite in two of the shear belts, and its presence in a third, is a result of brittle deformation closely associated with the ductile shear deformation, although pseudotachylite formation also occurred during later movements The change from ductile to brittle behaviour and *vice versa* at this level in the crust is regarded primarily as a result of variation in strain rate rather than of short term changes in temperature or tectonic level We believe the formation of pseudotachylite by shear fracturing to be necessarily accompanied by the release of elastic strain sufficient to generate seismic waves (see refs 18 and 19), although the generation of seismic waves is not necessarily accompanied by pseudotachylite formation

This conclusion implies that two and possibly three of the shear belts described represented well defined linear seismic zones at the time of their formation, at the tectonic level now exposed At higher tectonic levels all four belts were likely to have been seismically active The depth represented by the tectonic level exposed at present is uncertain, but is thought to be 10–15 km below the contemporary surface, that is, at a depth similar to the deeper earthquake foci on the San Andreas[20] and Rhine Graben[21] systems at the present time We anticipate that the deeper, aseismic displacements on the San Andreas,

Rhine and similar fractures are represented by ductile shear zones comparable to the examples in Greenland The comparison with neotectonic, linear seismic belts can be taken a stage further in the case of the Nordre Strømfjord Shear Belt, the truly linear nature of which is indicated by its curving map outcrop, which is consistent with a small circle configuration on a sphere (We emphasise, however, that the geometrical identification of a small circle configuration does not necessarily imply any dynamic significance)


Implications for Proterozoic tectonics

The shear belts represent singular events which cannot be related to one another by the traditional orogenic concept A suggestion[22] that the Nagssugtoqidian boundary, with which the Ikertôq Belt is associated, may represent a plate collision boundary has not received subsequent support, although the evidence of ductile overthrusting on which it was based remains valid

It is difficult to envisage large scale transcurrent displacements of the type described without involving the existence of a horizontal layer along which the horizontal translation could be accommodated, the existence of such a decoupling zone defining the base of the lithosphere is, however, the *sine qua non* of the plate tectonic theory, although the evidence for the existence of such a layer derives almost entirely from investigation of activity at plate edges We suggest, therefore, that the continental mass within which the Precambrian shear belts were formed has the essential characteristic of a lithospheric plate, that is, a lower bounding surface which permitted differential translation relative to the underlying material The downward widening of the Nordre Strømfjord Shear Belt (Fig 2) if continued, may show how vertical and horizontal shear layers are connected

Discussion of the significance of the shear belts in terms of plate rigidity and plate margins is circumscribed by problems of definition Neotectonic plate boundaries are represented by discontinuities, although the Precambrian shear belts do not represent significant discontinuities at the tectonic level now exposed they would have done so at higher tectonic levels On one scale the shear belts represent non-rigid zones bounding more rigid crustal blocks, but on a larger scale they can be thought of as representing distortion within a larger continental mass The question of whether the shear belts could be

Fig. 3 Metamorphic facies distribution in the coastal section of the Ikertôq Shear Belt

Granulite Facies [▓]   Amphibolite Facies [ ]   0 km 10

regarded as plate boundaries cannot, therefore, be answered simply There is no doubt, however, that they represent displacements within a single continental mass and alternative conclusions can be based on this premise

Rigidity of lithospheric plates is only relative and the internal rigidity of neotectonic plates may have been overemphasised, although the evidence for the lack of overall distortion of shape[23] is very persuasive The Precambrian shear belts may be expressions of occurrences that are qualitatively comparable to the intraplate activity now represented by, for example, the East African Rift system, the Rhine Graben, the North Sea Graben, or the South Siberian Fault system The apparently more intense Precambrian intraplate activity could be explained in terms of the greater time period represented by the western Greenland shear belts, which is possibly longer than the Phanerozoic

Alternatively, if the shear belts represent significantly greater intraplate activity during the Precambrian (thus indicating a significantly less rigid lithosphere) this would be consistent with a relative mechanical weakness resulting from a greater width–thickness ratio of the Precambrian lithosphere This could be because either the lithosphere was thinner, or because there was a large Precambrian plate, or it could be caused by a combination of the two

If, as is often assumed, middle and early Precambrian times were characterised by higher heat flows, a corresponding reduction in the thickness of lithospheric plates would be expected insofar as the lithosphere—asthenosphere boundary is defined by an isotherm The consequent reduction in mechanical strength, and its effect on tectonic behaviour, could then be compared with the more fractured nature of neotectonic plates where these are thinnest as a result of higher heat flows adjacent to constructive boundaries[23] Variation of rock composition, and melting point, with depth is, however, likely

to complicate any direct relationship between thermal gradient and lithospheric thickness The palaeomagnetic evidence[24] for the existence of a Proterozoic supercontinent at least 15,500 km wide, and possibly 21,000 km wide, is sufficiently convincing for the size of the Precambrian plate to be regarded as an important factor when mechanical behaviour is considered If both thickness and size varied then the width–thickness ratio of the Precambrian plate would, perhaps, be 3–5 times greater than that of a typical neotectonic plate

Groenlandaspis in Antarctica, Australia and Europe

Alexander Ritchie

The Australian Museum, Sydney, New South Wales 2000, Australia

Groenlandaspis is a member of the Arthrodira, a group of Devonian armoured fishes In the past Groenlandaspis has been found only in eastern Greenland but now Alexander Ritchie has recognised at least six species from sites in Greenland, Europe, Australia and Antarctica His account demonstrates that these arthrodires enjoyed a very wide geographical distribution during the Upper Devonian and that the family can be traced back into the Middle and Lower Devonian

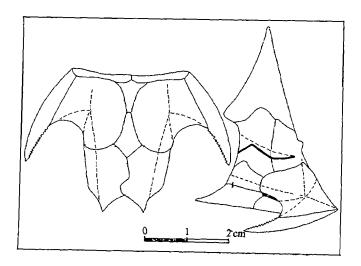
Groenlandaspis mirabilis Heintz, from the late Upper Devonian or earliest Carboniferous of eastern Greenland, is one of the last known members of the armoured arthrodiran fishes The original fossil material[1-3] is limited in quantity, disarticulated and fragmentary and there is insufficient to justify either a full description of the species or a reconstruction The specimens were collected mostly by Scandinavian expeditions to eastern Greenland in the 1920s and 1930s Although very poorly known, *Groenlandaspis* is generally accepted as a very late representative of a very important group of arthrodires (the arctolepids or dolichothoracids) which reached their peak in numbers and diversity much earlier in Lower and Middle Devonian times Until very recently *Groenlandaspis* had not been positively recorded from outside Greenland

As a result of field discoveries in Australia and Antarctica between 1968 and 1974, and finds made in existing European museum collections in early 1973, knowledge of the genus and its closest relatives has increased dramatically The family Groenlandaspididae is now known to have occurred on at least four continents and to range in time from Lower Devonian until the very end of the period and perhaps even into the Carboniferous The genus can now be recognised from material discovered in southern Victoria Land, Antarctica, half a world away from its original occurrence in Greenland At the time of writing at least six species of *Groenlandaspis*—several of them new to science—are known from the Upper Devonian of eastern Greenland, Ireland, England, south-eastern Australia, and Antarctica A new genus of the family Groenlandaspididae has been recovered from the Middle Devonian of western New South Wales, Australia and the family can be traced back into the Lower Devonian in the form of *Tiaraspis*, a small arthrodire from Germany[4]

Most of these occurrences are now represented by abundant, well-preserved material The discovery of *Groenlandaspis* on four widely scattered continents indicates a virtual worldwide distribution in the Upper Devonian and the genus may well prove of considerable value in intra and intercontinental correlation, supplementing the evidence already available from the antiarchs, *Bothriolepis* and *Remigolepis*, with which it is commonly, though not invariably associated

Geographical distribution

The sequence of events which led to the discovery and recognition of *Groenlandaspis* on four continents has been described elsewhere[5] Devonian fish remains from Antarctica were first discovered by members of Scott's last expedition in 1911–12 and were later described by Woodward[6] Material from other sites in southern Victoria Land, collected by Gunn and Warren[7] during the 1957–59 Commonwealth Trans-Antarctic Expedition, has been described by White[8] The very fragmentary material, apparently of Upper Devonian age, included arthrodires, antiarchs, palaeoniscids, crossopterygians and elasmobranchs

Two recent geological expeditions to the same area recovered more, and better preserved, Devonian fish material from many scattered localities[9,10] Preparation of this material has revealed that most of the remains of arthrodires from the Aztec Siltstone of southern Victoria Land can be attributed to one or more species of *Groenlandaspis*


By a curious coincidence the same genus came to light in Australia while the Antarctic studies were in progress In May 1972 I investigated two Upper Devonian sites, 40 miles apart, in central New South Wales (NSW) and I recovered material representing two new and quite distinct species of *Groenlandaspis* from each locality The only previous record[11] of *Groenlandaspis* in Australia is probably incorrect although a member of the Groenlandaspididae is now known to occur in the same fauna, that of the Mulga Downs Group of Middle Devonian age

The new Upper Devonian records, both from the Hervey Group, come from the Cloghnan Shale in the Jemalong Range, some 20 miles west of Forbes, NSW and the Hunter Siltstone, Redcliff Mountin, 11 miles NNE of Grenfell, NSW Large quantities of fish-bearing material from these sites are under preparation and study in the Australian Museum In both cases *Groenlandaspis* is associated with *Bothriolepis* and *Remigolepis* spp but *Phyllolepis* is present at Jemalong and absent at Grenfell and the faunas are quite distinct in other respects

Between December 1972 and April 1973 I carried out a study tour of Devonian vertebrate collections in Europe and discovered two more species of *Groenlandaspis* in museum collections, the first records of the genus from Europe Both came from very late Upper Devonian deposits and from faunas which had been known as early as the 1850s

The first came from the Portishead Beds, exposed on the shores of the River Severn 8 miles west of Bristol in south-western England Small arthrodiran plates occur, tentatively

identified[12] as *Coccosteus? disjectus* Woodward, a spe recorded from the almost contemporaneous late Upper Dev ian Kiltorcan Beds in southern Ireland These small pl: from a collection housed in the Department of Geol University of Bristol, possess, however, the diagnostic fea of a species of *Groenlandaspis*

The second European discovery of *Groenlandaspis* cam light in the Sedgwick Museum, University of Cambri A small collection of unidentified, unlocalised and unregist fish plates again showed the distinctive and by now fam features of *Groenlandaspis* but of a species quite distinct fi the Bristol occurrence I also examined a small collection fish plates in the Royal Scottish Museum, Edinburgh, wh proved to be from the same source as the material from Sedgwick Museum Both had apparently come from a Upper Devonian horizon near Kiltorcan in southern Irel: a site better known for its abundant and well preserved pl fossils than for the associated fish fauna The material ci originally from the Geological Survey in Dublin, having b excavated in the 1850s and 1860s During a brief visit Dublin I established, from the original registers, that o 400 fish plates had been recovered from the Kiltorcan B between 1858 and 1861 (ref 13) and that shortly afterwa representative samples of the fossil flora and fauna had b: sent to Cork, Galway, Belfast, Dublin (Trinity Colle Edinburgh, Oxford, Cambridge and London Although so of this material has been lost over the years a surprising amol has now come to light as the result of recent enquiries

Some of the Kiltorcan arthrodiran plates were descril originally[14] by Woodward as *Coccosteus disjectus*, an identifi: tion generally accepted in stratigraphic accounts until recentl; Miles and Westoll[16] pointed out that *C disjectus* was not a va species of *Coccosteus* and that it may even have been an arc lepid and not a brachythoracid arthrodire Their suspici: were well founded, virtually all of the Kiltorcan arthrodir plates I studied belong to *Groenlandaspis* and can be placed one species—*G disjectus* (Woodward) There is evidence suggest the presence of a second species in the Irish material

Re-examination of existing collections in the Australi Museum has led to the discovery of a third occurrence *Groenlandaspis* in the Upper Devonian of NSW A figur specimen among some fragmentary fish plates from the Herv Range, north-west of Barkes in NSW, which was formerl; identified tentatively as a "crossopterygian dermal plate" c: now be recognised as a left anterior dorsolateral plate *Groenlandaspis* sp , three more plates of the genus have be discovered in the same collection, but there is insufficie material for specific identification The original site has n yet been relocated

Middle and Lower Devonian Groenlandaspidid:

All of the *Groenlandaspis* occurrences mentioned above : from undoubted Upper Devonian deposits It is now appare that *Tiaraspis* (Fig 1), a small arthrodire from the Lov Devonian of Germany[4] is an early, possibly ancestral, memb of the family The apparent absence of Middle Devoni representatives of the family initially presented a problem t that has now been solved following the recognition of a n: genus of the Groenlandaspididae in the Mulga Downs Group western NSW which has yielded large quantities of dissociat arthrodiran material

Wuttagoonaspis, a new arthrodiran genus[18], forms the bt of the fauna But the abundant associated material conta: many arthrodiran plates which cannot be assigned read: to a genus or species It is now apparent that many of 1 plates display features approximately intermediate betwe those of *Tiaraspis* and *Groenlandaspis* On other evidence 1 fish beds of the Mulga Downs Group are thought to be of ea Middle Devonian age so the new member of the Groenland: pididae present in the fauna, probably representing a n: genus, falls neatly into place

Fig. 1 *Tiaraspis subtilis* (Gross) Lower Devonian, Germany Trunk armour seen in ventral and right lateral view Overlap areas indicated by dotted line (After Gross 1962)

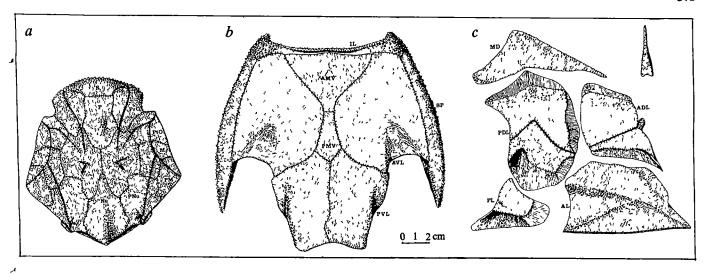
0   1   2cm


Fig 2 *Groenlandaspis antarcticus* sp nov, Upper Devonian, Aztec Siltstone, southern Victoria Land, Antarctica *a*, Headshield, *b*, ventral trunk shield, *c*, dorsal and right lateral trunk plates, shown detached All to same scale ADL,PDL, anterior and posterior dorsolaterals, AL,PL, anterior and posterior laterals, AMV,PMV, anterior and posterior median ventrals, AVL,PVL, anterior and posterior ventrolaterals, C, central, IL, interlateral, M, PM, marginal and postmarginal, MD, median dorsal, Nu, nuchal, P, pineal, PNu, paranuchal, PrO,PtO, pre and postorbitals, R, rostral, SP, spinal

Relationship between *Groenlandaspis* and the Groenlandaspididae

Although it is generally agreed that *Groenlandaspis* belongs in the family Arctolepida Heintz 1937 (=Dolichothoraci Stensio 1944) confusion exists concerning its relationships with other arctolepids, partly because there is inadequate material of the type species, *G mirabilis* Heintz

Denison[19] placed *Groenlandaspis* in the subfamily Phlyctaenaspinae whereas Obruchev[20] placed it in a family of its own —the Groenlandaspididae—and grouped it with the Holonematidae in a separate suborder, the Holonematoidei Miles[21,22] has shown that the Holonematidae are brachythoracid arthrodires at an advanced coccosteomorph level of organisation, although they are phylogenetically distinct from all other brachythoracids In spite of certain similarities between the Holonematidae and the Groenlandaspidae a close association seems unwarranted at present

I propose a classification which is a modified version of that of Miles[21] in which the name Arctolepida (which has precedence) is preferred over the name Dolichothoraci, and in which the Tiaraspididae are merged with the Groenlandaspididae

Suborder Arctolepida

Family 1, Actinolepididae, 2, Phlyctaenaspididae, 3, Groenlandaspididae, 4, Williamsaspididae, 5, Aggeraspididae
Amongst these the Groenlandaspididae are most closely related to the Phlyctaenaspididae on the evidence from the trunk armour

Family Groenlandaspididae Obruchev 1964

Obruchev[20] and Romer[23] included two poorly known genera, *Grazosteus* and *Tropidosteus*, in the Groenlandaspididae but Miles[22] has shown that these forms are of uncertain affinities and they are not here retained in the family At present only three genera are considered to be undoubted members of the Groenlandaspididae— *Groenlandaspis* (Upper Devonian), a new undescribed genus from Mulga Downs Group, western NSW (Middle Devonian), and *Tiaraspis* (Lower Devonian)
Groenlandaspididae Euarthrodira with unreduced lateral trunk shield, long contact between lateral and ventral trunk shield Pectoral fenestra of medium size Spinal plate large Median dorsal plate long, extremely narrow with high pointed laterally compressed dorsal ridge Anterior and posterior dorsolateral plates high, short Dorsolateral canal with angular, dorsally directed flexure over posterior dorsolateral plate Paired anteroventrals absent Craniothoracic articulation well developed, condyles situated rather close together Headshield subpentagonal, posterior margin convex or angular

Groenlandaspis

Type species *G mirabilis* Heintz 1932 Groenlandaspis Series, Upper Devonian (Famennian)-? Lower Carboniferous (Tournasian) Eastern Greenland

Discussion *G mirabilis* is a rather large arcolepid of which most of the plates of the trunk armour are known from isolated specimens and the headshield is known only from a natural mould of the posterior margin (and the articular fossae) and from an isolated central plate[1-3] From our present complete knowledge of the genus, based on the Antarctic material, it is clear that most of the Greenland specimens are identified correctly, except that the central plate figured by Stensio (ref 2, No 3, Fig 12) is the left, not the right, and should be reversed The posterior ventrolateral plate (PVL) figured by Miles (ref 3, Fig 9 *A-D*) at first sight seems to differ significantly from the PVL of *Groenlandaspis antarcticus* sp nov (Fig 2*b*) During examination of the original *G mirabilis* PVL in Copenhagen, it was found, however, that parts of two separate plates had been erroneously placed in close association, probably at the time of discovery in 1954 The posterior portion of the PVL, as restored, is incorrect and the shape almost certainly corresponded closely to that in *G antarcticus*

Although it would be difficult to distinguish between isolated or fragmentary plates of *Groenlandaspis antarcticus* sp nov and those of the type species, *G mirabilis* Heintz, there are sufficient minor differences to warrant separation in distinct species, at least until more complete material of the Greenland form becomes available The geographical separation alone suggest that it is unlikely that the Antarctic and Arctic faunas were conspecific

The genus *Groenlandaspis* can now be described in detail for the first time based on the excellent material from Antarctica, Australia and Europe Only the new Antarctic species is covered here but the diversity of the known species of the Groenlandaspididae is illustrated by a selection of the median dorsal plates of the new discoveries (Fig 3 *a-f*), the incompletely known MD of the type species, *G mirabilis* Heintz, is not shown here but seems to be close to that of *G antarcticus* sp nov (Fig 3*a*)

Groenlandaspis antarcticus sp nov (Fig 2 *a-c*)
Type the Australian Museum F54334, almost complete headshield, from Mount Ritchie, western side of Deception Glacier, south Victoria Land, Antarctica
Referred specimens AM F54336, F54314 (partial headshields), F56348 (complete ventral shield), F54337 (MD), F54382 (ADL), F54343, F54379 (PDLs), F54389 (AL), F54406, F56349 (PLs), F56222 (AMV), F55669 (PMV), F54344 (PVL), F56321-2 (IL)
Locality all from same locality and horizon as type, Mount Ritchie, Unit 62, Section A4 (24), with exception of F54314 (Portal Mountain), F56348 (Mount Metschel, southern end), F55669 (Section A2, small nunatak, north of Alligator Peak)
Horizon Upper Devonian, Aztec Siltstone, Taylor Group[24]
Description and discussion neither Woodward's material[6] nor that of White[8] from south Victoria Land contained specimens which can be positively attributed to *G antarcticus* sp nov The incomplete headshield of an aberrant arthrodire *Antarctaspis mcmurdoensis* White from Mount Crean differs strongly from the cranial material of *Groenlandaspis* collected by VUWAE 15 in 1970-1 The trunk plates figured by White (ref 8, Plate III, figs 1 and 2) as *Antarctolepis* show some groenlandaspid-like features but are quite distinct from the equivalent plates in *G antarcticus* There is some evidence for the presence of more than one species of *Groenlandaspis* in the Upper Devonian of Antarctica
The cranial shield, poorly known in the type species from Greenland, can be restored fully from the Antarctic discoveries An almost

complete specimen (AM F54334), recovered in many fragments from near the summit of Mount Ritchie, has been extracted and reconstructed Most of the remaining material has also been prepared

The restoration of the headshield of *G antarcticus* (Fig 2*a*) incorporates information from two other partial headshields and numerous fragments

The nuchal plate (Nu) is not particularly large, six-sided, bluntly pointed posteriorly and sharply pointed anteriorly The other median plates, the rostral and pineal (R, P), are separate, unlike in many arctolepids where they are apparently fused The pineal plate (P) is unusually large, extending posteriorly almost to the centre of the shield, completely separating the preorbital plates (PrO) and partly separating the large centrals (C) The latter are rather irregular in shape for an arctolepid, reflecting the extensive development of overlap areas to a degree more commonly found in brachythoracid arthrodires The articular fossae on the visceral surface of the paranuchal plates (PNu) are large, well developed and situated quite close together, as in *G mirabilis* The posterior margin of the PNu bears a prominent preglenoid process

The cranial sensory canal pattern is fairly conventional except for one feature not often found in arctolepids—the supraorbital canal extends beyond the preorbital plate (PrO) on to the central plate (C)

The trunk armour is known in considerable detail from many specimens of isolated plates (Fig 2*c*) and the ventral surface is restored (Fig 2*b*) from an especially fine, virtually complete specimen recovered from the southern end of Mount Metschel, Skelton Neve

The most distinctive plate of the *Groenlandaspis* trunk armour is undoubtedly the median dorsal (MD), an elongate, extremely narrow plate with a pointed dorsal crest and almost vertical lateral surfaces (Fig 2*c*) The ventral margin is shallowly indented for the insertion of the equally distinctive high but short, anterior and posterior dorsolateral plates (ADL, PDL) A unique feature in this genus is that the dorsal portions of the right and left PDLs meet one another in the middle, inside the very narrow base of the MD A broad rugose surface is developed over the area where they meet

A characteristic feature of the PDL in *Groenlandaspis*, already known from *G mirabilis* as shown by Stensio (ref 2, No 3, Fig 13), is the sharply flexed course of the dorsolateral canal crossing the plate The anterior and posterior portions of the canal meet almost at right angles This feature runs right through the family although it is not so extremely developed in *Tiaraspis* (Fig 1)

The anterior lateral plate (AL) is large and, for an arctolepid, relatively low and long The pectoral fenestra is closed behind by a smallish posterior lateral plate (PL) which is inserted dorsally into a deep groove in the PDL and attached ventrally to the dorsal lamina of the large posterior ventrolateral plate (PVL) On the ventral surface (Fig 2*b*) the most significant character is the absence of paired anteroventral plates which are present in the Actinolepididae The area is occupied by a large, semicircular anterior median ventral plate (AMV) which immediately suggests a close relationship between the Groenlandaspididae and the Phlyctaenaspididae[25]

Evolutionary trends

Through the known history of the Groenlandaspididae there is a noticeable trend towards progressive reduction in the height of the dorsal spine and a corresponding elongation of the median dorsal plate (MD) In the Lower Devonian *Tiaraspis* (Fig 1) the MD is short, very high and acutely pointed, in the new genus from the Middle Devonian Mulga Downs Group of western NSW (Fig 3*f*) the MD is slightly longer than high and less acutely pointed With the exception of the Grenfell form (Fig 3*e*) all of the Upper Devonian species of *Groenlandaspis* have an MD which is much longer than high (Fig 3 *a–d*), in all of them (Fig 3 *a–e*) the highest point is posteriorly placed and directed posterodorsally

A similar series can now be constructed for the other trunk plates, most usefully for the distinctive ADL and PDL plates, but there is often considerable variation within each fauna, the extent of which is still being analysed

Relative age of the known Groenlandaspididae

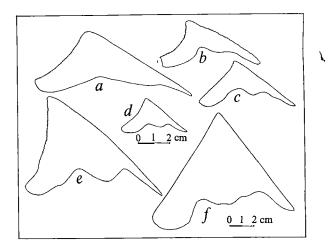
The three representatives of *Groenlandaspis* from the Northern Hemisphere (Greenland, Ireland and south-western England) are all known from the youngest Devonian rocks in their respective areas In Greenland the genus may last into the Tournasian The NSW specimens all occur in the Upper Devonian Hervey Group of central NSW (near Forbes, Grenfell and Parkes) but none of them come from the latest part of the Devonian sequence in their respective areas and it seems probable that they are somewhat older than the species from the Northern Hemisphere.


Fig. 3 Median dorsal plates of Groenlandaspididae in right lateral view *a–e*, All Upper Devonian and to same scale, *f*, Middle Devonian, slightly reduced scale *a*, *Groenlandaspis antarcticus* sp nov, southern Victoria Land, Antarctica, from Australian Museum F54337, *b*, *G disjectus* (Woodward) Kiltorcan, Ireland, Institute of Geological Sciences, London Zo3897, *c*, *Groenlandaspis* sp nov, Jemalong Range, Forbes, NSW, Australian Museum F56893, *d*, *Groenlandaspis* sp nov, Portishead, near Bristol, England, Bristol University Geology Department, BUGD 9926, 17850, *e*, *Groenlandaspis* sp nov, Grenfell, NSW, Australian Museum F56125, *f* gen et sp nov Mulga Downs Group, west of Cobar, NSW, Australian Museum F54567

Accurate dating and correlation of the specimens from NSW must await analysis of the rich associated faunas, but one unexpected feature is that the closest resemblances are not between those species of *Groenlandaspis* which are geographically close The Greenland and Antarctic species are alike in many respects as are the forms from Bristol, south-western England and Forbes, NSW But the Irish *G disjectus* and the distinctive new species from near Grenfell, NSW could not be confused with any of the other known occurrences

The value of the family for stratigraphic purposes has been demonstrated by the recognition of a groenlandaspid in association with a *Wuttagoonaspis* sp in the northern Dulcie Range, about 130 miles north-east of Alice Springs, Northern Territory, Australia (G Young, personal communication), a fauna which is clearly comparable to the Middle Devonian Mulga Downs Group of western NSW[18]

Unique and repetitive sequences in multiple genes for feather keratin

David J. Kemp

Department of Biochemistry, University of Adelaide, Adelaide, South Australia 5001

Embryonic chick feather keratins are a family of homologous polypeptide chains The mRNA coding for these has been obtained in a pure state and transcribed into complementary DNA (cDNA) using the reverse transcriptase from avian myeloblastosis virus Studies on the kinetics of hybridisation and reannealing of cDNA indicate that there are 25–35 different keratin mRNA species in the embryonic chick feather, and a total of 100–240 keratin genes in the chick genome Each keratin gene contains both a unique and a repetitive sequence It is proposed that the repetitive sequences are the keratin coding sequences and that the unique sequences correspond to untranslated regions

SINCE the original demonstration of highly repetitive, moderately repetitive and unique sequence classes in the nuclear DNA of higher organisms[1-3], it has been established that most highly repetitive sequences fall into a distinct class of simple-sequence non-coding DNA (satellites) occurring in long uninterrupted blocks in the genome[4,5] In contrast, the moderately repetitive DNA seems to be much more varied in function and organisation Much of the moderately repetitive DNA seems to occur in short segments intimately interspersed with unique sequences[1-3,6,7], and various models have attributed control functions to this class of DNA (refs 8–11) Whereas the structural genes for some (and presumably most) proteins occur in the unique DNA fraction[12-14], moderately repetitive structural genes have also been identified The genes for ribosomal RNA (r RNA) (refs 15 and 16), 5S RNA (ref 17), RNA (ref 18) and histones[19] are moderately repetitive and occur as tandem repeats in the genome Unique sequences are not, however, interspersed between these repetitive sequences and an example of a set of repetitive DNA sequences of known function, each directly linked to a unique sequence, as not previously been described

As chick feather keratins consist of a large family of homologous proteins[20-22], keratin genes must represent a family of non-identical moderately repetitive DNA sequences The availability of highly purified feather keratin mRNA (refs 23–25) affords an opportunity to study the organisation of this family of genes Feather keratin chains are the major protein products of the 14 day embryonic chick feather[26] About 20–25 distinct keratin chains, differing in primary structure by multiple amino acid substitutions, have been identified in the embryonic feather[20,21] Additional keratin chains are present in adult feather tissues[20] indicating at least 30 homologous keratin genes in the chick genome[22] These have presumably arisen by gene duplication and subsequent divergence

A 12S RNA species isolated from 14 day embryonic chick feather polysomes[23] was released from polysomes as an mRNP complex by EDTA treatment[24], bound selectivity to cellulose[23,24] and coded only for keratin chains in the wheat embryo cell-free system[25] Keratin mRNA migrated as one band of molecular weight 250,000 on formamide–acrylamide gels[24], indicating an untranslated sequence, including poly(A), of about 500 bases in addition to the keratin-coding sequence of 300 bases Since the keratin mRNA coded for at least four and probably all of the different keratin chains[25] is consists of a mixture of non-identical homologous keratin mRNAs of closely similar size

Keratin mRNA acted as an efficient template (ref 22 and D J Kemp, and G E Rogers, unpublished) for the oligo(dT)-dependent synthesis of complementary DNA (cDNA) by the DNA polymerase of avian myeloblastosis virus (AMV), as reported for other mRNAs (refs 27–29) Keratin cDNA migrated as a major peak (about 70% total) of apparent molecular weight 170,000 on formamide–acrylamide gels (D J Kemp and G E Rogers, unpublished), demonstrating that most keratin cDNA molecules must contain sequences complementary to at least parts of both the keratin-coding sequences and untranslated sequences I report hybridisation studies with keratin cDNA which demonstrate the presence of multiple keratin genes in the chick genome Each keratin gene contains interspersed unique and repetitive sequences

Hybridisation of keratin mRNA to keratin cDNA

The kinetics of hybridisation of cDNA to excess unlabelled mRNA are dependent on the sequence complexity of mRNA Comparison of the kinetics of hybridisation with those of a kinetic standard (for example, rabbit globin mRNA-cDNA, refs 30–32) allows an estimate of the complexity of keratin mRNA

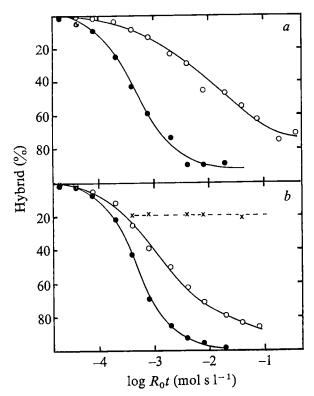
As determined by resistance of the hybrids to the single-strand specific nuclease S1 (refs 33–35), rabbit globin mRNA hybridised to globin cDNA in a sharp transition (Fig 1a) with a mid point ($R_0t_{\frac{1}{2}}$) of 4×10^{-4} mol s l^{-1} (refs 30–32) Keratin mRNA hybridised to keratin cDNA in a broad transition (Fig 1a) with a $R_0t_{\frac{1}{2}}$ of about 1×10^{-2} mol s l^{-1} The kinetics cannot be ascribed to non-mRNA impurities in the preparations as they were reproducible using batches of keratin mRNA which was transcribed at efficiencies as high as 43% of the theoretical maximum[27-29] In addition, the keratin mRNA


Fig. 1 Hybridisation of keratin and globin mRNA and poly(rA) to cDNA mRNAs were prepared from EDTA-treated polysomes as described[24] cDNA was synthesised in a system (50 µl) containing 50 mM Tris-HCl, pH 8 3, 8 mM dithiothreitol, 8 mM MgCl₂, 0 66 mM dATP, dGTP, dTTP, 0 1 mM ³H-dCTP (specific activity 26 2 mCi µmol⁻¹), 100 µg ml⁻¹ actinomycin D, 0 2–1 0 µg mRNA, 0 1 µg dT₁₂₋₁₈ and AMV–DNA polymerase, incubated for 1 h at 37°C, treated with 0 3 M NaOH and purified on Sephadex G-50 in 0 1 M NH₄HCO₃ (ref 28) The high molecular weight fraction (average about 170,000) of keratin cDNA, obtained by alkaline sucrose gradient sedimentation, was used for all experiments Hybridisations were at 60°C for 4 h in 0 18 M NaCl, 0 001 M EDTA, 0 01 M Tris-HCl, 0 05% SDS, pH 7 0 (NETS) The reaction mixtures (100 µl) contained 5,000 c p m keratin or globin cDNA (transcribed at 27 and 60% efficiency, respectively in the experiment shown) and varying amounts of mRNA For nuclease S1 assays, 10 µl aliquots were diluted into 150 µl of 0 03 M Na-acetate, 0 05 M NaCl, 0 001 M ZnSO₄, 5% glycerol, pH 4 6 (assay buffer) containing 12 µg of sonicated, heat-denatured calf thymus DNA, incubated with or without nuclease S1 (four units, purified through step four[35], at 45 °C for 30 min, TCA-precipitated and counted HAP assays (on aliquots of the same reaction mixture shown in (a) were as described[3] at 60 °C in 0 18 M Na-phosphate (Na⁺ molarity=0 18, pH 7 0) Where appropriate the results were normalised[6] to remove background and facilitate comparisons, the normalisation factor is shown in parenthesis for each curve, 0% indicates that a curve was not normalised *a*, Nuclease S1 assays ○, keratin mRNA–cDNA (0%), ●, globin mRNA–cDNA (5%) *b*, HAP assays ○, keratin mRNA–cDNA (10%), ●, globin mRNA–cDNA (20%), ×, poly(rA)–keratin cDNA (10%)

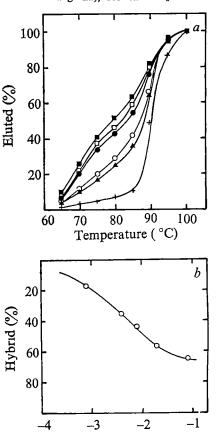
used here contained only one band on formamide gels and coded only for keratins in the wheat embryo system[24,25]

When hybridisation of keratin mRNA to cDNA was assayed on hydroxyapatite (HAP), a major transition was observed (Fig 1*b*) with a $R_0t_{\frac{1}{2}}$ of 9×10^{-4} mol s l⁻¹, about ten times faster than the same reaction assayed with nuclease S1 In contrast, the kinetics of hydridisation of globin mRNA–cDNA were identical whether assayed on HAP (Fig 1*b*) or with nuclease S1 (Fig 1*a*) The major transition of keratin mRNA cannot be explained by interaction of cDNA with the poly(A) segment of keratin mRNA as only about 20% of keratin cDNA molecules formed hybrids with poly(rA) (Fig 1*b*), and was not caused by self-complementarity of the cDNA since incubation of cDNA in the absence of mRNA for 0–4 h resulted in 10% binding to HAP


The thermal stabilities of keratin mRNA–cDNA hybrids changed as a function of R_0t (Fig 2*a*) At least two com-

ponents with T_m of about 72° and 90° were evident Hybrids which eluted from HAP at greater than 80° formed with a $R_0t_{\frac{1}{2}}$ of about $6-7 \times 10^{-3}$ mol s l⁻¹ (Fig 2*b*), a value similar to the rate observed using nuclease S1 (Fig 1*a*) In contrast, only one major component of high thermal stability was present in globin mRNA–cDNA hybrids (Fig 2*a*), demonstrating that the low thermal stability of keratin hybrids was not caused by their degradation under the incubation conditions used here

Reannealing of keratin cDNA with chick erythrocyte nuclear DNA

The reiteration frequency of sequences in cDNA preparations can be estimated by annealing cDNA with a vast excess of chromosomal DNA[13,14,36-38] As determined by nuclease S1 assays in low salt buffer (Fig 3*a*) chick DNA (labelled either with ¹²⁵I *in vitro*[39] or with ³²P *in vivo*) reannealed with a midpoint $(C_0t_{\frac{1}{2}})$ of about 1×10^3 mol s l⁻¹ (ref 38) Keratin cDNA reannealed to a vast excess of chick DNA with a $C_0t_{\frac{1}{2}}$ of about 4×10^2 mol s l⁻¹ (Fig 3*a*) As determined by nuclease S1 assays in high salt buffer (Fig 3*b*) ¹²⁵I-labelled chick DNA reannealed at a similar rate to that determined in the low salt assays but seemingly to a greater extent Assayed under these conditions keratin cDNA gave a broad curve (Fig 3*b*) suggesting two transitions with $C_0t_{\frac{1}{2}}$ values of about 4×10^1 and 1×10^3 mol s l⁻¹, respectively

Fig 2 Thermal stabilities of mRNA–cDNA hybrids Aliquots as described in Fig. 1 were diluted into 0 18 M Na-phosphate (pH 7 0) containing 100 µg partially re-associated calf thymus DNA and loaded on to HAP at 60 °C Hybrids which could not be eluted at 60 °C were melted by raising the temperature in 5 °C increments Two 2 5 ml washes (0 18 M Na-phosphate) were collected at each temperature and TCA-precipitated *a*, ○ Keratin mRNA–cDNA hybrids, after incubation to R_0t values (mol s l⁻¹) of ■, 8×10^{-4}, □, 4×10^{-3}, ●, 8×10^{-3}, ○, 2×10^{-2}, ▲, 8×10^{-2}, +, globin mRNA–cDNA hybrids, 8×10^{-4} *b*, Rate of formation of keratin mRNA–cDNA hybrids eluting from HAP at greater than 80 °C The normalised percentage cDNA bound to HAP at 60 °C (data from Fig 1*b*) was multiplied by the percentage of this bound cDNA which eluted at greater than 80 °C (data from Fig 2*a*), for each R_0t value shown

When assayed on HAP (Fig 3c) chick DNA reannealed with a major transition at a $C_0t_{\frac{1}{2}}$ of about 4×10^2 mol s l⁻¹, a value compatible with estimates of the size of the chick genome[3,14,40,41] Keratin cDNA gave two distinct transitions (Fig 3c) with $C_0t_{\frac{1}{2}}$ values of 7 mol s l⁻¹ (about 60% total) and 5×10^2 mol s l⁻¹ (about 30% total)

The thermal stabilities of the keratin cDNA–DNA duplexes (Fig 4a) changed with C_0t in a manner similar to but more marked than the mRNA–cDNA hybrids (Fig 2a) Two components with T_m of about 73° and 93° were evident Duplexes which eluted from HAP at greater than 85° (Fig 4b) formed with a $C_0t_{\frac{1}{2}}$ of about 6×10^2 mol s l⁻¹ From the data in Figs 3b, 4a and b it can be calculated that of the keratin cDNA duplexes with T_m lower than 85° at a C_0t of 6×10^1 mol s l⁻¹, more than 70% of these same molecules have T_m greater than 85° at a C_0t of $1\ 2\times10^4$ mol s l⁻¹

Interspersed unique and repetitive sequences in keratin genes

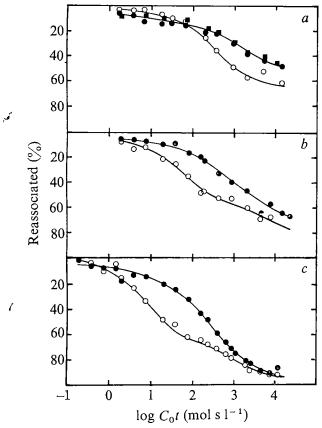
The striking features of the results are the greater apparent rates of formation of keratin cDNA duplexes when assayed with HAP compared with nuclease Sl and the progressive increase in average thermal stability of the duplexes with


Fig 3 Reassociation of keratin cDNA with excess chick erythrocyte nuclear DNA Chick erythrocyte DNA, prepared as described[51], was sonicated (mean length 0 16 μm) Reaction mixtures (in NETS) contained 9 1 mg ml⁻¹ sonicated DNA plus about 35,000 c p m ml⁻¹ keratin cDNA, ¹²⁵I-chick erythrocyte-DNA (ref 39) (specific activity 1×10^5 c p m μg⁻¹), or ³²P-labelled chick embryo DNA, and were denatured (100 °C for 5 min) before incubation at 60 °C to the C_0t values shown For nuclease Sl assays in low salt buffer, 50 μl aliquots were diluted into assay buffer and incubated with or without nuclease Sl (150 units) for 30 min at 45 °C Nuclease Sl assays in high-salt were identical except that the assay buffer contained 0 3 M NaCl and incubation was at 37 °C HAP assays were as in Fig 1b After Sl digestion or HAP fractionation, all samples for any one curve were made up to the same final DNA concentration before TCA precipitation to avoid errors resulting from differential quenching Normalisation factors are shown as for Fig 1 a, Nuclease Sl assays in low-salt ●, ¹²⁵I-DNA (0%), ■, ³²P-DNA (0%), ○, keratin cDNA (0%) b, Nuclease Sl assays in high-salt ●, ¹²⁵I-DNA (14%), ○, keratin cDNA (0%) c, HAP assays ●, DNA (A_{260}) (12%), ○, keratin cDNA (10%)

increasing C_0t The data can be explained if there are multiple homologous keratin genes in the chick genome each containing two distinct sequences of approximately equal length, namely (1) a similar but non-identical sequence common to all the keratin genes ('reiterated sequence'), covalently attached to (2) a sequence so different in base sequence to that of any other keratin gene ('unique sequence') that it seems to be unique in the genome under the experimental criteria used here

The rapid transitions of keratin cDNA observed on HAP (compared with nuclease Sl in low salt conditions) can be explained as follows The reiterated sequences cross-hybridise early in the reaction (Figs 1b and 3c), forming duplexes which bind the entire molecule to HAP (ref 3) The unpaired unique regions would, however, be completely susceptible to nuclease Sl The low thermal stability of these duplexes indicates that about 20% of the base pairs are mismatched[42] The slow formation of duplexes of high thermal stability (Figs 2b and 4b) would result from hybridisation of the unique regions to their exact complements, forming concatenates of the early structures These duplexes would be stable to nuclease Sl

On this model, two distinct transitions would be expected after assaying hybridisation with nuclease Sl, the faster corresponding to the rapidly formed duplexes of the reiterated sequences and the slower corresponding to the unique sequences This was not observed when nuclease Sl assays were carried out in low salt (Figs 1a and 3a) The single transition observed, however, occurred over three decades of R_0t (Figs 1a and 3a), a sure indication of heterogeneity[3] Under high salt conditions in the Sl assays two distinct transitions were observed with keratin cDNA–DNA duplexes (Fig 3b) The extent of this early transition (Fig 3b) suggests that the reiterated sequences occupy about 50% (that is, about 250–300 bases) of the cDNA molecules

The difference in Sl-resistance of early keratin cDNA–DNA duplexes in low and high salt (compare Fig 3a and b) can be explained if the mismatched duplexes are degraded to an extent of about 50% in low salt and are completely resistant in high salt Therefore, although two distinct transitions are not apparent in Figs 1a and 3a, the first 20–30% of the observed transition can be attributed to mismatched duplexes of the reiterated region which are partially degraded by nuclease Sl, resulting in a final extent of only 70–80% resistance of the hybrids to nuclease Sl (Fig 1a) The presence of high-salt concentrations did not protect cDNA–mRNA hybrids against degradation by nuclease Sl (data not shown) The smaller slow transitions of keratin cDNA observed on HAP (Figs 1b and 3c) could result from thermal scission, incomplete transcription, impurities in mRNA, or a combination of these factors

Estimation of the number of molecular species in embryonic chick keratin mRNA

The kinetic complexity of the unique sequences in keratin mRNA estimated by the nuclease Sl procedure (Fig 1a) was about 25 times that of globin mRNA, and estimated by the rate of formation of hybrids eluting from HAP at greater than 80° (Fig 2b) was about 18 times that of globin mRNA Since the α and β chains of rabbit globin mRNA and cDNA do not cross hybridise[30-32] the complexity of globin mRNA is about 1,100 bases, giving an apparent complexity of about 20,000–28,000 bases for keratin mRNA Since these unique sequences only occupy about half of the mRNA, this adjusts to 10,000–14,000 bases when corrected for the actual concentration of unique sequences instead of total mRNA, equivalent to 25–35 different unique sequences about 400 bases long This estimate of 25–35 different mRNA species is compatible with the minimal number of 19 to 25 keratin chains[21,22] detected in embryonic chick feather keratin

Estimation of the number of keratin genes in the chick genome

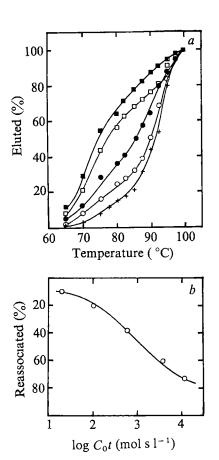
Keratin cDNA reannealed to chick DNA about two to three


Fig 4 Thermal stabilities of keratin cDNA–DNA duplexes Reaction mixtures as in Fig 3 were treated as in Fig 2, except that carrier DNA was not added until after fractionation on 2 0 ml HAP columns *a*, Keratin cDNA–DNA duplexes after incubation to C_0t values (mol s l^{-1}) of ■, $1\,9\times10^1$, □, $1\,0\times10^2$, ●, $5\,7\times10^2$, ○, $3\,06\times10^3$, +, $1\,15\times10^4$ *b*, Rate of formation of keratin cDNA–DNA duplexes eluting from HAP at greater than 85 °C, calculated from the data of Figs 3*c* and 4*a* as described for Fig 2*b*

Nature of the unique and reiterated sequences in keratin genes

The limited available sequence data[21] indicate that individual embryonic chick feather keratin chains dffer from each other in amino acid sequence by a maximum of about 8% and that most of these differences are the result of single base changes In the conditions used here, stable hybrids form between mouse globin cDNA and rabbit globin mRNA (ref 43), although mouse and rabbit globin chains differ by 19% in amino acid sequence Keratin structural genes should therefore cross hybridise with each other unless mutations which do not change the amino acid specified (relative to those that do change the amino acid specified) occur in keratin structural genes much more frequently than in globin structural genes It is therefore likely that the reiterated sequences are the keratin structural genes, that there are about 100–240 of these in the haploid chick genome, that on average they have diverged from each other by about 20% in base sequence, and that many of them are not expressed, or expressed at a very low level in the embryonic feather

If this interpretation is correct, it follows that the unique sequences are the untranslated regions and that these have diverged at a much greater rate, to the extent that each seems to be unique in the haploid genome A similar situation has been observed in the case of sea-urchin histone genes[44] In this case the spacer sequences are also thought to have diverged at a greater rate than the histone structural genes[44] This also seems to be true for the spacer sequences of ribosomal genes[45] Preliminary results indicate that shorter keratin cDNA molecules obtained using *Escherichia coli* DNA polymerase I to copy keratin mRNA contain only the unique sequences, suggesting that the unique sequences are localised toward the 3' end of keratin mRNA

Recent studies indicate that most eukaryotic mRNAs are transcribed from unique sequences[12-14,30,37,38,46,47], although a small fraction which seems to be transcribed from repetitive sequences has also been reported[30][46-48] In contrast to the situation in keratin mRNA, however, these repetitive and single-copy transcripts are not covalently interspersed[46,47] Whereas the genes for duck globin seem to be adjacent to repetitive sequences in the genome[50], keratin genes seem to be the first example of repetitive sequences of known function which are interspersed with unique sequences The occurrence of both unique and repetitive sequences in keratin genes should greatly facilitate studies on their arrangement in the chick genome

times faster than the unique sequence fraction of chick DNA as determined by the nuclease S1 procedure in low salt, indicating that the unique regions are reiterated two or three times The strong dependence of the kinetics on the salt concentration in the nuclease S1 assays suggests that this could be an overestimate This interpretation is supported by the kinetics of formation of keratin cDNA–DNA duplexes eluting from HAP at greater than 85° (Fig 4*b*), which indicate that the unique sequences occur only about once in the haploid genome

The reiterated sequences in keratin mRNA hybridised to keratin cDNA with a $R_0t_{\frac{1}{2}}$ of 9×10^{-4} mol s l^{-1} when measured on HAP (Fig 1*b*), about four times slower than the rate expected for a single perfectly complementary species Mismatching of about 20% (ref 42) would lower the reaction rate by a factor of about four[42], giving a corrected apparent complexity of about one for the reiterated sequence This implies that most if not all keratin mRNA species share the sequence

The reiterated sequences reannealed to chick DNA about 60 times as fast as the unique sequence fraction of chick DNA when determined on HAP (Fig 3*c*) and about 25 times as fast when assayed with nuclease S1 in high salt (Fig 3*b*) When corrected by the factor of four for the reduction in rate caused by mismatching, the reiteration frequency of this sequence seems to be 100–240 If, however, the low T_m of duplexes of these regions is a consequence of the sequences being very short rather than poorly matched, the factor of four may not apply and the estimate may be too high This would not invalidate the conclusion that there are two distinct sequence classes present in each keratin gene

Variable X-ray source near Cen X-3

THE satellite Ariel V, launched on October 15, 1974, as part of the US-UK collaborative space programme, contains a rotation modulation collimator experiment designed to measure the positions of X-ray sources, which was built by the Mullard Space Science Laboratory The experiment responds to X rays in the quantum energy range 3 1–9 3 keV, the area of the proportional counters being 256 cm² which, allowing for grid transmission, counter efficiency and so on, leads to an effective area of 102 cm² at 6 0 keV The pitch-to-separation ratio of the collimator grids is 112, corresponding to a full width at half maximum (FWHM) of the image of a point source of 15′ (ref 1) The spin axis was manoeuvred to point towards a number of sources in succession in the Centaurus region, including the important binary source Cen X-3, from December 17, 1974 to January 31, 1975, to carry out position and spectrum determinations Soon after arriving at the first pointing direction in the sequence, a correlation map produced by overlaying data from orbits obtained on December 17–19 showed the presence of a new source not listed in the Uhuru (3U) catalogue, which we have designated A1118-61 from the position given below The field of view of the experiment is 17°

Fig 1 Counting rate of variable source in Centaurus region as a function of time after subtraction of background The symbol circle with a vertical bar indicates typical ±1σ values near the maximum intensity, as noted in the text this arises partly from fluctuations in source strength on successive orbits The standard deviation of the fluctuations in background level is one-half of this or less The variation in the magnitude of the upper limits is because of changes in the distance of the source from the spin axis, except on December 20 for which the data were of relatively poor quality

FWHM, so that the light curve could be followed over an interval of 46 d The light curve is given in Fig 1 in units of counting rate in our detector, which can be converted approximately to Uhuru counts by multiplication by 8 In the initial and final periods of observation, the source was rather weak, and could be detected at a satisfactory significance only by overlaying orbits, with a consequent reduction in time resolution The latter improved to one orbit (101 min) when the source was near its maximum brightness We have, for clarity, averaged the intensity over 12 h in this period, but significant intensity variations, exceeding those attributable to counting statistics, were observed in the one-orbit averages Where an upper limit only is given, it corresponds to three standard deviations of the background level

Both at the beginning and at the end of our observation period the emission from the source was detectable It is possible that the event we observed is a rather strong flare of the kind observed in Sco X-1 On the other hand, if it is assumed that the emission rose to the level we observed immediately before our observations, and that it decayed further afterwards, then the X-ray light curve strongly resembles that shown at optical wavelengths by some moderately fast novae, which may exhibit a 'pre-maximum halt', a dip and a rise to the maximum The structure in the light curve on JD 2, 442, 404–5 is real, the emission before and after the sharp peak being at a low level, on which we could place only upper limits The intensity change on either side of the dip exceeds 5 σ, and would correspond to the dip in the nova light curve The X-ray light curve from this source differs considerably from that of Cen X-4 (ref 2) which showed no pre-maximum dip At times when the pointing direction was sufficiently close, another experiment on Ariel V obtained data on the short-period fluctuations which are described in the accompanying letter[3]

We have obtained a position for this source Our experiment is most accurate when another X-ray source of accurately known position is simultaneously in the field of view and we hoped to use Cen X-3 for this purpose Unfortunately from December 17 to January 10, Cen X-3 was in an 'extended low' After this its intensity increased only rather slowly and by this time the brightness of the new source had diminished considerably We were, however, able to obtain four simultaneous observations of the two sources We also observed two other Uhuru sources, 3U1223−62 and 3U1254−69, and a second, new, variable source By considering all the simultaneous observations of these sources with one another and with Cen X-3, we have been able to improve this estimate of the position, with the final result RA 11 h 18 min 59 ± 13 s, declination −61° 35 3 ± 1 8′ These are 1950 coordinates, the errors being ±2σ The position used for Cen X-3 was RA 11h 19 05 min, declination −60° 21′ (ref 4) We note that our observations place both the 3U sources outside of and to the north-east of their 3U error boxes, though by varying amounts, which may indicate a systematic error in our results which is not allowed for in the position error we have quoted We have looked for such a systematic error and failed to find any direct evidence for it On the basis of the position of 3U1254–69, which has the smallest error box, we estimate the maximum value of any error at 4′, such that the source would lie to the south-west of the position given

Although the X-ray emission may now have decayed below the value we first observed, we suggest that optical observation of possible candidate stars may still be worthwhile in view of the periodicity described in ref 3

Observations of a transient X-ray source with regular periodicity of 6.75 min

During planned observations, by the satellite Ariel V, of the X-ray source Cen X-3 (3U1118-60), a previously unreported source nearby was detected by the collimated proportional counter of 100 cm^2 provided by the Mullard Space Science Laboratory The source was monitored over a period of 39 d between December 19, 1974, and January 27, 1975 Here we report measurements of the light curve, spectrum and of a regular variability with period of 6 755 ±0 010 min The position of the source is given in the accompanying letter[1]

The intensity of the source is shown plotted against time in Fig 1 for the period December 19, 1974 to January 1, 1975, during which time Cen X-3 was in an extended low state The first observations on December 19–20, 1974, indicated a weak source of 0 006 photon cm^{-2} s^{-1} keV^{-1} in the energy range 3–30 keV The intensity increased by a factor of four during the period December 20–25, 1974, peaking at a strength of 0 02 photon cm^{-2} s^{-1} keV^{-1} Subsequently, the intensity decayed with an e-folding time of approximately 7 d The intensity at the time of the final observation on January 27, 1975, had fallen to 0 004 photon cm^{-2} s^{-1} keV^{-1} This and other data after January 1, 1975, were taken during Cen X-3 binary off periods

The last two points on Fig 1a show an increase in intensity and are coincident with a predicted[7] binary transition of Cen X-3 from off to on Immediately after this, the spacecraft moved away from Cen X-3 for 7 d It seems likely that this marks the first turn-on of Cen X-3 after the extended low

Spectra of the source have been obtained with 32 pulse-amplitude channels analysing the output from the proportional counter in two energy ranges, 1 5–15 keV and 3 0–30 keV The data discussed here refer predominantly to the former

Table 1 Best-fit parameters

Phase	Coefficient	Power	N_H	χ^2
Before	0 11±0 02	1 10±0 07	(5 5±0 8)×10^{22}	3 2
During increase	0 21±0 03	1 07±0 07	(6 6±0 8)×10^{22}	3 2
At maximum	0 22±0 03	0 91±0 05	(5 8±0 6)×10^{22}	5 3
During decay	0 22±0 03	1 14±0 05	(5 9±0 6)×10^{22}	4 7

Spectra have been obtained from the different regions of the light curve—before and during the increase, at maximum and during the decay In each case, the data are best fitted with a power law spectrum rather than an exponential or blackbody spectrum No such simple model spectrum satisfactorily describes the data, however The best-fit parameters are shown in Table 1, the errors being (χ^2+1) values

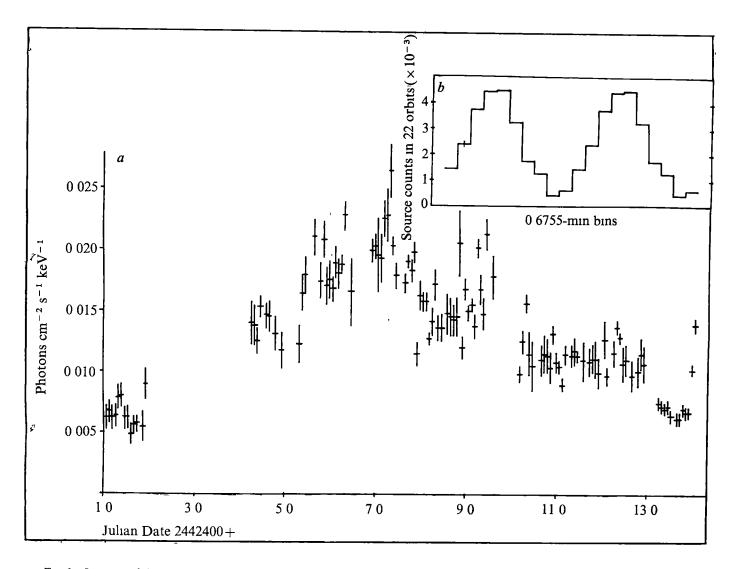
Except for a marginally significant flattening of the spectrum at peak intensity, the spectral shape above 4 keV is constant


Fig 1a Intensity of the source averaged over one orbit (1 6 hours), as a function of time (1 day ≈ 14 orbits) Errors shown are statistical There may be an additional uncertainty of up to 6 % caused by errors in the spacecraft attitude solutions *b* 6 755-minute period light curve of the source The error shown is statistical

throughout the observations The low energy spectrum, below 4 keV, shows a photon deficiency, independent of source model, indicating considerable absorption—amounting to 6×10^{22} N_H atoms cm^{-2}, assuming the abundances of Brown and Gould[2] This value did not change during the observation Measurements of 21-cm emission[3] give a column density to the edge of the Galaxy, in the direction of this source, of $1\,2 \times 10^{22}$ atoms We conclude, therefore, that there is significant absorption from material local to the source

The source intensity was measured on December 31, 1974, with a time resolution of 64 s Periodic variability was apparent in the raw data and by folding the data from successive orbits with trial periods near that observed in the raw data, a period of $6\,75 \pm 0\,03$ min was obtained Data were also obtained with a time resolution of 48 s on January 21 and 23, 1975, when the source strength had decayed to 0 005 photon cm^{-2} s^{-1} keV^{-1} The regular variability was again present with unchanged period, within the limits of the uncertainty of $\pm 0\,03$ min In each case, the depth of modulation was large—greater than 80%

Combining all these data allows the period to be refined to $6\,755 \pm 0\,010$ min The light curve of this periodicity is shown in Fig 1*b* The depth of modulation is 85 ± 3%

As the 6 755-min periodicity and large depth of modulation persisted, unchanged, within the accuracy of our measurement,

to a stage at which the source intensity had fallen below the level of the initial sighting, it is likely that this periodicity is a constant characteristic of the source and not a transient periodicity associated with the flare

Another significant feature of this observation is the constancy of the spectral shape, both in the soft X-ray absorption and higher energy slope

Regular variability in X-ray sources may be divided into two classes—those with periods of a few seconds or less, believed to be associated with the rotation period of a compact star, such as a neutron star, and those with periods of a few hours or more, associated with the orbital motion of a binary system The present periodicity falls between these two groups

The quasi-sinusoidal nature of the light curve seems to rule out an origin for the pulses from beamed radiation from rotating neutron stars, and square wave modulation, as might occur in an eclipsing binary system may also be excluded

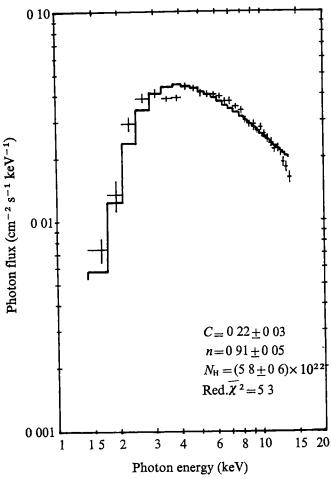
The light curve of the present periodicity is not unlike that of the 4 8-h periodicity of Cyg X-3[4] In a model for Cyg X-3[5,6] the X-ray source is proposed to be a white dwarf associated, in a binary system with a red dwarf The X-ray modulation is the result of electron scattering in a column of material whose optical depth varies with the orbital phase of the white dwarf about its companion


Fig 2 Comparison between the sum of the data collected during five consecutive orbits over the period of maximum intensity and best fitting power law spectrum $(I = C \exp(-N_H)E^{-n})$

If the 6 755-min period is attributable to orbital motion of a binary system, the system must be appreciably more compact than the Cyg X-3 system In this new source, Ariel 1118-61, both objects must be compact

Occurrence of diamond in a mica–garnet lherzolite xenolith from kimberlite

ALTHOUGH graphite has previously been reported from upper-mantle garnet lherzolite xenoliths from kimberlite intrusions, diamond has not previously been found in upper-mantle garnet lherzolite xenoliths from kimberlite intrusions Diamond of primary terrestrial origin is found mainly in the rare ultramafic, potassic rock, kimberlite Although the precise source of most diamonds in kimberlite is unknown it is generally assumed that most of the diamonds originate from the kimberlite matrix itself A few have, however, been found enclosed in eclogite xenoliths of widely varying composition[1-3] and also in rare xenoliths of garnet serpentinite from the Aykhal kimberlite diatreme in Siberia[4] We report here on the occurrence of diamond in a xenolith of garnet lherzolite, the material generally believed to dominate the Earth's upper mantle on density, seismic and experimental grounds

The xenolith (BD2125) was collected from the kimberlite of the Mothae kimberlite diatreme[5] in northern Lesotho During preparation of a thin section, a small, extremely hard grain was encountered Preliminary tests (Moh's hardness > 9, insoluble in hydrofluoric acid HF) and subsequent single-crystal X-ray diffraction proved that it was diamond The crystal is irregular with maximum and minimum widths of 0 8 and 1 4 mm, respectively, it weighs 2 7 mg The precession X-ray patterns show twinning on (111), but the position of the twin boundary is unknown The surface has one near-planar face—identified as (111) by X rays—but is mostly irregular, ranging from rounded parts to irregular hackly parts, perhaps showing multiple exposures of cleavage surfaces or growth features A prominent re-entrant at one end may result from the twinning The diamond is essentially colourless Surface and internal impurities occur, the latter including thin veils and two thin, flat rods about 0 01 mm long lying parallel to the flat face One of the rods is yellow-brown and the other is colourless Two more rods lie close to the surface, and at least one (probably several) body projects inwards from the surface

The host xenolith is angular 6 × 8 × 9 cm The rock is very fresh and has a distinct fabric, with the long axes of the olivine and orthopyroxene grains showing preferred orientation parallel to the longest axis of the xenolith In the terminology of Bouiller and Nicolas[6] the texture is coarse tabular There are some triple boundaries of approximately 120° between adjacent grains, which often have curved grain boundaries, some orthopyroxenes and olivines show undulose extinction This complex texture indicates recrystallisation towards an equilibrium texture (though this is not quite achieved), perhaps with late-stage deformation The mode of the rock is variable, with olivine and orthopyroxene always dominant, garnet is a consistent minor mineral, but clinopyroxene is relatively rare and sporadic The olivine and orthopyroxene grains measure up to 6 mm long, and the garnets are up to 4 mm across, the clinopyroxene grains do not exceed 3 mm in length The garnets are surrounded by a narrow (0 2 mm) reaction rim of clinopyroxene, orthopyroxene and equant brown spinel Three mica crystals were found in the four polished thin sections prepared for electron microprobe study Two of them abut each other next to the reaction rim of a garnet, are about 1 × 0 5 mm in size, show light-brown pleochroism, and are multiply kinked A third crystal in another thin section is similar in all respects

Electron microprobe analyses showed uniform compositions irrespective of texture Representative analyses are given in Table 1 The olivine (Fa_7) and enstatite (Fs_6) are highly magnesian, the latter containing small amounts of Al_2O_3, Cr_2O_3 and CaO The garnet is pyrope-rich with 5 5 weight% Cr_2O_3 and little TiO_2, it thus resembles the pyrope found in most common garnet lherzolites It differs, however, from the garnets in the diamond-bearing garnet serpentinites from the Aykhal kimberlite, in which the two analysed pyropes contain 8 2 and 14 1 weight% Cr_2O_3, respectively In addition, one of the Aykhal garnets contains only 1 9 weight% CaO which, although in this respect resembles some garnet inclusions in diamond[3,7], serves to set it apart from the garnet in the xenolith discussed here The clinopyroxene is a sodic diopside containing small amounts of Al_2O_3 (1 9 weight%), Na_2O (1 5 weight%), Cr_2O_3 (1 6 weight%) The mica is a phlogopite with low TiO_2 (0 14 weight%) and intermediate Cr_2O_3 (0 86 weight%) These values fall in the range for primary micas from peridotite xenoliths[8] In short, the mineral chemistry is quite consistent with that of other upper-mantle, granular, mica-garnet lherzolites[9]

* 1, garnet, 2, olivine, 3, orthopyroxene, 4, clinopyroxene, 5, mica Electron microprobe analyses by Chicago 1974 11-element system Special analyses for minor elements gave TiO$_2$ garnet, 0 075 weight%, olivine, 0 002 weight%, orthopyroxene, 0 014 weight%, clinopyroxene, 0 021 weight% Cr$_2$O$_3$ olivine, 0 029 weight% Na$_2$O garnet, 0 021 weight%

The Ca/(Ca+Mg) ratio of diopside and the Al$_2$O$_3$ content of enstatite provide an estimate[10] of temperature and pressure for pyrope-lherzolites, but the details are controversial The Ca/(Ca+Mg) ratio of 0 451 ± 0 002 for the clinopyroxene from this xenolith indicates an equilibration temperature of 1,040 °C (using the Di–En join of Davis and Boyd[11]) and 980 °C (using new electron microprobe data[12] for the Di–En join at 3 × 10^5 kPa) Four analyses using a Di$_{85}$Jd$_{15}$ standard gave Ca/(Ca+Mg) ratio of 0 449, 0 451, 0 452, 0 452) The empirical fit of Wood and Banno (ref 13, equation 27) to cover the substitution of the minor elements, especially Fe, Al, Cr and Ba, leads to a positive correction of about 70 °C Preferring the direct chemical data[12], however, we tentatively propose an equilibration temperature of 1,050 °C The Al$_2$O$_3$ content, 0 79 weight%, is too low to read from Fig 2 of MacGregor[14], and the spacing of the isopleths is nonlinear An empirical extrapolation of experimental data by Boyd and England together with the correction for minor elements (ref 13, equation 17) yields an estimated pressure of 5 2 × 10^5 kPa, substitution of MacGregor's[14] data yields a value of 4 6 × 10^5 kPa (B J Wood, personal communication) The shield geotherm of Clark and Ringwood[15] passes through 150 km at 1,050 °C, which is fairly consistent with the estimated pressures, and is just inside the stability field of diamond

Apart from the intrinsic interest of this first published record of diamond in a mica–garnet lherzolite, several points should be discussed

First, the irregular rounded shape of the diamond (apart from the flat face which may be a cleavage artefact from preparation of the thin section) is perhaps relevant to the observation[16] that some diamonds are a combination of two distinctive growth forms One represents an earlier stage in which the habit is rounded or mamillary (except for limited octahedral flat faces), and the other is an overgrowth with a distinctly octahedral habit With the proven existence of a rounded diamond in garnet lherzolite, it may be possible to speculate that during the disruption of garnet lherzolite into a kimberlite melt, small rounded diamonds act as nuclei for diamond which precipitates from the magma with a regular habit

Second, the xenolith we have discussed contains phlogopite and the inferred pressure and temperature fall at the upper end of the range for mica-bearing lherzolites[10] Two of the lherzolites described by Boyd[10] contain graphite as well as phlogopite, in contrast to his phlogopite-free specimens which contain no graphite and have inferred pressures and temperatures that place their equilibration within the stability field of diamond If the phlogopite in our xenolith grew in equilibrium with the diamond, it may be inferred that the phlogopite field does extend into the stability field of diamond

Finally, the presence of graphite in garnet lherzolite xenoliths could arise from either primary growth on the low-pressure side of the graphite–diamond curve or from the breakdown of diamond attendant on upward movement of the host lherzolite out of the diamond stability field or from a combination of both factors The latter would occur in a manner analogous to the breakdown of pyrope in lherzolites during their rise to the Earth's surface[17] This may be brought about by upwelling of an upper-mantle diapir connected with kimberlite magmatism (see ref 18)

Age of a new carbonatite locality in northern Kenya

THE ages of carbonatites which occur within the Suregei–Asille Volcanics of northern Kenya cannot be obtained at present by direct radioisotope dating, but can be derived from the ^{40}Ar/^{39}Ar K–Ar isochron ages of intercalated felsic ignimbrites The Suregei–Asille Volcanics crop out over an area of some 1,000 km^2 to the north-east of Lake Rudolf They rest unconformably on the Precambrian basement and comprise several volcanic formations The rock types include flood basalts, Strombolian cinder cones, aa- and pahaoehoe-flows varying in composition from ankaramitic basalt to trachyte, felsic airfall and ash-flow deposits, lahars, carbonatite volcanics, and a variety of reworked volcanic ashes, volcaniclastic and fluviatile sediments

Fig. 1 $^{40}Ar/^{39}Ar$ age spectra and K–Ar isochrons obtained from samples of juvenile volcanic sanidine separated from two strati-graphically adjacent alkaline felsic ignimbrites (ER47RW and ER46RW) from the Gum Dura Formation of the Suregei–Asille Volcanics, northern Kenya In each case the analytical data are plotted both as an age spectrum and as an isochron[2,10] The shape of the age plateau obtained from ER46RW suggests the presence of a minute discrepancy caused by argon loss, but this is seen to have had a minimal effect on the isochron determination The age plateau and K–Ar isochron from ER47RW are perfect examples of the results to be expected from completely non-discrepant dating samples

An important marker horizon within the Suregei–Asille Volcanics is a thin welded ignimbrite of considerable extent This distinctive felsic ignimbrite forms part of the Gum Dura Formation (R T W, unpublished) Within this formation, fine-grained carbonate rocks of volcanic origin are particularly important These newly discovered carbonatites are of exceptional petrogenetic interest first they seem to be pyroclastic rocks emplaced by ash-flow and air-fall eruptions, second, their association is with alkali-basalts and felsic ignimbrites rather than with feldspathoidal lavas and undersaturated alkaline intrusive rocks Elsewhere in the Suregei–Asille Volcanics there are discrete volcanic centres, lava flows and pyroclastic rocks of similar carbonate mineralogy[1] Recrystallisation and silicification are commonly developed in these carbonatites The presence of thick, carbonate-rich horizons within the volcanics which surround and underlie the East Rudolf Plio–Pleistocene sedimentary basin may explain, at least in part, the frequent occurrence of calcite mineralised fault planes, calcite veining and the widespread presence of calcite cementation in the rocks of the basin

Two ignimbrites within carbonatites of the Gum Dura Formation were sampled for dating using the $^{40}Ar/^{39}Ar$ single sample K–Ar isochron technique[2] The first sample (ER47RW) was taken from the prominent marker horizon already mentioned The second (ER46RW) is a check sample from a less extensive ash-flow unit which underlies the first at the collection locality (ref BH810850 on the Kenya National Grid), a river gorge on the Il Dura branch of the upper Il Eriet, some 5 km south of the Kenya–Ethiopia border Discoloration in sample ER46RW suggests that it has been subjected to some kind of weak hydrous alteration that did not penetrate the overlying, more strongly welded horizon Concentrates of euhedral juvenile volcanic sanidine for dating were extracted from each rock sample by crushing and hand picking using a stereoscopic polarising microscope

The results of full $^{40}Ar/^{39}Ar$ step-heating age analysis of the two sanidine concentrates are illustrated in Fig 1 The results from the first dating sample (ER47RW) indicate that it contains only one age component, producing a single plateau on the age spectrum and defining a perfect K–Ar isochron of apparent age $16\ 22\pm0\ 10$ Myr ($^{40}Ar/^{36}Ar$ intercept value 288 ± 4) The

shape of the age spectrum obtained from the check sample (ER46RW) suggests that a slight discrepancy resulting from argon loss may be present, although the isochron plot reveals that any argon loss is virtually insignificant and a nearly perfect K–Ar isochron of apparent age $16\ 14\pm0\ 13$ Myr ($^{40}Ar/^{36}Ar$ intercept value 280 ± 6) was also obtained from this sample The two K–Ar isochron ages are in agreement within the experimental limits, therefore, the marginally superior age of $16\ 22\pm0\ 10$ Myr obtained for the prominent marker horizon can be accepted with confidence Both isochrons intersect the $^{40}Ar/^{36}Ar$ axis at a ratio of less than $295\ 5$, indicating the presence of initial argon which had an argon isotope ratio unlike that in the modern atmosphere thus any conventional K–Ar age determinations or calculations relating to these samples will produce discrepantly low apparent age values The K–Ar isochron age accepted for the upper felsic ignimbrite in the Gum Dura Formation is consistent with, but considerably superior to, previous K–Ar dates from the Suregei–Asille Volcanics In particular, it is in agreement with both the average, conventional K–Ar apparent age of $17\ 3\pm1\ 4$ Myr obtained from a basalt slightly lower in the succession north of the Buluk Gap[3], and with the average, conventional K–Ar apparent ages of $14\ 1\pm1\ 4$ Myr, $12\ 3\pm1\ 4$ Myr and $11\ 6\pm0\ 5$ Myr obtained from basalts higher in the succession along the Suregei Cuesta[4,5]

This precise, geologically acceptable K–Ar isochron age, confirmed from an adjacent but independent ash-flow, is an excellent example of the efficacy of the $^{40}Ar/^{39}Ar$ single sample (or step-heating) K–Ar isochron dating technique In addition, the generation of reproducible, perfect and near perfect isochrons from volcanic sanidines in this study makes it unlikely that complex age spectra obtained from similar analyses of the same mineral (for example, sanidine concentrates separated from pumice occurrences in the reworked tuffs of the East Rudolf sedimentary basin[4,5]) can be explained away or rejected as artefacts of the $^{40}Ar/^{39}Ar$ irradiation technique

The association between voluminous felsic volcanism and carbonatitic ash-flow volcanism in the Gum Dura Formation is unique The firm dating of this extremely unusual episode of carbonatite magmatism at $16\ 22\pm0\ 10$ Myr places it in the early Middle Miocene At this time the Suregei–Asille region

formed part of a shallow structural depression lying between the rising Ethiopian and Kenyan basement swells[6] Volcanism has been important on both swells as well as in the intervening Turkana depression since their inception If, as seems likely, these swells and the rift valleys that eventually developed across their crests can be regarded as the surface expressions of two adjacent mantle plumes, then a detailed knowledge of the sequence and changing petrography of the magmas erupted throughout this East African Rift Province is an essential prerequisite to our understanding of these phenomena Volcanism on the Kenya swell began with the appearance during the Lower Miocene of a number of isolated melanephelinite-phonolite central volcanoes Further north, in the Turkana depression and in Ethiopia, extensive alkali-basalt lineage eruptions with associated ignimbrite volcanism became prevalent around this time

Dissection of some of the large, Miocene central volcanoes in western Kenya and eastern Uganda has revealed that they possess intrusive ijolite–carbonatite cores (for example, Napak[7,8]) The dating of these intrusive carbonatites and their associated ijolites has proved to be particularly difficult It has been suggested from purely geological considerations that an age within the latter part of the range 22–16 Myr may be more reasonable for the central complex of Napak than are those obtained from direct conventional K–Ar age analysis of the core rocks[9] If it can be shown that carbonatite magmas of very different petrogenesis and volcanic association were available contemporaneously in East Africa during the Middle Miocene, then it may be possible to explain these differences in terms of structural setting in relation to the mantle plumes that have dominated East African geology over the past 25 Myr

Origin of magnesium and potassium ions in Lake Vanda, Antarctica

THE Dry Valley area of southern Victoria Land is one of the greatest ice-free areas in Antarctica and contains lakes and soils which are noted for their saline character Particular attention has been focused on the origin of these salts, first because it contributes to an understanding of Antarctic weathering and soil formation, second because it is related closely to the glacial history of the Dry Valley area, and third because it is connected with marine invasion and the Pecten gravels[1] in Wright Valley

Suggested sources for the salts in the Dry Valley area include marine invasion of the valleys, atmospheric precipitation and rock weathering Most published chemical studies reject marine invasion of Wright Valley because of the hydrological barrier created by the valley threshold, although Webb[2] presented convincing palaeoecological evidence for marine penetration of the valley Nakai[3] concluded from the stable sulphur isotopic measurements of sulphates around Lake Vanda, Wright Valley that sulphates in the lake sediments of Hole No 4 of the Dry Valley Drilling Project[4] and sulphate minerals around the lake originated from seawater, indicating marine invasion or atmospheric precipitation The origin of salts in Lake Vanda has also been discussed on the basis of the distribution of evaporites and soil salts[5]

Many workers have analysed six kinds of ions—Na^+, K^+, Ca^{2+}, Mg^{2+}, Cl^- and SO_4^{2-}—in the saline lakes of the Dry Valley area These ions are also main components of seawater The ionic composition of the water in the lakes is, however, different from that of seawater There are extensive deposits of thenardite, halite, sodium nitre, calcite and gypsum around Lake Vanda Therefore, contemporary distributions of Na^+, Ca^{2+}, Cl^- and SO_4^{2-} are likely to bear little relation to primordial levels in the lake On the other hand, magnesium and potassium salts are not found around Lake Vanda except in rare occurrences of epsomite and dolomite Thus, contemporary distributions of Mg^{2+} and K^+ are likely to bear some relation to primordial distribution

Further evidence justifying selection of Mg^{2+} and K^+ for study arises from the types of salts formed during the concentration of brine The ground temperature in Wright Valley averages between $-25\,°C$ and $-30\,°C$ from March until September[6] Therefore, it would be more reasonable to suppose that salts deposit as a result of fractional freezing rather than by normal evaporation In frigid conditions, the concentration curves[7] for Mg^{2+} and K^+ in seawater undergoing progressive cooling exhibit a fairly constant relationship between 0 and $-45\,°C$ Values for the Mg/K ratio range from 3 to 4 There is a steady increase in concentration of both ions down to $-36\,°C$, further lowering of temperature causes sedimentation of magnesium chloride and potassium chloride, and a reduction in concentration These data were obtained during progressive freezing of brine samples, and the thermal history of the lake and its surroundings are probably different, in the natural situation it is probable that Mg^{2+} and K^+ would remain in residual brine without the crystallisation of magnesium and potassium salts Furthermore, if the ionic composition of primordial brine were similar to that of seawater, the Mg/K ratios would remain constant below $-36\,°C$ at which temperature the magnesium and potassium salts begin to crystallise Therefore, it is likely that, under prevailing temperature conditions, the Mg/K ratio was relatively undisturbed during the freezing of brine in the lake

Because of their high solubility any superficial deposits of magnesium and potassium salts on the surrounding land may be washed into the lake From the considerations mentioned already we suggest that the Mg/K ratio of this component will also remain close to the primordial value

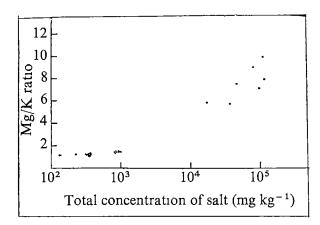
Using the chemical composition data for samples of lake water collected from various parts of Lake Vanda[8] we classified the samples according to the values of the Mg/K ratio Figure 1 shows the plot of the value of the Mg/K ratio against the concentration of total salts (sum of six components) in lake water There are two types of brine in the lake water according to the values of the Mg/K ratio The boundary value is nearly 4, which is the same as that in seawater Since the value of the Mg/K ratio is nearly 1 in freshwater ponds in the Dry Valley area, Mg^{2+} and K^+ in samples for which the ratio is less than 4 probably originate from the weathering of rock and from sea


Fig 1 The Mg/K ratio against the concentration of total salts in water of Lake Vanda

spray These samples exist mainly in the shallower parts of the lake, and are less dense than seawater Rock weathering and sea spray are possible sources for salts throughout the Dry Valley area and these processes are occurring at present

On the other hand, we suggest that Mg^{2+} and K^+ in samples for which the ratio is greater than 4 originate from seawater These samples mainly originate from parts of the lake deeper than about 45 m In comparison with a seawater distribution, however, Mg^{2+} is enriched relative to K^+

Although Mg^{2+} and K^+ have similar concentration characteristics in a progressive cooling situation, this is unlikely to be true for all real situations in which temperature fluctuates Nakai[3] concluded from the stable oxygen isotopic measurements of water in Lake Vanda that most of the present lake waters originate from a freshwater source It is probable that in the initial stages of formation of the lake the isolated seawater evaporated to form salt deposits Since Lake Vanda has no outlet, these salts in the Wright Valley may have been washed into the lake at persistently low temperatures when there was a paucity of liquid water In these conditions Mg^{2+} is 3 to 4 times more soluble than K^+, and $MgCl_2$ $12H_2O$, $MgCl_2$ $8H_2O$ and $MgCl_2$ $6H_2O$ are stable from $-34\,°C$ to $-17\,°C$, from $-17\,°C$ to $-3\,°C$ and from $-3\,°C$ to $117\,°C$, respectively A temperature rise causes a phase change to a less heavily hydrated salt and the liberation of its own water of crystallisation in which the salt dissolves readily On the other hand, deposited potassium chloride requires a much slower diffusion of liquid water into the region of the crystal before solution can occur This mechanism may help to explain the enrichment of Mg^{2+} relative to K^+ during the accumulation of freshwater in the lake

Measurement of the frequency of the methane-stabilised laser at 3.39 μm and of the R(32) transition of CO_2 at 10.17 μm

ACCURATE, infrared, frequency and wavelength measurements now constitute the best means of determining the speed of light, and provide a link between the standards of length and time We measured the frequency of the methane-stabilised He–Ne laser at 3 39 μm, and found good agreement with the result obtained by Evenson *et al*[1] The methane frequency was related to the caesium standard by using both the R(12) transition of CO_2 at 9 3 μm, which has already been measured[2], and the R(32) transition of CO_2 at 10 17 μm

Our result for the $F_2(2)$ component[3] of the P(7) transition of the v_3 band of methane is

$$f_{CH_4} = 88,376,181,610 \pm 70 \text{ kHz},$$

where f_{CH_4} and its uncertainty are rounded to the nearest 10 kHz

The frequency which we obtained for the CO_2 R(32) transition at 10 17 μm is

$$f_{R(32)} = 29,477,160,862 \pm 21 \text{ kHz}$$

The uncertainties consist of the root sum of squares of the random and systematic components which are, respectively, ($\pm$ parts in 10^{10}) 2 1 and 7 4 for f_{CH_4} and 1 8 and 6 8 for $f_{R(32)}$

The laser frequencies were measured by using the harmonic mixing properties of metal–insulator–metal point contact diodes (see ref 2) The frequency measurements were carried out in two stages

$$f'_{R(32)} = f'_{R(12)} - 3f_{HCN} - 27 \text{ GHz} + \Delta f_{beat} \quad (1)$$
$$f_{3\ 39} = 3f'_{R(32)} - 55 \text{ GHz} + \Delta f_{beat}, \quad (2)$$

where $\quad f_{3\ 39} = f'_{CH_4} - 50 \text{ MHz}$

The primes indicate that the frequencies are those of stabilised lasers rather than those of the reference transitions The parameter f_{HCN} is the frequency of an 891 GHz, HCN laser[2], and $f_{3\ 39}$ is that of a 40 mW, single mode He–Ne laser (offset locked to the methane-stabilised laser) introduced to provide sufficient power for harmonic mixing

In stage (1) 39 blocks of 10 readings were obtained on three days over a 12 week period The standard error of the mean, σ_m, of the 39 averages was 1 3 parts in 10^{10} In stage (2) about 60 readings per day were obtained on five days over a three week period For each day's results, σ_m was approximately 1 1 parts in 10^{10} and, because of the larger uncertainty of the correction applied to each daily mean for the background slope, there was no further improvement in the random uncertainty (In each of the two stages the standard deviation of a single reading was about 1 part in 10^9 and the day-to-day variation in the mean corrected result was about ± 3 parts in 10^{10}) The total random uncertainties (parts in 10^{10}) for our $f_{R(32)}$ and f_{CH_4} results, 1 8 and 2 1, respectively, arise from combining 1 3 from the base CO_2 R(12) measurement[2] with 1 3 from stage (1) for $f_{R(32)}$ and with the further 1 1 from stage (2) for f_{CH_4}

The two CO_2 lasers were each stabilised by controlling the frequency with reference to the saturated-absorption dip observed using the 4 3 μm fluorescence[4] from an external CO_2 gas cell Details of these stabilised lasers will be published

O

Table 1 Systematic uncertainties ($\pm$ parts in 10^{10})

Source	Contributions to $f_{R(32)}$ and to f_{CH_4}	
Rubidium standard against caesium	0 3	
Counting errors	2	
Room temperature drift	2	
HCN laser asymmetry*	2	
CO_2 R(12) laser reproducibility	3	
CO_2 R(12) transfer (quadrature sum)†	4 6	
CO_2 R(32) laser reproducibility	3	3
CO_2 R(32) offset from transition centre	4	
CH_4 stabilised laser reproducibility		4
CH_4 offset from transition centre		3
Quadrature sum	6 8	7 4

*An allowance for any difference between the frequency measured by time-averaged counting and that obtained by observing a spectrum analyser display

†The CO_2 R(12) transfer sum combined with a further 4 parts in 10^{10} to allow for offset from the transition centre gives our present estimate of systematic uncertainty (6 1 parts in 10^{10} against the previous 8 3) for the CO_2 R(12) measurement (see ref 2) (The allowances for HCN laser asymmetry and CO_2 laser reproducibility have been reduced as a result of further experimental investigation)

The methane-stabilised He–Ne laser[5] had a d c -excited gain tube which produced maximum power output at a frequency 100 MHz lower than the methane saturated-absorption feature This was a small peak in the output power produced by an intracavity absorption cell 100 mm long, filled to 40 mTorr This cell resulted in a feature only 0 2 % as high as the maximum power output The first-derivative technique used for locking necessitated a correction of about 60 kHz (6 8 parts in 10^{10}) for the background slope The main contributions to systematic uncertainty, including those now considered appropriate to our previous CO_2 R(12) result, are summarised in Table 1

This measurement of the methane frequency agrees well with that of Evenson *et al* (88,376,181,627$\pm$50 kHz) It is of interest that their value, together with four independent measurements of the wavelength, was used in June 1973 by the Comité Consultatif pour la Définition du Mètre to arrive at a recommended value for the speed of light[6] with an uncertainty of $\pm$4 parts in 10^9 Although this uncertainty stems mainly from the determinations of wavelength, and is much larger than the quoted uncertainty of the National Bureau of Standards (NBS) frequency measurements, the good agreement of our result with theirs reduces the chance that some unsuspected error remains, the more so because our experimental method differed considerably in detail, though not in broad principle, from that of the NBS group

The systematic uncertainties associated with the methane-stabilised laser are much reduced in an improved type now being tested, and further frequency measurements will be made These results were communicated (with a provisional assessment of the uncertainties) to the Conference on Precision Electromagnetic Measurements, in London on July 4, 1974

Capillary rise in porous media

Usually the porespace in a porous medium is visualised as a more or less complicated assembly of isolated or interconnected capillaries, and such porespace models are used in describing transport phenomena in porous media If capillary rise of a (wetting) liquid in a homogeneous irregular packing of rotund particles is considered, however, it seems that none of the existing porespace models is capable of explaining, not even qualitatively, the observed phenomena[1]

This may be illustrated by presenting two experiments, the capillary rise of glycol and of *n*-heptane, in a homogeneous packing of polystyrene spheres When equilibrium has been reached, it can be observed that for glycol there is a sharp front between the completely saturated part of the porous medium and the dry part of the porous medium, that is, no saturation gradient is displayed by the system glycol–polystyrene In the case of heptane a wide saturation gradient is observed in the equilibrium situation (Fig 1) Within the conventional porespace models the former result suggests a model of equally sized cylindrical capillaries, whereas the latter result suggests a model of capillaries of varying size It can therefore be seen that these two results lead to inconsistent pictures of what is physically the same packing

Numerous experiments show that the contact angle, θ seemingly has some bearing on this anomaly The contact angle is a notorious parameter to determine for flat smooth surfaces, and for particles (such as beads or sand) a direct determination is almost impossible From the work of Zisman[2] and others it may be concluded that $\theta = 0°$ for heptane–polystyrene and $25°$–$50°$ for glycol–polystyrene Capillary rise of water in sand yields a wide saturation gradient at equilibrium when the sand has been cleaned by heat treatment No saturation gradient (and a lower capillary rise) is observed when the sand is slightly contaminated Apparently, a wide saturation gradient corresponds to θ being approximately zero and the absence of a saturation gradient corresponds to θ being above some critical value

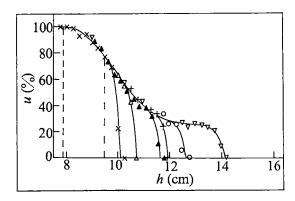
We can explain the correlation between θ and the width of the saturation gradient for irregular sphere packings The basic


Fig 1 Capillary rise of *n*-heptane in a homogeneous packing of polystyrene spheres (particle size 175–250 µm), h is the height above the free liquid surface and u is the volume per cent porespace filled with liquid The results are from two different experiments with two different packings The exact form of the saturation gradient at equilibrium is somewhat uncertain because, at the times involved (10–40 d), secondary phenomena (capillary condensation, temperature fluctuations) become significant The homogeneity of the packing and the liquid saturation is measured using an X-ray absorption technique[5] The absence of a saturation gradient, as for glycol, means, operationally, that the saturation gradient is smaller than 1 mm First experiment after $\times$, 4 h, ▲, 40 h Second experiment after — — — — , 0 5 h, — — — — , 2 5 h, △, 5 h, +, 50 h, ○, 122 h, ▽, 480 h

reason why all porespace models fail is that they entail the presence of a large number of isolated menisci in the 'pores' of the porous medium This is not the case During capillary rise the liquid front consists of one continuous meniscus From this it necessarily follows that the meniscus consists of concave parts separated by anticlastic parts

Anticlastic means that the two main radii of curvature are of opposite sign We shall use the term 'meniscus' as an abbreviation for the 'concave or anticlastic part of the liquid-vapour interphase'

The anticlastic parts or α menisci lie between the adjacent parts of two spheres The concave parts or γ menisci are contained by three or more spheres and three or more α menisci The mechanism of capillary rise is governed by a continuous merging and generation of α and γ menisci in the porespace, consisting of 'cavities' connected by 'windows' Continuity of transport is sustained by two intersupporting mechanisms First, the filling of windows by merging α menisci, (the closure of the window generates new α menisci Second, the filling of cavities by merging γ menisci (the closure of cavities generates new α and γ menisci) Primarily, capillary rise is dependent on the first mechanism—that is, both α and γ menisci contribute to the advancement of the liquid front, but the α menisci are the leading agents The merging α menisci in a window may generate enough new α menisci to maintain continuity of transport by α menisci only The γ menisci are necessary to fill the cavities but they cannot, by themselves alone, maintain continuity of transport, because, on average, the number of γ menisci necessary to close a cavity is larger than the number of new γ menisci generated by the closing cavity

The maximum possible amount of capillary rise is determined by the curvature at which two α menisci merge in the smallest window of the packing, that is in any window between three contiguous spheres For $\theta = 0$ this curvature is given by $Cd = 0\ 11$, where C is the sum of the inverse radii of curvature and d is the particle diameter[4]

The curvature calculated from the observed maximum capillary rise (that is, the top of the saturation gradient, about 14 cm in Fig 1) of various liquids in glass beads and polystyrene spheres yielded values of Cd in the range $0\ 10$–$0\ 12$

As a first approximation the saturation gradient at equilibrium after capillary rise is a function of part of the window-size distribution In an irregular sphere packing there are a large number of smallest windows[3], so it is possible that no saturation gradient is observed when the α menisci filling the smallest windows can maintain continuity of transport, together with the γ menisci Quantitative data on the curvature of α and γ menisci and the statistical properties of particle packings are required to predict the width of the saturation gradient Even for the most simple cases these values are not—or are hardly—known It is known, however, that with increasing θ the curvature of the α menisci decreases more rapidly than that of the γ menisci[4,6] This implies that at higher values of θ the contribution of the γ menisci becomes more important, and thus that less α menisci are necessary to maintain continuity of transport Therefore, the hypothesis is put forward that the width of the saturation gradient decreases with increasing θ Above some critical value of θ the maximum capillary rise is determined solely by the filling of the smallest windows by merging α menisci, and thus no saturation gradient is observed

The modulation contrast microscope

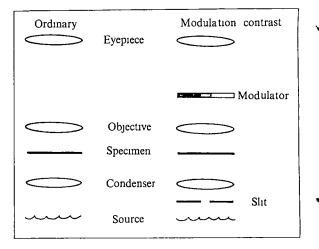
THE 'modulation contrast microscope' is a new type of imaging system with which transparent or phase objects can be visualised with a clarity and contrast equal to, or greater than, that of other light microscope systems A bright field microscope is readily converted into a modulation contrast microscope by the addition of an aperture slit before the condenser and a modulator after the objective in a plane conjugate to the slit, the Fourier plane (Fig 1) The modulation contrast microscope makes visible phase gradients, optical gradients and surface slopes


Fig 1 Modulation contrast microscope schematic compared with bright field microscope

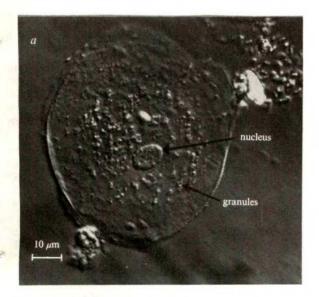
Images viewed under modulation contrast are unobscured by phase objects above or below the plane of focus (optical sectioning) A transparent specimen, the human epithelial cheek cell, when viewed under a $\times 40$ objective, NA0 65 (Fig 2a), reveals nucleus and cytoplasmic granules and cell edges as a three-dimensional image Focused at another level, the cell membrane's corrugated folds and adhering bacteria are resolved (Fig 2b)


Modulation contrast is most sensitive to gradients normal to the slit orientation, the system is directional, as indicated by the direction of the optical shadowing at the boundaries of the nucleus in Fig 2a The image is shadowed in the direction of gradient detection, bright on one side and dark on the other

The resolution of the modulation contrast microscope is shown to be comparable to bright field and interference contrast A test object for the $\times 40$ objective is the diatom, *Pleurosigma angulatum*, the pore spacing of which is at its resolution limit These pores are clearly delineated by modulation contrast

The principles underlying the design of the modulation contrast microscope may be explained by describing the operation of the modulator, a specially designed filter in the Fourier plane An elementary modulator (Fig 3a) has three zones of different transmittances such that there is a dark region, T_D, a grey region, T_G, and a bright region, T_B, with values such that

$$T_B > T_G > T_D$$

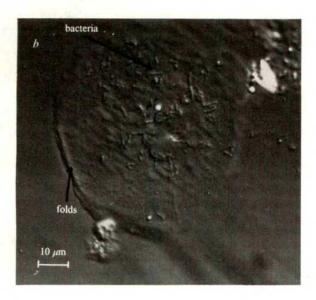
For most objects, transmittance values approximating $T_B = 100\%$, $T_G = 15\%$ and $T_D = 1\%$ provide satisfactory images of a wide range of gradients The modulator is placed in the Fourier plane beyond the objective where the luminous image


Fig. 2 Human epithelial (cheek) cells seen under modulation contrast with ×40 objective, demonstrating optical sectioning. a, Nucleus and cytoplasmic granules seen; b, cell surface without obscuring by lower structures; cell membrane folds and adhering bacteria seen.

of the slit falls on and coincides with the grey region of the modulator. A schematic diagram (Fig. 4) shows that light passing through the specimen where there are no gradients must pass through the grey region of the modulator where it is reduced to 15% of its former intensity and proceeds to the image plane, producing, for the most part, a grey background illumination. Light passing through positive gradients is refracted, in whole or in part, into the bright region, producing brighter features in the microscopic image; negative slopes direct rays which are attenuated by the dark region to produce darker features in the image. This type of modulation leads to an illusion of three-dimensionality which does not represent the geometric object, but the variation in optical density. The modulator affects only light amplitude and does not cause phase changes. Measurements on a Michelson interferometer confirmed phase changes, if any, as below $\lambda/20$.

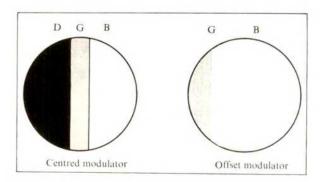
Similarly, the three zones may be regions with different colours, but with transmittance ratios as in a neutral density modulator. Each optical gradient then produces intensities as before, but in colour; similar gradients will have similar colours.

Resolution is dependent on the exit pupil of the Fourier plane which is approximately the bright region of the modulator. In a symmetrical system, where the grey region is on the optic axis, the resolution approaches λ/NA_{obj}, equivalent to axial illumination as described by Abbe. To maximise resolution, the grey region is offset to the edge of the exit pupil; then the dark side of the modulator is outside the exit pupil (Fig. 3b). To match the offset modulator, the aperture slit is also offset. In these conditions, resolution approaches $\lambda/2NA_{obj}$, that of oblique illumination, and is maximised.

An objective containing a modulator can be used successfully for bright field observation of stained specimens by removing the slit aperture.

The theory underlying modulation contrast microscopy shows that phase gradients in the object plane distribute zero order amplitude across the entire exit pupil. The modulator preserves the sign of the gradient, processing differently the zero orders of opposite gradients, and the image contrast and visibility is relative to background intensity, set, primarily by grey region modulator transmittance.

A plane wave entering the system in complex notation, is e^{-ikz} where k, the wave constant in air, is $2\pi/\lambda$ and z is the direction of the optic axis. The wave constant for a ray passing through the object is then $k' = (n_o - n_m)k$ and $z = x\tan\alpha$ where α is the gradient. Let $\varphi = k'\alpha$, then $e^{-i\varphi X}$ describes the wave leaving the gradient. The object function in the Fourier integral is then $e^{-i\varphi X}$ and the maximum energy for different gradients is distributed across the Fourier plane.

When $e^{-i\varphi X}$ represents the gradient in any phase object, then the amplitude function in the Fourier plane is


$$U_{(\theta)} \sim \int e^{-i\varphi X} e^{-i\theta X}/\mathrm{d}X \qquad (1)$$

where θ is the angular dimension in the Fourier plane and φ represents the phase gradient in the object and X is the dimension in the object plane. The amplitude distribution across the Fourier plane is

$$U_{(\theta)} \sim \sin(\theta \pm \varphi)/(\theta \pm \varphi) \qquad (2)$$

For simplicity, the width of the object has been omitted. The maximum amplitude in the Fourier plane for any phase gradient in the object is not at zero angular position, but at $\theta = \pm\varphi$. In the absence of phase gradients, the maximum amplitude would be located at $\theta = 0$, or at the conjugate of the source aperture. In practice, the offset modulator is used. Then, for an incident angle of illumination, γ, φ is replaced by $\gamma \pm \varphi$. For gradients with $\varphi \neq 0$, the zero order amplitude is shifted out of the grey region and is modulated above or below this

Fig. 3 Elementary modulator design with three transmittance regions within exit pupil. a, with centred grey region; b, with offset grey region to maximise resolution.

Centred modulator

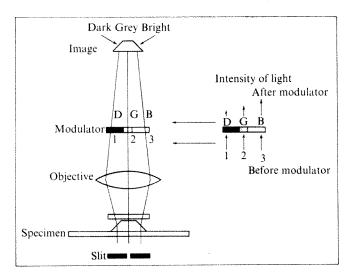
Offset modulator


Fig. 4 Schematic diagram indicating the regions of the modulator which process light from the phase gradients in the object to form an image of contrast. No phase changes are introduced by the modulator.

value by modulator action, producing image contrast. This type of modulation leads to a three-dimensional appearance in the image plane.

Our experimental results are consistent with equation (2). Phase gradients shift the maximum intensity peak (zero order) of the diffraction pattern of a specimen feature away from the grey region and distribute the zero order (as well as higher orders) throughout the Fourier plane. It has been said that the zero order of the pattern carries no information[1]. We have shown this to be untrue. The location of the zero order in the Fourier plane is a measure of the optical gradient. Its intensity, with or without modulator processing, controls the intensity or contrast in the final image; without a modulator, there is no contrast between the gradients and the background. Abbe[2] developed the diffraction theory of image formation for amplitude objects: Zernike[3] extended the theory to phase objects. Dodd[4] discusses his schlieren microscope, stating that gradients shift zero orders. We have carried the imaging theory further by preserving the sign of phase gradients while maintaining full resolution; the theory is described in detail elsewhere[5].

We thank Michael Brenowitz for assistance. Bernard Friedman and the Nikon Instrument Group of Ehrenreich Photo-Optical, Inc. for the use of their instruments and James Rlazarian for assistance in preparing Fig. 2.

Early domesticated sorghum from Central Sudan

LARGE quantities of carbonised *Sorghum bicolor* (L.) Moench grains, spikelets (Fig. 1*a*) and inflorescence fragments sorted from about 2 foot[3] of charred material found in a storage pit at Jebel et Tomat (13° 36′N, 32° 34′E) in Central Sudan (Fig. 2), and small amounts of carbonised sorghum found in eleven levels of the midden excavated there, suggest that sorghum

was the staple grain of people who inhabited the site. The date of 245±60 AD (UCLA 1874M) was obtained from a concentration of carbonised plant remains in the floor of the pit, which was dug into the dark clay loam on which the midden rests (Fig. 3) probably at about the same time as the accumulation of the middle or beginning of the upper unit of the midden. The remains of wickerwork matting and many fragments of thick stalks of cereal grass suggest that the pit may have been a silo lined with stalks and mats. If so, it is not dissimilar to the pits made today in the area for storing grain.

Most of the carbonised sorghum grains examined had 'popped' or become distorted in shape in the process of carbonisation, but sufficient specimens were well enough preserved to indicate the approximate size and shape of the grain. Undistorted carbonised grains were 3–3.4 mm long and 2.3–2.9 mm wide (Fig. 1*b*).

Jebel et Tomat is an inselberg of granite, gneiss and basic igneous rocks. Radiocarbon dates of settlement debris excavated on the jebel indicate the site was occupied from about 40 BC to 430 AD. Charcoals from the excavations identified by the Jodrell Laboratory, Kew, as *Acacia* sp., *Salvadora persica*, *Ziziphus* sp. (probably *Z. spina-christi*), and *Ficus* sp., are evidence that the region was about as arid during the period of midden accumulation as it is today (G. Wickens, personal communication). The abundance of opal phytoliths in the midden further indicates that there was then no scarcity of grass and reeds in the immediate vicinity of the site[1].

The settlement debris suggests a sizeable population, because it covers more than 12 acres and because 80–120 cm, on average, is the depth of the occupation midden, which consists of a grey-brown sandy loam, stony in the upper levels and more compact in the lower but lacking any clear evidence of disconformity. Scattered through the midden were potsherds, grindstone fragments, flaked stone debris and tools, pottery labrets and anthropomorphic and zoomorphic figurines of baked clay, together with bones from food waste, shells, charcoals and fragmentary plant remains. The prehistoric population seems to have been negroid, similar to that from Jebel Moya[2] and, although they were still using stone for cutting equipment and ground axes, a trace of iron is present, together with beads of blue faience and zeolite that were probably obtained through trade.

On the basis of colour, consistency and small changes in lithology, the deposit has been divided into three units the accumulation of which could have followed brief periods when the site may have been abandoned (Fig. 4). Pits for storage and other uses as well as graves dug by the later occupants into the earlier beds have been the cause of no small amount of disturbance. A run of five radiocarbon dates (Table 1) was obtained and these reflect this disturbance since the three lower ones are reversed. The dates obtained, however, confirm the evidence of the cultural remains (pottery and stone tools) that the accumulation represents a single, continuing occupation of not particularly long duration at the beginning of the first millennium AD and so broadly contemporary with Meroitic civilisation in Nubia. The well known site of Jebel Moya, some 60 km to the east and excavated in 1910–14 by Sir Henry Wellcome[3], is believed to be in part contemporary with Jebel et Tomat since the pottery traditions from both are similar.

The economy at both Jebel et Tomat and Jebel Moya was one of mixed farming. At Jebel et Tomat most of the meat was obtained from domestic cattle and sheep/goats, supplemented by fishing, fowling and the hunting of gazelle and small antelope; *Pila* shells were also collected, either for food or bait.

Examination of the carbonised plant material led to the following conclusions:

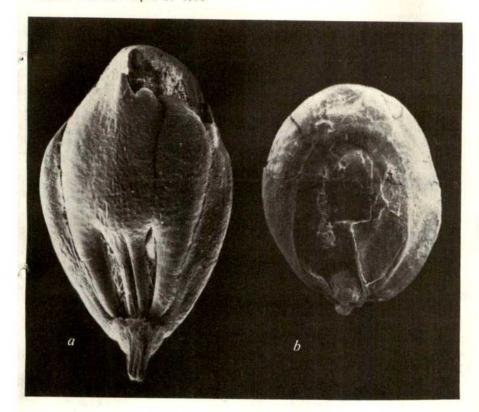
(1) The sorghum from the storage pit was fully domesticated, domestication being indicated by the loss of anatomical features which facilitate dispersal of seed by natural agents. Spikelets bearing grain in the storage pit were still attached to branchlets of the inflorescence or rachis fragments. If the sorghum were not domesticated, the spikelets bearing the grain


Fig. 1 *a*, Electron micrograph (×12) of spikelet of *Sorghum bicolor* (L.) Moench race bicolor, from the storage pit excavated at Jebel et Tomat. The top of the grain expanded in the process of carbonisation. Attachment of branchlet of the inflorescence indicates that this is domesticated sorghum. Photo: J. N. Brunken, *b*, Electron micrograph (×12) of a carbonised grain of *Sorghum bicolor* race bicolor from the Jebel et Tomat storage pit. This view shows the embryo. Photo: J. N. Brunken.

would have been separated from the supporting branchlets by formation of a zone of abscission at the base of the glumes which facilitates dispersal of seed.

(2) The sorghum from the storage pit belongs to the race bicolor of *Sorghum bicolor*. This is indicated by the fact that the grain is fully enclosed by the glumes[1]. The size and shape of the carbonised grain and spikelets are well within the range of variation of cultivated sorghum of race bicolor grown in many parts of Africa at present.

(3) There is no readily apparent difference in the shape and size of sorghum grains found in various levels of the midden excavated at Jebel et Tomat when compared with sorghum from the storage pit.

(4) Sorghum grain preserved in the storage pit and midden is smaller and more 'primitive' in morphology than that grown in the area at the present. There are several possible explanations for the apparent difference.

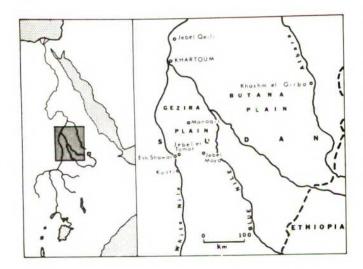
First *Sorghum bicolor* race bicolor preserved in the storage pit at Jebel et Tomat may have been only one of several kinds of sorghum grown in the area 1,700–1,900 yr ago. Larger-grained sorghum may have been stored in other pits which simply were not preserved.

Second *Sorghum bicolor* race bicolor may represent the only kind of sorghum grown at Jebel et Tomat but may not be an indication of how much progress had been made in selection of highly derived sorghums in other parts of Africa by 245±60 AD.

Third sorghum from Jebel et Tomat may indicate the progress made by 1700 BP in the course of selection of highly derived sorghums now grown in the north-eastern part of the African savanna. If so, the selection and change resulting in the greater size and the morphological characteristics of sorghums now typical of much of Central and southern Sudan may have occurred in the last 1,700 yr.

Table 1 Radiocarbon dates from the prehistoric settlements at Jebel et Tomat and Jebel Moya

Sample	Jebel et Tomat excavation	Location	depth (cm)	¹⁴C date (yr b.p.)	AD/BC date
UCLA1864	T.T.1	Upper unit A/1	40–50	1,600±80	350±80 AD
UCLA1874I	T.T.1	Middle unit A/0	60–70	1,930±60	20±60 AD
UCLA1874J	T.T.1	Middle unit A/1	70–80	1,770±60	180±60 AD
UCLA1874K	T.T.1	Middle unit A/1	80–90	1,735±60	215±60 AD
UCLA1874M	T.T.1	Upper/Middle Unit A/O (Storage pit)	110–120	1,705±60	245±60 AD
SUA-67	Soil pit on periphery of midden	Dark clay loam	40–80	4,540±200	2,590±20 BC
	Jebel Moya				
UCLA1874D	Test pit: western perimeter	Compact light brown gritty sandy loam (unit 3)	80–90	4,200±80	2,250±80 BC
UCLA1874E	Test pit: western perimeter	Compact light brown gritty sandy loam (unit 3)	90–100	4,200±80	2,250±80 BC

The above dates are on charcoal excepting SUA-67 which is on shell.


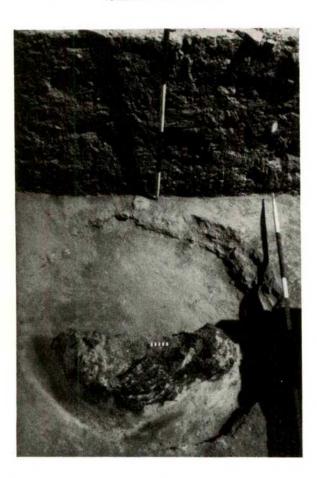


Fig. 2 Map of the area and the sites referred to in the text.

In the Jebel et Tomat excavations no evidence of dwelling or other structures was found, so these are most likely to have been built of temporary materials—grass or mats and poles—and to have been either easily transported (if the population was nomadic) or rebuilt every year, in either case without leaving any permanent record. Considering all the evidence available on the palaeoecology[5] and economy of Jebel et Tomat and other sites in central Sudan, it seems most probable that the Jebel et Tomat population of the early first millennium was transhumant, living along the Nile from mid-January to June

Fig. 3 Lower part of the storage pit dug into the dark clay loam, showing one half of the concentration of carbonised plant remains. Photo: J. D. C.

when they moved east with their herds to Jebel et Tomat to graze the Manaqil ridge and the surrounding grasslands. Sorghum and, no doubt, other crops such as dukhn (*Pennisetum americanum*) and lubia (*Vigna* supp.) were planted in the summer growing season and reaped in November–December after which the people moved west to the Nile again. Such a pattern is not unlike that followed today.

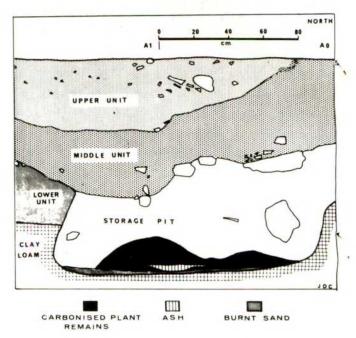
The evidence from Jebel et Tomat is not alone in indicating the importance of sorghum in economies of Central Sudan in the early part of the present era. Sorghum, provisionally identified as the bicolor race (Eklass Abd El Bari, personal communication) has been found at Handal, a somewhat later site in Nubia. Also from Nubia comes a bouquet of sorghum


Fig. 4 North-South section across centre of storage pit containing carbonised Sorghum, Jebel et Tomat; excavation T.T.1.

inflorescences of race bicolor (identification verified by J. R. Harlan and J. M. J. de Wet, personal communication) found in a (?)ritual pit dug into a late Meroitic pavement at Qasr Ibrim[6].

In the engraving of the Meroitic King Sherkarer (12–17 AD) at Jebel Qeili in the southern Butana, about 60 km north of Khartoum, heads of sorghum appear to be represented (ref. 7 pages 51 and 159) and millet, presumably sorghum, is referred to in particular by the geographer Strabo following his visit to Egypt in 25–24 BC. He stated: "The Ethiopians live on millet and barley from which they also make a drink . . ." He goes on to say "But some have grass as food, as also tender twigs, lotus and reed roots; and they use meats, blood, milk and cheese"[8]. This suggests that cereal cultivation had not yet become universal on the Nubian Nile and was probably subsidiary in importance to stock herding, as it is today.

Evidence cited above suggests that sorghum was a major crop of the Meroitic Kingdom, but how much earlier it was domesticated remains to be shown. Both Jebel et Tomat and Jebel Moya shared a number of cultural traits in common with what has been called the Butana Industry from Khashm et Girba in the Atbara drainage some 340 km to the east north-east where there are similar substantial midden accumulations at six sites. Site N125 is not yet excavated, but a charcoal sample (Tx445) from *in situ* in a test pit gave a result of 4,410±90 b.p. (2460 BC), in general agreement with the earlier dates at Jebel et Tomat and Jebel Moya[9]. All these sites belong to a single long lived cultural tradition that had its beginnings in the

early third millennium BC in the Khartoum Neolithic and that, in its later stage, shows a number of traits in common with Meroitic culture in the centuries immediately before and following the beginning of the present era. It is not inappropriate to term this the "Jebel Moya tradition" and, when a search for plant remains from the third millennium settlements is carried out, it would not be unexpected if an early form of domestic sorghum were found to be present.

We thank Rainer Berger for the radiocarbon dates; Gerald Wickens for charcoal identifications; Donald Adamson for identification of sponge spicules in the Jebel et Tomat pottery; Eklass Abd El Bari for information on her provisional identification of the Handal sorghum; and Peter Shinnie for information on the Nubian sites yielding sorghum. We also thank Andrew Smith, Daniel Stiles and Kenneth Williamson who took part in our excavations and were responsible for analysis of cultural and faunal material; Martin Williams and Donald Adamson for their help and close collaboration in the field; the Sudan Department of Antiquities and members of the Departments of Botany, Geology and Archaeology at the University of Khartoum; and Betty Clark for secretarial assistance. The archaeological investigation was made possible by grants from the British Academy and the Ford Foundation.

First direct evidence of life under Antarctic shelf ice

A TOPIC of current interest to Antarctic marine biologists is the possibility of a biome at considerable distances from the open sea under the vast, permanent ice shelves that fringe areas of Antarctica. Such biological information is one of the aims of the present Ross Ice Shelf project[1], an attempt to drill through ice 500 m thick at 82°30'S, 166°00'W, a site 450 km from the ice front in the Ross Sea. We have already obtained, under unusual circumstances, direct evidence of a biome under shelf ice at least 100 km from the open sea.

During the 1973–74 austral summer we carried out a limnological survey between latitudes 70°48'S and 71°20'S on the west coast of Alexander Island (Fig. 1). King George VI Sound, which separates the island from the continent (Palmer Land), is covered by shelf ice 100–500 m thick[2]. The shelf ice receives glacier ice from both Palmer Land and Alexander Island. The resultant force is towards the northwest and rows of pressure ridges, 10–15 m high, lie along the west coast of Alexander Island in this latitude.

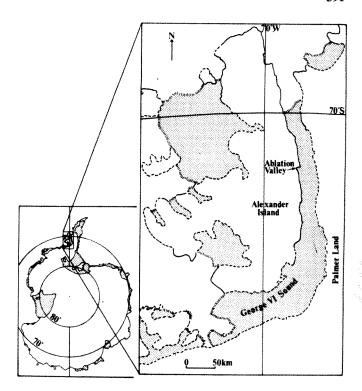
We caught four specimens of a common Antarctic marine benthic fish, *Trematomus bernacchii*, in a large (5 × 4 km) proglacial lake, lying in Ablation Valley (70°49'S, 68°25'W), (Fig. 2). The lake is over 117 m deep and has a permanent ice cover, 4.0–4.5 m thick in winter, 2.5–3.0 m thick in summer. The annual mean air temperature is approximately −9 °C. Ice


Fig. 1 Outline map of Alexander Island and its position in Antarctica. Ice coastline definitive/approximate is shown by continuous/dotted line. Ice shelf, stippled area. Front of ice shelf, dashed area.

from the Sound pushes into the lake along the 70 m depth contour for 3.4 km. Salinity measurements revealed that the top 55 m of water were fresh (0.1–1.0‰) but below 66.5 m the salinity was 32‰. The halocline was very steep and between 66.00 and 66.25 m the salinity rose from 18 to 31.5‰. The lake surface moved up and down with an irregular diurnal tidal rhythm. Variation in salinity profile with tidal movement indicated that the saline layer was in direct contact with the seawater of the Sound. The seawater extended for 4.0 km into the lake. Approximately 12% of available light entered the lake during the summer and we estimate that less than 0.05% reached the seawater layer. Heat gain by the water is restricted by the high latent thermal capacity of the lake and Sound ice, and the seawater. Temperatures remained almost constant throughout the period of investigation, the profile ranging from +0.10 °C to −1.60 °C (seawater). The oxygen content of the water was between 100 and 90% saturation in the freshwater layers, falling to 53% saturation in the seawater layer.

The fish were caught in a trap lying in 70 m of water. Seal meat was used as bait. The statistics of the fish are recorded in Table 1. The fish were in good condition although the weight–length ratios were lower than those recorded by Hureau[3] and Wohlschlag[4] for specimens captured in the equally cold waters off Terre Adelie and in McMurdo Sound. Only one of the Ablation Valley specimens had mature gonads, a female of 12.60 cm standard length. Hureau[3] found that females of the Terre Adelie population became mature when 17.50 cm standard length on average (recorded range 16.20–20.00 cm), males when 14.50 cm standard length (range not given, smallest 13.00 cm). The contrast is sufficient to suggest that the individuals caught in Ablation Valley are of a smaller growth form.

The stomachs of the fish contained the remains of nektonic, planktonic and benthic organisms (Table 2). Muscle tissue attached to crustacean skeletal material indicated that the fish had fed recently. The freshwater layer of the lake has been colonised by a calanoid copepod, *Pseudoboeckella* sp. (average concentration recorded 0.5 individuals l⁻¹, including naupliar stages) but the remains removed from the fish were of different

Fig. 2 Aerial photograph of Ablation Valley. The lake occupies the whole of the wedge-shaped valley floor. King George VI Sound lies in the foreground. (Photography flown by the US Navy for the US Geological Survey).

and larger species. Phytoplankton production measurements by standard radiocarbon technique on 2 d at the height of the summer indicated that the amount of carbon fixed per day was about 60 mg m^{-2} for a zone 20 m deep. The only benthic vegetation seen during a SCUBA search covering about 10,000 m^2 in the freshwater zone was a thin film of algae on the occasional rock jutting out of a silt floor. We conclude that the productivity of the freshwater layer is probably extremely low and insufficient to support a fish population. Furthermore the fish were not adapted to freshwater and showed signs of acute distress when brought to the surface.

A cyclopoid copepod, as yet unidentified, was collected below 40 m depth from water of salinity range 0.6–32‰. The maximum concentration recorded was 0.06 individuals l^{-1}, although only 67 m of tubing were available for the sampling pump and this only just reached the marine layer. Although the cyclopoids were able to tolerate fresh/brackish waters they were presumably more numerous at greater depths.

T. bernacchii is a slow-growing fish of very sedentary habit. Our evidence suggests that there is a marine biome under the

Table 2 Gut contents

permanent ice of King George VI Sound, and in Ablation Valley which lies 100 km (northwards) and 334 km (southwards) from the open sea. There are two areas along the eastern shore of the Sound where the ice is fissured and seawater lies within a metre of the ice surface (Carse and Horse Points). Working through these 'holes' could provide further information on this remarkable biome.

We thank M. Macrae for the loan of his home-made fish-trap, A. Wheeler (British Museum) for identifying the fish, members of the Marine Section, British Antarctic Survey, for identifying some of the stomach contents, and Dr I. Everson for helpful comments.

Lack of response to background colour in *Pieris brassicae* pupae reared on carotenoid-free diet

THE Large White butterfly (*Pieris brassicae* L.) is a toxic species[1], aposematic at all stages of its life-cycle. Probably for this reason, the pupa responds to the colour of its background in a somewhat different manner from that of many other Pierid species, displaying heterochromy (background contrasting) rather than homochromy (background matching). In this respect, there is some genetical variation between different strains (M. R., unpublished).

Gardiner[2] noted that in the Cambridge strain of this butterfly the diapausing pupa is invariably green, whereas most over-wintering cryptic British butterfly pupae are brown, and those of the summer broods green (ref. 3 and Allister Smith, unpublished). Non-diapausing pupae of the Cambridge strain are more labile and respond to background and other environmental cues, by colour changes, varying from silvery white, grey and green to brown, with more or less extensive blotching and freckling with dark brown or black. Non-diapausing pupae of *Papilio polyxenes asterias* Stoll are also more labile[4] than diapausing pupae, which are consistently brown in this species.

When caterpillars of *P. brassicae* (Cambridge strain) are reared on standard artificial diet lacking cabbage[5] (Table 1), virtually devoid of carotenoids (but not vitamin A), both the resulting diapausing or non-diapausing pupae are invariably turquoise-blue in colour, freckled with small black spots (Class 1 of the Oltmer melanisation scale)[6,7]. The cuticular keel and spiracles are white (Table 1). In such specimens (several thousands have been tested) there is no visible response to background, whether the caterpillars or prepupae are exposed to long or short hours of daylight, dim or bright illumination, or reared on smooth-surfaced artificial diet, or on rough-surfaced artificial diet in containers covered with: coarse dark

Table 1 Carotenoids in pupae of *P. brassicae* and their diets (selected examples*)

Food of larvae (not diapausing) at 70 °F	Number and colour of pupae and cuticle	Total carotenoids (μg per g dry weight)	Lutein (μg per g dry weight)	Carotenoids per insect (μg)
(1) Cabbage leaves Greyhound cultivar (2,750 μg per g carotenoids); pupating on wood	12 ♀ (whole) Silver-grey; melanin Class 5 or blacker; yellow cuticular keel	535.5	221.3 (41.6%)	17.75
	13 specimens; cuticle and epidermis only; same coloration	22.6	17.8 (78.8%)	0.24
(2) Artificial diet containing xanthophyll extract; (207 g per 100 g) pupating on wood	10 cuticles + epidermis 8 specimens, green; 2 specimens silver-grey; melanin Class 5 or blacker; yellow keel (indistinguishable from control, No. 1)	16.8	16.8 (100%)	0.15
(3) Artificial diet containing wheat germ; pupating on wood	9 specimens; Turquoise blue; melanin Class 1; white keel	1.2	ND	0.038
(4) Cabbage leaves 'January King' cultivar; pupating on white netting at sides of cage	6 specimens (whole) Green; melanin Class 1; yellow keel; indistinguishable from No. 5	247.6	139.2 (56.2%)	10.7
(5) Artificial diet containing wheat germ and xanthophyll extract from cabbage and β carotene pupating on white netting on sides of cage	6 specimens (whole); green; melanin Class 1; yellow keel; indistinguishable from control, No. 4	286.8	162.4 (56.6%)	8.6
(6) Artificial diet containing wheat germ; pupating on white netting on sides of cage	6 specimens (whole); turquoise-blue; melanin Class 1; white keel	13.7	13.7 (100%)	0.50
(7) Artificial diet containing xanthophyll extract; reared and pupating on glass	20 cuticles + epidermis; green; melanin Class 1; yellow keel	8.8	7.3 (83%)† 1.5 (5,6-mono-epoxy-α-carotene)	0.14

* Extraction methods were as described previously[19]. Other experiments with different cultivars and diets will be published elsewhere. The xanthophyll extract (NBC, Cleveland, Ohio) contained twelve or more different xanthophylls. Lutein made up only 1.4% of total carotenoids (5.4 mg per g dry weight), whereas 5, 6-mono-epoxy-α-carotene (69.7%) was the most abundant single xanthophyll in this extract. Wheat-germ, the overspill of manufactured Bemax, contained traces of four carotenoids—β carotene, lutein, zeaxanthin and flavoxanthin[18]. Hoffman LaRoche supplied β carotene, and Valadon and Mummery extracted the cabbage lutein.
† Contained 1.5 μg g^{-1} 5,6-mono-epoxy-α-carotene (17%) as well as 83% lutein.
ND, not determined.

brown hessian, in deep shade; smooth, light-coloured natural wood, in bright summer sunlight; rough white bath towelling in winter sunlight; or in glass jam jars in various conditions.

If lutein is added to the artificial diet (0.5 ml lutein extracted from African marigold added to 100 g standard diet, (see Table 1)), the resulting pupae are bright green instead of turquoise-blue, with a yellow cuticular keel and spiracles, and Class I black freckling. Lutein can then be shown to be present in the epidermis and cuticle (Table 1). Of 40 such pupae, several responded to the background and developed melanisation to varying degrees (Classes 1–5). Moreover, two were indistinguishable, both in colour and pattern, from the silvery grey and heavily blackened cabbage-fed controls (derived from the same egg batches) pupating alongside them on the wooden walls of the breeding cage and its glass front.

Relatively small (but not less than 1 μg) concentrations of carotenoids per individual seem to be required to mediate background response, since those pupae reared on white cabbage (131.9 μg g^{-1} carotenoids) contain only 1.58 μg of carotenoids per pupa, and are indistinguishable from green cabbage-reared specimens which each contain 12–19 μg per individual. Nevertheless, the 207 μg Xanthophyll per 100 g diet (Table 1) must be close to the lower limit which enables biliverdin and the carotenoids themselves to be partially excluded from the cuticle and epidermis[8,9], since only 6% of these lutein-reared pupae exactly matched the typical silvery grey and black coloration of the controls.

It has been generally accepted[8–11] that the colour and

pattern of *Pieris* and various other Lepidoptera pupae are controlled or modified by endocrine factors released from the anterior end of the body in response to a formidable and confusing array of sensory cues and biological mechanisms. It has been suggested that the melanisation of the cuticle and the distribution of ommochromes in the tissues of *P. brassicae* are controlled by different hormones from those which control the presence or distribution of bile pigments and the carotenoids themselves. Kayser and Angersbach[8], however, believe that the degree of melanisation and bile pigment content are regulated by the same hormonal factor. Our experiments indicate that at least in the case of the Cambridge strain of *P. brassicae*, carotenoids—possibly only lutein—function as a mediator, without which light cues associated with the insects' ability to respond to background do not operate. In the absence of dietary carotenoids the blue bile pigments[12,13] synthesised and released during the fifth larval instar and the 'sensitive' prepupal stage[8,14] remain in the haemolymph and epidermis and are neither re-routed nor degraded as in those pupae which turn silvery grey and black.

It is possible that carotenoids play some role in determining the colour modifications known to be associated with photoperiod, and characteristic of spring and summer broods of many Pierid butterflies[15–17]. It is also worth considering the influence of these substances in examples of circadian rhythms which, it has been suggested, could involve a photosensitive molecule participating in the clock mechanism[18]. In any case careful note should be taken of the carotenoid content of pupae and larvae

of Lepidoptera, whether reared on natural or artificial diet, which are used in experiments involving light cues.

We thank Dr P. Cherbas for his help and encouragement and for allowing us to read his unpublished thesis on Insectocyanin.

Mass production of marine algae in outdoor cultures

TWENTY-FIVE years ago the large scale culturing of unicellular algae was viewed with great enthusiasm as an alternative method for producing protein[1]. This hope diminished by the late 1960s when it seemed that the process was uneconomical because of a combination of technical problems, most notably the recovery of the algal product and its subsequent conversion to a human food and/or food supplement.

Quite recently though, there has been renewed interest in producing single-celled protein by mass culturing unicellular algae. This interest has been stimulated in part by the demonstration that algal systems can be used for both pollution control and protein production by directly recycling the nutrients in wastewater into the biomass of freshwater algae[2]. Recently, it has been shown that a marine counterpart, in which algae are grown on mixtures of wastewater and seawater, can serve the same roles with distinct advantages over freshwater algal cultures[3].

The algae are readily removed by utilising the microscopic organisms as the first link in marine food chains leading to multicomponent and integrated aquaculture systems[4].

As part of our efforts in developing the above process, we have been experimenting outdoors with continuous-flow algal pond cultures, trying to optimise biomass yields. We report here the results of long term experiments conducted during the past two years at Woods Hole, Massachusetts (May–October 1973) and Ft Pierce, Florida (May–October 1974).

The experiments were performed on the Woods Hole Oceanographic Institution dock and adjacent to the Harbor Branch Foundation Laboratory at Ft Pierce. The culture

Table 1 Effect of dilution rate on mean algal yield in two locations

	Mean algal yield (g dry weight $m^{-2} d^{-1}$)	
Dilution rate	Woods Hole (lat. 41°52'N)	Ft Pierce (lat. 27°28'N)
0.25	7.6 (2)	
0.50	12.4 (8)	18.0 (6)
0.75	13.3 (2)	15.3 (1)
1.00	12.4 (1)	23.6 (1)
1.50		0* (1)

Values in parentheses represent number of replicate experiments. Each experiment consisted of determining the steady-state algal yield at the stated dilution rate. The mean algal yields, where applicable were determined by averaging the data from the replicates. Variations from the means were less than $\pm 20\%$.
* Steady-state algal growth could not be maintained and the culture washed out.

units were two replicate ponds each of 2,000-l capacity, (2.3 m diameter and 50 cm deep) and lined with glass fibre. Secondarily treated domestic wastewater was obtained daily from local treatment facilities and stored in polyethylene tanks. Seawater was pumped continuously through 1-μm filters and blended with the wastewater into the ponds at the desired flow rates and mixture. The ponds were well mixed continuously with rotating arms and by recirculation through pumping so that they resembled completely mixed reactors.

Algal yield in a continuous culture is defined as the product of biomass concentration and flow rate on a per unit surface area basis. Thus by varying the dilution rate (fraction of volume turnover per day) in these studies from 0.25 to 1.50, we were able to determine the maximum attainable areal yields. For each dilution rate we establish relative steady-state conditions by maintaining a constant flow rate for 7–10 d.

A true steady state was impossible to establish because algal biomass concentrations were affected by daily variations in sunlight intensity and pond temperatures. Once relative steady-state conditions were established, however, there was no more than a $\pm 10\%$ daily change in biomass concentration. In both studies we added a mixture of 50% wastewater and 50% seawater to the ponds and continuously monitored inorganic nitrogen and phosphorus concentrations to ensure that nutrients never limited algal growth. We estimated algal biomass by measuring particulate carbon concentrations on a Perkin-Elmer 240 Elemental Analyzer; we then converted these values to ash-free dry weights by assuming that carbon comprises 45% of the total organic matter in algae, following experimental determination of this relationship.

Our results indicate that algal yields were relatively constant between dilution rates of 0.50 and 1.00 (average of 12.7 g dry weight $m^{-2} d^{-1}$ in the Woods Hole study and 19 g dry weight $m^{-2} d^{-1}$ in the Ft Pierce study), but were significantly reduced (7.6 g dry weight $m^{-2} d^{-1}$) at a dilution rate of 0.25 and were zero (cell washout) when the dilution rate was 1.50 (Table 1). The experiments at each location had to be spread over the May–October study periods; therefore, effects of seasonal changes in sunlight intensity and temperature were not eliminated as experimental variables. Some of the variations in the results, both in replicate experiments and at different dilution rates (Table 1), could be accounted for by changes in these environmental factors.

In both studies we did not innoculate the ponds with a particular algal species. Rather, when the ponds were first filled with wastewater–seawater mixtures, virtually a monoculture of a marine diatom species was quickly established from the indigenous algae present in the seawater. In the Woods Hole experiments *Phaeodactylum tricornutum* dominated during May and June, followed by *Amphiprora* sp. which prevailed until late August when *Amphora* sp.

became dominant. In late September through October *Amphiprora* sp. returned as the dominant alga. During the entire Ft Pierce experiment *Nitzchia closterium* was the main diatom.

We feel that our results are particularly noteworthy because they represent the first reported experiments on successful mass production of marine algae in fully continuous outdoor cultures that were maintained with little difficulty for the entire study periods indicated. In contrast, virtually all the data available on yields in outdoor cultures of marine and freshwater algae have been attained by intermittent collection in semicontinuous or batch cultures[5-8]. We have also shown the effects of geographical location on algal yields—the average yields at Ft Pierce were more than 50% greater than the average achieved at Woods Hole.

Our results compare favourably with yields of 10–20 g dry weight $m^{-2} d^{-1}$ that have been reported for freshwater algae in several European studies[5,6] and are considerably better than the 5–12 g dry weight $m^{-2} d^{-1}$ attained so far in marine mass cultures[7,8]. They are consistent with Ryther's original estimate[9] that, based on sunlight availability only, a maximum yield of about 27 g dry weight $m^{-2} d^{-1}$ can be sustained in a water body. It seems then not to be possible to achieve yields much above the values we have attained. As has been shown[9,10], these production values are comparable with those for the fastest growing agricultural crops such as sugar and rice.

We thank Holger Jannasch for his critical review of this manuscript. The research was supported by the US National Science Foundation and the Atlantic Foundation.

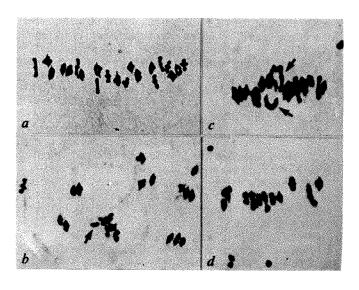
Genetic control of diploid-like meiosis in hexaploid tall fescue

ALLOPOLYPLOIDY has played a vital role in the evolution of plant species useful to man. Hybridisation between related species followed by chromosome doubling has given rise to some of our most important grain, forage and fibre crops. The successful establishment of a sexually reproducing polyploid would, however, depend on the integration of the constituent genomes into a meiotically and, hence, reproductively stable form which could be achieved only by means of a precise diploidising mechanism. In the case of bread-wheat it has been conclusively demonstrated that diploid-like meiotic behaviour is genetically controlled[1,2] and there is a strong indication of a similar control in other crop species, for example, hexaploid oats[3] and tetraploid cottons[4].


Tall fescue (*Festuca arundinacea* Schreb.) is an allohexaploid ($2n = 6x = 42$) comprising diploid genomes of three related diploid species of the *Lolium–Festuca* complex. That the three genomes are homoeologous is borne out by the fact that there is extensive, in some cases complete, pairing in the diploid, auto-

allotriploid and trispecific hybrids between the putative progenitors[5] and that some monosomics isolated by the author are fully fertile and morphologically indistinguishable from the sister euploid plants. Thus, although it contains three closely related homoeologous genomes, tall fescue regularly forms 21 bivalents between homologous chromosomes (Fig. 1*a*) indicating the possibility of genetic control of bivalent pairing. The evidence which strongly points to the presence of such a control is discussed here.

In a cross between the Algerian (*Bn 273*) and Israeli (*Bn 488*) ecotypes of tall fescue, all the five euploid ($2n = 42$) hybrids studied formed 21_{II}. The four euploids from the reciprocal cross (*Bn 488 × Bn 273*) also regularly formed 21_{II} (Fig. 1*a*). A sister plant which was a monosomic ($2n = 41$) numbered 90–64–7 formed some trivalents, quadrivalents (Fig. 1*b*), pentavalents and hexavalents, in addition to bivalents (Table 1). Another three monosomic plants of different genotypic background showed normal bivalent pairing. As all the euploid progeny from the cross *Bn 273 × Bn 488* regularly formed 21_{II} and the other monosomic lines had regular chromosome pairing (Table 1), it is reasonable to conclude that the missing chromosome in the monosomic 90–64–7 is critical for normal bivalent pairing. The consistent formation of 21_{II} in the parents of this cross and in all the euploid hybrids rules out the possibility of the occurrence of translocations in the monosomic 90–64–7. The occurrence of a hexavalent ,or a VI + IV or III, or V + IV or III, or IV + III, or 3 IV in the same cell would further discount the translocation hypothesis. The monosome itself was also sometimes involved in multivalent formation. It can therefore be inferred that multivalents in the monosomic 90–64–7 resulted from homoeologous pairing which was presumably caused by the removal of 'genetic regulator' on the missing chromosome. On this premise it seems that the genetic system controlling bivalent pairing in the hexaploid tall fescue is not effective in the hemizygous state, or at least, is not as effective as in the diploid state.

Clearly, in the other three bivalent-forming monosomics (Table 1), genetic information for the regulation of pairing was not located on the missing chromosome. For want of a full series of monosomics and nullisomics in tall fescue, however, it is not at present possible to conclude that the gene(s) system regulating bivalent pairing is solely confined to this particular chromosome involved in the monosomic 90–64–7.

The above inference receives substantial support from the

Fig. 1 *a–c*, Chromosome pairing in euploid and monosomic *F. arundinacea Bn 488 × Bn 273*; *a*, euploid hybrid with 21_{II}; *b*, monosomic 90–64–7 with 2_{IV} (arrowed) $+ 16_{II} + 1_{I}$ (note stickiness); *c*, monosomic 90–64–7 with $20_{II} + 1_{I}$ showing secondary associations of bivalents into groups of three or two bivalents, lower centre group of five bivalents and the univalent (arrowed); *d*, *L. perenne × F. rubra* hybrid with $12_{II} + 4_{I}$; note five ring bivalents.

Bn 273, Tall fescue from Algeria.
Bn 488, Tall fescue from Israel.

study of meiosis in the tall fescue polyhaploid ($2n = 21$) in which a mean of 4.01_{II} and 12.96_{I} were observed with 7_{II} in nearly 18 % of the cells analysed[6]. These bivalents and a trivalent must have resulted from homoeologous pairing and is in accordance with the theory that the genetic system controlling bivalent pairing is ineffective in the hemizygous state. On the contrary, in wheat[1] and oats[3], the polyhaploids show very little chiasmate pairing because genetic control is effective in the hemizygous state. It also seems that the regulator in the hemizygous state in the monosomic 90–64–7 permits multivalent formation without markedly affecting chiasma frequency (Table 1).

It is interesting to note that there was a conspicuous tendency for secondary associations among bivalents in the monosomic 90–64–7. Chromosome spreading was more difficult because of stickiness (Fig. 1*b*), but even in well spread metaphase plates the secondary associations were clearly evident (Fig. 1*c*). Since secondary associations are now known to take place between bivalents of genetically and evolutionarily related chromosomes[7], it is reasonable to infer that the grouped bivalents have related chromosomes with synaptic potentiality and that they tend to be closely associated, presumably as a result of the relaxation of genetic control in this monosomic.

Further support for the existence of a regulatory system in tall fescue, which is not effective in its haploid complement, comes from the study of several other hybrids and amphiploids between tall fescue and diploid *Lolium* species. Thus, in the 28-chromosome hybrids between *L. multiflorum* ($2n = 14$) and *F. arundinacea* ($2n = 42$), Lewis[8] observed a maximum of 14_{II} in several cells, whereas the mean for three hybrids was 9.52_{II} per cell. Some of these bivalents, and associated trivalents and quadrivalents must have resulted from extensive homoeologous pairing resulting from the breakdown of the regulatory mechanism in the haploid complement of tall fescue. In the amphiploids ($2n = 56$), however, when its full complement was present, and hence the regulator in the double dose, normal chromosome pairing was largely restored. Up to 28_{II} (mean of three amphiploids $= 24.23_{II}$ per cell) were observed and the multivalent frquency was much lower compared to the 28-chromosome hybrids. Since the amount of differentiation between *Lolium* and *Festuca* chromosomes is very low and permits little preferential pairing[5], the synaptic behaviour of the *multiflorum–arundinacea* amphiploids can be explained only on the basis of genetic regulation.

As far as the author is aware, a hemizygous ineffective regulator of diploid-like pairing has not been recorded in any other polyploids of Gramineae or any other family. It may well be, however, of wide occurrence in the grass family. That other polyploid fescues have a similar regulator is borne out by the study of two intergeneric hybrids between *Lolium perenne* L. ($2n = 14$) and *Festuca rubra* L. ($2n = 6x = 42$). Whereas the

parents formed 7_{II} and 21_{II} respectively, the hybrids (Fig. 1*d*) showed a mean of $0.03_{IV} + 0.10_{III} + 11.57_{II} + 4.69_{I}$. Twenty-eight per cent of the cells had 13 or 14 bivalents, and the frequency of ring-bivalents was high (mean chiasmata $= 19.85$ per cell). It seems that there was extensive homoeologous pairing as a result of the hemizygous state of the regulator in the haploid *rubra* complement in these hybrids. In the hexaploid *rubra*, however, no homoeologous pairing is observed because of the fully effective regulator in double dose.

Similar results were obtained in another intergeneric cross between *L. multiflorum* ($2n = 14$) and *F. arundinacea* var. *letourneuxiana* ($2n = 70$) and its amphiploid[9]. Whereas meiosis in the parents is characterised by bivalent formation, the hybrids ($2n = 42$) formed a mean of 13.72_{II}, and several trivalents, quadrivalents, pentavalents and hexavalents. The amphiploid ($2n = 84$), however, showed almost regular meiosis forming predominantly bivalents (mean 38.27_{II} per cell, some cells with 42_{II}). These results of Malik and Thomas[9] and those of Chandrasekharan and Thomas[10] and of several earlier workers like Crowder[11] and Lewis[8] can be more meaningfully explained on the basis of the existence of a 'genetic regulator' in tall fescue and other polyploid fescues, which exercises its regulatory control on homoeologous pairing when it is present in the double dose but is haplo-insufficient.

The hemizygous ineffectiveness of the regulator is clearly of evolutionary significance in that, in the hybrids, it could have permitted the gene flow from one species to another, but subsequent chromosome doubling resulted in stable amphiploids in nature. This would at least partly account for the widespread introgression of characters between taxa.

The possible existence of such a regulator could have important implications for the cytogenetic relationships of the entire *Lolium–Festuca* complex and the strategy of the plant breeder in making use of this group. To avoid loss of the 'genetic regulator' even on one chromosome, more emphasis will have to be laid on incorporating the full complement of hexaploid fescues, for example, tall fescue and red fescue, in the production of agronomically superior, stable *Lolium–Festuca* amphiploids. The precise location of the regulator in tall fescue and other polyploids in the Festuceae could open up new avenues in forage breeding of the type being witnessed in wheat[12,13].

Origin of extragonadal teratomas and endodermal sinus tumours

TERATOMAS are usually differentiated tumours, containing tissues derived from ectoderm, endoderm and mesoderm, and may arise in the gonads or elsewhere. Benign ovarian teratomas are parthenogenetic tumours derived from a single germ cell after the first division of meiosis, as studies of chromosome markers and enzyme variants have shown[1,2]. We have now found that extragonadal teratomas develop in a different manner. We have examined single gene products and chromosomes in extragonadal teratomas and report here our results. We include data on endodermal sinus tumours because of their similarity to teratomas[3,4].

phoretic phenotypes of the following enzymes were determined: adenylate kinase (AK), phosphogluconic dehydrogenase (PGD), phosphoglucomutase (PGM$_1$ and PGM$_3$), glutamic-pyruvic transaminase (GPT) and glucose-6-phosphate dehydrogenase (G-6-PD). HL-A typing was perfomed on Terasaki plates[5] after mild trypsinisation.

The results showed that in four cases normal host tissue was heterozygous at seven loci (Table 1). In all seven situations when the host was heterozygous the tumour was also heterozygous.

Chromosome studies showed that the teratoma of case 3, the patient with Down's syndrome, had trisomy 21 (47,XX,+21) (Fig. 1). If this tumour had been derived from a germinal cell after meiosis, two or four doses of chromosome 21 would have been expected. But there were three doses, as anticipated with normal mitosis. The 46,XY karyotype in the endodermal sinus tumour from a male (case 5) is likewise consistent with mitosis rather than meiosis at the time of inception of the tumour. A 46,XY chromosome constitution has also been observed[6] in a benign sacrococcygeal teratoma.

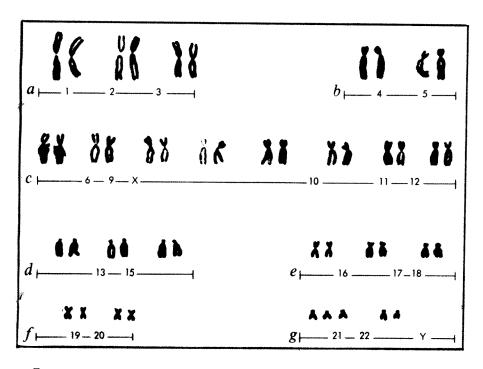
Thus all our results suggest that these tumours develop from a mitotic cell. The cell of origin could be either a somatic cell or a


Fig. 1 Karyotype analysis of cultured cells from a retroperitoneal teratoma in a person with Down's syndrome. The normal host cells and those of the teratoma are 47,XX,+21.

Extragonadal tumours and normal tissues were obtained at surgery from five patients (Table 1). One sacrococcygeal teratoma and two retroperitoneal teratomas were benign, while the two endodermal sinus tumours were malignant. Four of the patients were female. One (case 3) had Down's syndrome.

Tissues were grown in monolayer cultures and the electro-

misplaced germ cell which failed to undergo meiosis and had proceeded directly into mitosis.

G-6-PD data may shed light on the question of whether the tumours have a unicellular or multicellular origin. This enzyme is X-linked[7], and in normal female cells one of the two alleles (*A* or *B*) undergoes random, irreversible inactivation[8,9] early in

embryonic development[10]. G-6-PD heterozygotes with an AB phenotype have two populations of somatic cells, one with the A and the other with the B phenotype. Some tumours such as leiomyomas of the uterus manifest only one G-6-PD phenotype (A or B), suggesting their origin from a single cell[11]. Tumours with a heterozygous G-6-PD phenotype[12,13] are thought to have originated from two or more cells.

The G-6-PD phenotype of the host in case 1 was AB, and so was her sacrococcygeal teratoma (Fig. 2). This teratoma could have originated from several cells, at least one of which was A and the other B. This presupposes that the tumour arose after X-inactivation. The times of X-inactivation and tumour inception in man are, however, too imprecise to know which came first: X-inactivation or the embryonal tumour. Another possibility therefore is that the tumour arose from a single cell before X-inactivation and that by chance in some cells the *A* allele was inactivated, while in others it was the *B* allele. A third possibility—that the teratoma arose from a cell with both G-6-PD alleles active—can be excluded, since no AB hybrid band was observed[14,15].

Reaction of mouse strains to skin test for ectromelia using an allied virus as inoculum

Ectromelia, or 'mouse pox', is a highly infectious virus disease of mice which can be present as a subclinical enzootic or a clinically apparent epizootic condition. As a result of importation of infected mice, an outbreak of this disease occurred in research establishments in the London area during late 1973 and the early part of 1974. These mice showed immunological evidence of infection without overt signs of disease, and those in contact were affected by the acute form of the infection. Detection of the infection is usually effected by one of three methods: inoculation of suspect material on to the choriollantoic membrane of 10-d-old chick embryos, in which typical pocks lesions are produced 3 d later if virus is present; serologically, using haemagglutination test[1]; using the tail scarification test with vaccinia virus, a closely related pox virus, as inoculum.

During the outbreak, screening of large numbers of mice by the Laboratory Animals Centre (LAC) was carried out using the tail scarification method as the principal test. Marked variations in response to inoculation were observed between the different inbred strains screened. Briody[1] gave 1.0×10^4 pock-forming units (PFU) of IDH-E strain of vaccinia as a vaccination dose and noted that reaction to the inoculation varies with the strain at this level of infection, but that at 1.0×10^6 a typical lesion should result.

We have compared the effect of inoculation on a range of specific-pathogen-free (SPF) inbred and non-inbred mice

ND, not done, 0, negative, +, positive Grades of reaction represented by number of plus signs
Mixed reaction represented by subscript plus   *Groups of three mice only

known to be free of ectromelia A total of 24 different strains maintained within the SPF unit of the LAC were tested for their response to the Lister strain of vaccinia and also to a weak strain of the virus donated to the LAC 4–5 yr previously As the strain of this virus is not definitely known, it will be referred to in this paper as the 'LAC' strain Observations were also made on other strains of mice sent for screening on which only the Lister vaccine was used

The virus antigen used for screening was freeze-dried small-pox vaccine (Lister Institute) in 25 dose ampoules for human use, and had approximately $1 0 \times 10^9$ PFU ml^{-1} The weak LAC strain originating from a human vesicle was passaged four times through eggs and assessed as being less than $1 0 \times 10^2$ PFU ml^{-1} Groups of 6 SPF mice between 6 and 8 weeks of age from each of the following strains were used for testing both Lister and LAC vaccine A, A₂G, AKR, B10 A, B10 D2, B10 LP-a, BALB/c, C3H/He, C3H/He-mg, C57BL/10ScSn, C57BL, C57BR, C57L, CBA/Ca, CE, DBA/1, DBA/2, ICFW, LACA, LACG, NMRI, +/nu, NZB Other strains, using the Lister vaccine only, were 129, AKM, B10 A(4R), B10 Y, CBA/H-T6, CBA/Y, CRH, CSI, HTT, NIH, B105R, PY All groups of mice, whether from the SPF unit or sent from outside for screening, were placed in PVC boxes fitted with a filter lid made from sterilised FG50 glass fibre filter material After inoculation, the groups were maintained in similar filter containers until tested

A small area of the dorsal surface at the base of the tail was carefully scraped with a sterile scalpel until the upper epidermal layers were removed and blood was drawn A microdrop of the virus antigen was placed on the scarified area, and the test read 8–10 d later In a positive reactor, the site of inoculation was usually swollen with either a raised pinkish cream blister or had a reddish focal area in the centre of the oedematous tissue In non-reactors the site of scarification had completely healed and returned to normal

Results obtained from the majority of mice inoculated with Lister vaccinia vaccine were good, and those of the LAC vaccine variable (Table 1) A poor response to the Lister strain was noted in only one of the coloured strains, the NZB Fig 1b, a mixed response in five groups, the B10 D2 and +/nu, B10 A(4R), CSI and CRH All albino strains responded very well to the Lister vaccine with very little variation and Fig 1a shows a typical example of a good reaction in AKR strain The coloured strains varied in response slightly but all were recognisably positive (Table 1) Strains A, DBA/2 and C57BL/10ScSn reacted well to the LAC vaccine, as did LACA, C57BL, CBA/Ca The NMRI and ICFW strains, on the other hand, showed a reduced reaction, the C3H/He-mg produced a very weak response and the B10 D2, NZB and the 129 strains were all negative (Fig 1c and d) Variation in response to the Lister vaccine by individuals within a strain was on the whole very limited Some B10 D2 and +/nu did not give a marked response, but all were clearly positive In all other strains the six mice in each group tended to show a uniform reaction

Despite the very low PFU of the LAC vaccine, reactions equivalent to the Lister vaccine occurred in six of the strains tested—A, LACA, DBA/2, C57BL, C57BL/10ScSn and CBA/Ca Three strains showed marked variation—the +/nu, DBA/1 and B10A—which all had mixed positive and negative reactions Three strains were clear negatives—B10 D2, NZB and 129 All other strains, although eliciting a weaker reaction than with the Lister strain, gave clear positive reactions Thirteen other strains were tested with the Lister vaccine Fewer mice were available for testing, but each gave very good positive reactions (Table 1)

The tail scarification method seems to be a very useful method of screening, provided it is carefully carried out It does not seem likely that false negatives would be found using the Lister vaccine with its high PFU Of 37 strains tested all produced a recognisably positive result, and it is fairly easy to read even in poor reactors, as the blisters, however small, are unmistakable It is important, however, that wherever possible the same operator should perform the scarification and application of the antigen, to ensure uniformity of technique The importance of uniformity in technique was indicated by the tests run on the CE strain As a result of a change of technician, irregular results were obtained from both vaccinated groups The test was rerun and uniform results recorded from both groups Also, suitable controls are necessary when testing inbred strains Where possible, SPF mice of the same strain should be used as controls whenever suspect colonies are to be screened

We thank Dr Parish of the Lister Institute for donating the smallpox vaccinia virus

Mitigation of virus-induced foetal growth retardation in mice by dietary casein hydrolysate

EXPERIMENTAL infection of pregnant mice with Coxsackievirus B3 induces retarded foetal growth and development of the plasma proteins[1,2] Subsequent work in mice indicated that the clinically mild illness induced by the virus in the mother may be largely responsible for the impaired foetal development, even though a direct effect of the virus in the foetus could not be ruled

Table 1 Influence of dietary casein hydrolysate supplement on foetal development in mice infected with Coxsackievirus B3

Days of pregnancy when casein hydrolysate is given in diet	Treatment	No of animals	Maternal weight (g)	Total no of live foetuses	Total no of resorptions	Foetal weight (g)	Foetal plasma Alb/AFP

* Standard error foetal weight ±0 172
† Standard error Alb/AFP ratio ±0 103

out[3] The infection resulted in maternal pancreatitis within 2 d, with the animals being incapable of digesting adequate amounts of important dietary constituents, notably proteins, to maintain normal foetal growth[4], in spite of a higher intake of food by the infected mothers We concluded that the pancreatic lesions resulted in infected animals being deprived of essential dietary proteins, and therefore determined whether the effects of the pathogen could be mitigated or perhaps overcome by the administration of a readily assimilable diet

Pregnant mice (20–25 g on day 1 of pregnancy) were fed a powdered diet for breeding rodents supplemented with 10% w/w casein hydrolysate (Sigma, St Louis) On day 8 of pregnancy 0 3 ml of a suspension of Coxsackievirus B3 containing $10^{5.85}$ ml^{-1} of $TCID_{50}$ was given intramuscularly A second group of mice, which received no dietary supplement, was also injected with the same virus suspension

Table 1 shows that the foetuses from the supplemented group at day 18 of gestation, when the experiment was terminated, did not differ significantly in weight from the controls given heat-killed virus suspension, whereas those which had no supplement were significantly lower in weight ($P < 0.01$)

In a second series of experiments dietary supplement was not given until 2 d after the virus suspension was administered The group of mice which had received the supplement was significantly heavier (Table 1) than those which were given live virus alone ($P < 0.01$), but similar in weight to the controls which received heat-killed virus

The plasma protein pattern from each group of foetuses was examined by two-dimensional immunoelectrophoresis Groups which received virus alone had a low albumin/α_1-foetoprotein ratio (Alb/AFP), which has been shown previously to be associated with retarded foetal development[1,2] The Alb/AFP ratio of foetuses from virus-infected mice receiving a diet supplemented with protein hydrolysate was only slightly lower than that of the control group given heat-killed virus (difference not statistically significant) The degree of mitigation was independent of the time when feeding of the dietary supplement began

These results indicate that supplementation of the diet of pregnant mice infected with Coxsackievirus B3, by the addition of suitable quantitites of simple peptides and amino acids in the form of protein hydrolysate, can mitigate the effects of the virus on foetal growth retardation It seems that the dietary supplementation compensates for foetal protein deficiency arising as a consequence of the virus-induced destruction of maternal pancreatic exocrine tissue Immunoelectrophoretic studies of foetal plasma proteins show that this mitigation is not merely limited to increasing the weight of the foetus but also extends to annulling the effects of the virus on the development of the normal plasma protein patterns

Although the results of these studies apply to Coxsackievirus B3 infection, it seems possible that they may also apply to other infections which adversely affect foetal growth indirectly by their pathological effects on maternal organs necessary for optimal foetal development

Mycobacterium microti may protect itself from intracellular destruction by releasing cyclic AMP into phagosomes

PATHOGENIC mycobacteria are able to survive and multiply within macrophages How they do this is not known, but recent quantitative electron microscope surveys of intracellular events in macrophages infected *in vitro* with either *Mycobacterium tuberculosis* or *M microti* revealed a lack of discharge of lysosomes into phagosomes containing live bacilli, whereas dead bacilli were associated with discharged lysosomal contents within phagolysosomes[1,2] Possibly the living bacteria produce a factor which inhibits fusion between phagosomal and lysosomal membranes and thereby prevent the discharge of putatively bactericidal lysosomal contents into the bacterial environment Since high intracellular levels of cyclic adenosine 3',5'-monophosphate (cyclic AMP) mediate pharmacological inhibition of lysosomal discharge in leukocytes[3,4] we reasoned that increased amounts of this nucleotide may occur in macrophages infected with living mycobacteria but not in those infected with dead ones We report here experiments with *M microti* showing that this is so and suggesting a bacterial origin for the additititional cyclic AMP

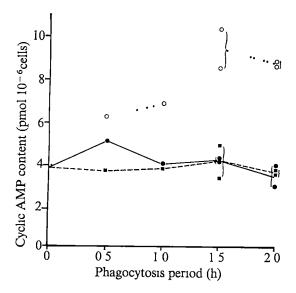
Marked elevation of the cyclic AMP content was observed only in monolayers ingesting live bacilli (Fig 1) Minor disparities in the rates of association of the live and heat-killed bacteria with the macrophages as detected by light microscopy could not account for the difference The increase in cyclic AMP correlated ($P < 0.01$) with the number of cell-associated live bacilli (Fig 2) and was remarkable since in other studies human polymorphonuclear leukocytes showed no change in cyclic AMP content during phagocytosis of latex spheres[9,10] or zymosan[11] Furthermore, macrophages ingesting either bacilli killed by ultraviolet irradiation, latex spheres, colloidal gold or *M lepraemurium* showed little or no increase in cyclic


Fig 1 Macrophage cyclic AMP content during phagocytosis Macrophage monolayers were obtained from CFLP mice (Anglia Alconbury, UK) and 6–13 d later exposed to bacteria and other ingestible particles as described previously[1] except that the cells were maintained in plastic Petri dishes (diameter 5 cm) with about 1 0 × 10⁶ cells per dish M microti was grown in a chemostat in an asparagine–casamino acid medium (Dubos Broth Base, × 4 concentration, Difco) at a dilution rate of $D = 0 016$ h⁻¹ and about 8 × 10⁸ organisms ml⁻¹ Samples were centrifuged, resuspended in infection medium (2 5% horse serum in Hanks' balanced salt solution (BSS)) to yield 1–8 × 10⁸ bacilli ml⁻¹, essentially free of clumps and 100% viable BSS-rinsed monolayers were overlaid with the suspension at a bacteria–cell ratio of 300–2,200 1 for 2 h at 37 °C Monolayers of 8 4 × 10⁵ macrophages were incubated with 4 ml infection medium either alone (■) or containing 2 0 × 10⁸ live (○) or heat-killed (●) M microti ml⁻¹ At 0 5 h intervals monolayers were chilled on ice, rinsed twice with ice-cold BSS and the majority of the cells scraped free into 2 ml BSS After adding 1 ml 12% (v/v) perchloric acid they were briefly ultrasonicated and duplicate aliquots assayed for DNA (ref 5) and cyclic AMP Cyclic AMP was assayed using a competitive protein binding method[6] after initially purifying neutralised aliquots on AG50W–×8 H⁺ resin by washing with 1 mM potassium phosphate buffer, pH 7 0, and eluting with water[7] The number of macrophages per monolayer was calculated from the DNA recovered (28 6 μg = 10⁶ cells) Since bacterial DNA contributed significantly to the total DNA in monolayers exposed to bacteria, the mean of the DNA contents of the resting (infection medium alone) monolayers was used throughout for calculating the cyclic AMP–cell ratios Typically, the coefficient of variation of the resting cell DNA values was about 12% The rates of phagocytosis of living and of dead bacteria were similar, as estimated by light microscopy of the residual monolayer cells stained using Kinyoun's modification of the Ziehl–Neelsen stain[8] Random fields were examined until a total of 200 cells had been counted, the numbers of cells containing 0, 1–10, 11–20, 21–50 or > 50 bacilli were recorded and the mean number of bacilli per cell calculated assuming 0, 5, 15, 35 and 60 per cell in each respective score group

AMP (Table 1) The lack of response with M lepraemurium, in spite of an average of up to 12 cell-associated bacilli per cell, is consistent with the lysosome–phagosome fusion observed with this organism[2] its success as an intracellular parasite may result from a special lipid coat protecting against inimical lysosome contents[12]

That the elevation of cyclic AMP in monolayers exposed to live M microti was not caused by the cellular biochemical events of phagocytosis was suggested by experiments in which monolayers were thoroughly rinsed after a phagocytosis period of 2 h and incubated for a further 2 or 4 d in maintenance medium[1] before assay Increased levels of cyclic AMP were still apparent (Table 1) In this instance the lysosomes were labelled with colloidal gold before phagocytosis of mycobacteria so that lysosome–phagosome fusion could be assessed by electron microscopy[1] of monolayers treated identically to

those assayed for cyclic AMP Phagolysosome formation, as revealed by electron-dense gold particles in the same vesicles as bacilli, was detected only in cells exposed to dead organisms

Although a contribution from macrophage metabolism has not been discounted, the additional cyclic AMP in M microti infected cells could have originated from the bacteria as shown by measurement of their cyclic AMP content and generating capacity Typically, 2×10⁷ bacteria from the chemostat contained 0 24 pmol, this was not changed significantly after 2 h at 37 °C in infection medium but it was lost after heat-killing Thus, if their cyclic AMP content was unaltered during the infection process, 20 live bacteria per cell would have contributed 0 24 pmol to 10⁶ macrophages This is inadequate to account for the 4 pmol increase observed (Fig 2) Allowance must be made for possible underestimation of bacterial numbers by light microscopy with heavily infected cells and for possible increase in the rate of bacterial cyclic AMP synthesis within phagosomes Preliminary studies revealed that the environment of the bacillus can affect cyclic AMP synthesis sufficiently to remove the discrepancy 2 × 10⁷ organisms produced 4 pmol cyclic AMP within 1 5 h at 37 °C in phosphate buffered saline (Dulbecco A, Oxoid, London)

M microti inefficiently retained the synthesised nucleotide, in the chemostat 80% was extracellular and in phosphate buffer 88% was released within 3 5 h The bacillus clearly possesses potential for liberating cyclic AMP into phagosomes in amounts which may inhibit lysosomal fusion Mammalian cells are relatively impermeable to exogenous cyclic AMP (ref 13) If the 3–7 pmol cyclic AMP increment detected 4 d after infection (Table 1) was produced by the bacilli residing in phagosomes of 1 5 × 10⁻¹⁵ (the approximate bacterial volume) impermeable to cyclic AMP an intraphagosomal concentration of about 7 × 10⁻⁵ M could be inferred from the number of bacteria present This is similar to the 10⁻⁴ M extracellular cyclic AMP which inhibited macrophage lysosome fusion[3]

Other successful intracellular pathogens which are able to prevent lysosome–phagosome fusion are Toxoplasma gondii[14], chlamydia[15] and perhaps Neisseria gonorrhoeae[16] Measurements of cyclic AMP levels in cells infected with these agents

Fig 2 Dependence of macrophage cyclic AMP content on degree of infection Data were pooled from five similar independent experiments in which levels of cyclic AMP were determined in macrophages which had been either resting or ingesting live or heat-killed M microti for up to 2 h Symbols and experimental details as in Fig 1 except that the difference in cyclic AMP content between ingesting and resting cells is plotted and the number of macrophages per monolayer and the dose of bacteria varied between experiments Regression of y on x was fitted by the least squares method

Spontaneous progressive multifocal leukoencephalopathy (PML) in macaques

PROGRESSIVE multifocal leukoencephalopathy (PML) is a demyelinating disease of the central nervous system (CNS) which has so far been recognised only in man[1,2] Although it is an infrequent cause of clinical neurological disorder[3], it is of particular interest because of its frequent association

with diseases in which immunological competence is impaired[4-7], and because it is the only chronic demyelinating disease of man in which a virus (papovavirus) has been consistently demonstrated[4,5,8,9] So far, efforts to transmit the disease to non-human primates have failed[8] This report of a spontaneous disease in macaques with striking similarities to PML seems to be the first recorded instance of such a condition in animals

While reviewing the histology of approximately 400 monkey brains collected at autopsy, we found eight macaques (seven *Macaca mulatta* and one *M speciosa*) with lesions similar to those described for PML Electron microscopic examination of formalin-fixed brain tissue revealed papova-like virions in six of these monkeys

A precise age (Table 1) was known for the two animals born in captivity The remaining six were captured in the wild and had been at this centre 23–64 months, all were adults estimated to be over 8 yr old The disparity in sex—seven females and one male—is a reflection of sex distribution of monkeys of this age in the colony All monkeys received isoniazid in their diet while at the centre as prophylaxis for tuberculosis (227 mg isoniazid and 11 37 mg pyridoxine per pound of food)

Macroscopic lesions consisting of soft translucent foci were recognised when slices of fixed brain tissue were examined closely These foci were usually 1–2 mm wide, and were randomly located, mainly in the subcortical white matter (Fig 1), hypothalamus, medulla oblongata and adjacent to the cerebral aqueduct A firm nodule, 1 cm in diameter, was present in the basilar meninges and compressed the adjacent brain in case 7 In case 6, the left optic nerve was encased by a layer of fibrous tissue which extended to the eyeball

Histological foci of demyelination were present in all brains Larger demyelinated areas seemed to result from confluence of smaller foci Most demyelinated foci encompassed or were immediately adjacent to blood vessels

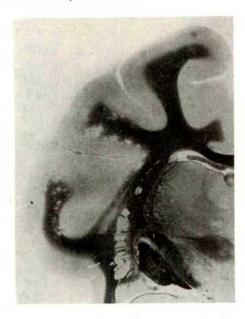
Microglia and large astrocytes (gemastete glia) were present in and adjacent to foci of demyelination Some nuclei of the oligodendrocytes in these areas were enlarged Large polygonal cells, judged to be of astrocytic origin, with eosinophilic fibrillar cytoplasm and large vesicular nuclei, were present among the cellular accumulations (Fig 2) These cells often contained


Fig. 1 Foci of demyelination typical of the changes present in monkeys with PML. (Luxol Fast Blue × 2.3).

multiple nuclei and on rare occasions mitotic figures. Similar focal cellular accumulations were present in the grey matter.

Basophilic and eosinophilic intranuclear inclusion bodies were present in oligodendroglia and astrocytes of all eight monkeys. Cells with inclusions were in or adjacent to lesions in the grey and white matter but varied considerably in frequency from case to case. Eosinophilic inclusions were usually separated from a ring of marginated chromatin whereas the basophilic inclusions filled the nucleus (Fig. 2).

Perivascular cuffs consisting of lymphocytes, monocytes and rarely plasma cells were present in all brains. In three cases the cuffs were prominent but in the other five they were minimal to moderate in extent.

The spinal cords of seven monkeys were examined. Lesions similar to those in the brain were present in four. The optic nerve and retina were similarly affected in two out of five monkeys.

The nodule in the basilar meninges of case 7 and the fibrous tissue surrounding the left optic nerve of case 6 were interpreted as unusual fibroproliferative lesions. A marked reactive gliosis was present in the neuropil adjacent to these meningeal lesions. A similar nodule approximately 0.5 mm in diameter was present in the left frontal lobe of case 5.

Electron microscopic examination was carried out on formalin-fixed brain tissue which had been processed in the usual fashion and embedded in Epon, or, on paraffin sections stained with haematoxylin and eosin which had been re-embedded in Epon[10]. Particles which were round, without envelopes and approximately 30 nm in diameter were found in

cells with inclusion bodies. Some particles were uniformly dense while others consisted of a dense peripheral ring (capsid) surrounding a lucent core. The particles were usually numerous and randomly distributed throughout the nucleus (Fig. 3). Occasionally large or small aggregates formed a lattice or crystalloid arrangement. Viral particles were rarely found in the cytoplasm and no filamentous forms have been observed. In our experience in monkeys, these particles are unique to the cases described here.

Most human cases of PML have occurred in elderly patients with lymphomas or chronic inflammatory processes[1,2]. Others have been associated with immunosuppressive therapy[4,11].

The disease is characterised clinically by progressive neurological abnormalities lasting 3–12 months[3]. In rare cases patients have shown no neurological signs[8] or had no other concomitant disease processes[12-14].

The histological changes are characterised by focal demyelination[1,2]. Large oligodendrocytes and astrocytes, some of the latter having been described as giant and bizarre, are

Fig. 2 Photomicrograph from the periphery of a focus of demyelination demonstrating the typical cellular reaction. A giant cell and a basophilic nuclear inclusion body are present. (Haematoxylin and eosin × 560).

found in and adjacent to the demyelinated foci. Intranuclear inclusion bodies can usually be found in the oligoglia and less frequently in astroglia. An inflammatory cellular reaction is variable, being absent or modest in most cases but prominent in others.

While immunological competence was not determined in the monkeys reported here, observations in other monkeys having

Table 1 Summary of spontaneous progressive multifocal leukoencephalopathy in eight macaques

Case no.	Species	Sex	Age	Neurological signs	Concomitant disease(s)	Severity of CNS lesions	Papova-like virions in glia

spontaneous lymphoma or avian tuberculosis suggest impairment occurs (T. G. Terrell and C. A. Holmberg, personal communication). Isoniazid had been included daily in the diet of these monkeys and it has been suggested that this drug may impair immunological competence also[15,16].

Jungherr *et al.*[17] examined the CNS of macaques experimentally infected with a papovavirus (SV40), and described non-suppurative inflammation. Hypertrophied, or 'pseudo-giant', ependymal cells were observed in some cases but no mention was made of inclusion bodies, or demyelination. All animals were killed on days 17–21 after inoculation.

We believe that the CNS disease described here in macaques has more similarities than differences to PML in man, and is a manifestation of infection by a papovavirus. Further search and evaluation of the factors causing the disease in monkeys may give insight into PML in man and other chronic viral infections of the CNS.

Helper effect of normal and irradiated thymus cells on transferred immunoglobulin production

The cellular transfer of immunoglobulin (Ig) production in mice by various lymphoid cell preparations has been demonstrated previously by the use of allotype congenic mouse strains[1,2]. Lymphoid cell suspensions from one mouse line are injected intravenously into histocompatible but allotype-different, partner-strain mice without deliberate immunisation, and the resulting Ig production ascertained by donor allotype analysis of the sera taken at various times. We have used this transfer system to determine whether anti-μ pretreatment of lymphoid cells results in suppression of subsequent IgG production[2], and in studies on the radiosensitivity of the B cell series (R.E.A., and N.L.W., unpublished). In analysing the results of Ig transfer in such experiments, it has become evident that the possible role of T cells in either augmenting or suppressing the Ig transfer by B cells must be determined, and here we present evidence that such T cell involvement can be demonstrated to varying degrees.

Immunoglobulin transfer between three pairs of allotype congenic strains was studied. BALB/c (Ig^a allotype) and C57BL/6 (Ig^b) mice were used as recipients for spleen cell transfers from the respective donor strains BABB-14 (Ig^b allotype), (Herzenberg), BALB/c.Ig^b N.12 (Ig^b allotype), and C57BL/6.Ig^c (Ig^c allotype) (both Hall Institute). All donor mice were homozygous at Ig loci and were derived by inbreeding after 14, 12 and 6 backcross generations, respectively. Single cell suspensions of donor spleens were prepared from 6–10 week old mice by teasing spleens through stainless steel sieves into 10% foetal calf serum in MEM. All cell transfers were made intravenously to groups of five to eight recipient mice 6–10 weeks of age, that had received 400 rad whole-body irradiation within the previous 24 h. Recipient mice were bled at various intervals and the levels of donor type IgG$_2$ allotype quantitated by radioimmunoassay[3]. All results are expressed as the amount of donor type IgG as a percentage of a standard

Fig. 1 Effect of added thymus cells on Ig transfer by allotype congenic spleen cells. Donor spleen cells—4×10^6 C57BL/6.Ig^c. All thymus cells added at 1:1 ratio. ●, Non-irradiated 7 week old thymus cells; ○, 1,000 rad 7 week thymus cells; △, Non-irradiated 7 month thymus cells. Amount of donor type (Ig^c) Ig was assayed 1, 2 and 4 weeks after transfer and the relative amount of Ig in recipients of added thymus cells expressed relative to the amount with spleen transfer alone. Vertical bars and points show mean $\pm$ s.e.

*All mice (21 out of 21) showed donor type Ig levels in the range 10–40%
†Mean donor level for all mice (17) includes ten mice with ratios in the range 9–40% and a group of seven mice all having <2% donor Ig
The mean value for the ten mice showing >9% donor Ig was 25 8±4 7%, that is, similar to that in the 21 out of 21 intact recipients

adult serum pool of donor strain type In experiments on the addition of thymus cells, cell suspensions were similarly prepared from thymuses of mice of various ages that were syngeneic to the recipient strain

As most of the previous cell transfer experiments have involved whole spleen cell preparations (that is, T and B cells), transferred into sublethally irradiated but otherwise intact recipients (that is, the recipient also has T cells), we first determined the effect of eliminating T cells from the donor inoculum with anti-θ treatment In three such experiments (Table 1, experiments 1–3), anti-θ treated spleen cells were still capable of donor type Ig production after transfer, although in one experiment, a 50% reduction in donor type Ig was observed in the 1 week sample Similarly, the use of spleen cells from nude mouse donors (on CBA (Ig^a allotype) background) transferred into lethally irradiated C57BL recipients also resulted in Ig production As these four experiments all involved transfer into recipients possessing T cells the functional capabilities of which in this context may be radioresistant, we performed one cell transfer experiment with anti-θ treated BALB/c Ig^b spleen cells into homozygous nude BALB/c (Ig^a allotype) mice (of six backcross derivation from BALB/c, Holmes) Whereas 21 out of 21 normal BALB/c recipients had donor Ig levels between 10% and 40% 14 d later (mean 23 2), 7 out of 17 of the nude recipients failed to support any detectable donor Ig production, and the remaining 10 had similar values to the intact mice (range 9–40, mean 25 8%)

These experiments suggest that the level of Ig production by donor B cells is not markedly influenced by either the proportion of T to B cells present in donor spleen preparations, the possible subtypes of T cells present, or the absolute number of transferred T cells These results, however, do not deny the possibility that subpopulations of B cells in the spleen may be relatively dependent on help from T cells, and that in this

system of total Ig transfer without deliberate antigen injection, the past environmental exposure of the donor animal may influence the proportion of these B subtypes in spleen, and, for example, in experiment 1, the population dependent on T cells may be present to a relatively greater degree Resolution of this aspect is being approached by the use of defined B cell populations separated by the Los Alamos fluorescence-activated cell sorter

The results obtained in experiment 5 with transfer of anti-θ cells into nude recipients suggest that some nude mice may be incapable of supporting Ig transfer whereas others can do so It is generally considered that nude mice are devoid of T cells, although several recent studies[4], (Gutman, G, personal communication) suggest that this may not always be the case, and varying numbers of T cells may be found in the lymphoid tissues It may therefore be that this Ig transfer system has an absolute requirement for at least a minimal number of T cells (in either donor cells or host animal), and the 7 out of 17 nude recipients may represent this total T-deficient state Apart from this latter possibility, the present conclusion from these studies is that a large part of the Ig transfer is T-independent

We therefore investigated whether additional T cells would augment or suppress the Ig transfer The basic system was to use added thymus cells of mouse strain syngeneic to the recipient (in both allotype and histocompatibility) Numerous experiments of this type were performed with attention to several variables ratio of thymus to spleen cells, age of thymus donor, strain combination, time of assay post transfer, and effect of irradiation of the thymus cells

The effect of additional thymus cells on Ig transfer ascertained at several times after transfer is shown in Fig 1 Addition of 7-week-old thymus cells at a 1 1 ratio to spleen cells, and using either intact or irradiated (1,000 rad) thymus, resulted in a fourfold increase in donor Ig transfer at 7 d, declining to no difference at 4 weeks Over this period the absolute amount

Table 2 Effects on transferred immunoglobulin production of thymus cell addition to spleen cells

Experiment no *	Donor type immunoglobulin (% standard†)			Relative‡ increase	
	Control	With thymus cells	With irradiated thymus cells	Thymus 400/ thymus	Thymus 400/ control

*The conditions of transfer for each of the experiments in terms of several variables were as follows 1, Spleen donor C57BL/6 Ig^e, thymus donor 10 week C57BL, ratio thymus spleen 1 2, serum assay d 7 2, Spleen donor BABB-14, thymus donor 5 week BALB/c, ratio thymus spleen 1 1, serum assay d 14 3, Spleen donor C57BL/6 Ig^e, thymus donor 7 week C57BL, ratio thymus to spleen 1 1, serum assay d 14 4, As for 3 but 6 d serum assay 5, Peyer's patch lymphoid cell donor BABB-14, thymus donor 5 week BALB/c, ratio thymus to spleen 2 1, serum assay d 13 6, Spleen donor CB57BL/6 Ig^e, thymus donor 1 d old C57BL, ratio thymus to spleen 4 1, serum assay d 14 All recipients are syngenic to thymus donor Irradiated thymus cell suspensions all given 400 rad
†The results are expressed as percentage donor spleen type adult serum pool±s e mean
‡Ratio of donor type Ig levels for groups given spleen cells and irradiated thymus cells to either spleen cells alone or spleen and non-irradiated thymus

of donor Ig was increasing in the control mice, thus indicating a more rapid production of Ig in the thymus-added group, but reaching the same final level The addition of 7-month-old thymus cells had a less pronounced effect, indicating a possible change in the thymus cellular population at this age

A summary of six experiments is given in Table 2 and experiment 3 is depicted in Fig 1 The relative effect of added intact thymus cells assessed 1-2 weeks after transfer shows that in five experiments (control mice not available in number 5) augmentation of Ig transfer was achieved in three, with little change or suppression being observed in the other two In all six experiments, however, addition of irradiated (400 rad) thymus cells gave marked augmentation In four experiments, Ig production resulting from added irradiated thymus was greater than with added non-irradiated thymus

Further studies on the cellular specificity of this effect are in progress, although at present little augmentation has been observed with added bone marrow cells Two observations suggest that these results are indicative of alternative functions of subsets of T cells on the B cell system First, addition of 7-month-old or newborn thymus had relatively little augmentative effect, also indicating that the results are not nonspecifically related to some filler cell function which might be contributed by any added cell, and second, the increased relative effect of irradiated thymus to intact thymus is consistent with the thesis that a subpopulation of T cells can suppress Ig transfer, that is, perhaps analogous to suppressor T cells as described in other systems[5], and that this suppressor population is relatively radiosensitive in comparison to the helper T cell subset, an observation made previously[6,7] Also, the effect of radiation in distinguishing help from suppression was most pronounced with the newborn thymus, perhaps inferring the presence of a relatively greater proportion of suppressors at this age

These results may also infer that the transfer of Ig or antibody production by direct injection of marked thymus cells could be markedly dependent on the relative proportions of helper and suppressor T cells in the thymus cell suspension relative to the 1-2% of contaminating B cells found in most thymus cell preparations[8]

The use of the cellular transfer system of allotypically marked immunoglobulin is now being assessed as a model system for the analysis of the ontogeny of suppressor T cells and also, with appropriate allotype congenic NZB mice, in the role of suppressor T cells in spontaneous autoimmune disease The relatively minor effect of T-cell depletion on Ig transfer reinforces the previous suggestion[2] that inhibition of IgG transfer following anti-μ chain treatment is a result of inhibiting μ-bearing cells which otherwise were destined to switch to IgG secretion Further analysis of this latter point is being made by direct use of cells sorted on the basis of membrane-bound Ig

T-cell dependence of immune response to hepatitis B antigen in mice

THE presence of hepatitis B surface antigen (HB_sAg) in blood is a marker of infection with hepatitis B virus (HBV) Persistence of the antigen in the blood of 'carriers' is a manifestation of proliferation of HBV in liver cells and this carrier state can be associated with various types of liver disease[1] In guinea pigs and chimpanzees, immunisation with HB_sAg in Freund's complete adjuvant (FCA) elicits a cutaneous delayed type hypersensitivity (DTH) response[2,3] It is believed that integrity of the thymus-dependent cell-mediated immune system in man is necessary for resistance to HBV, and that deficiency of cell-mediated immunity could predispose to development of the carrier state[4,5] We therefore investigated the contribution of thymus-derived cells to the immune response to HB_sAg in mice by immunisation of BALB/c mice, mice heterozygous for the nude mutant gene (nu/+), and congenitally athymic mice of the nu/nu strain, using purified HB_sAg

From the plasma of an adult asymptomatic carrier (subtype adw), HB_sAg was isolated by a combination of isopycnic banding and rate sedimentation using CsCl gradients[6] The purified HB_sAg was free of human serum components A reduced and alkylated form of HB_sAg (RA-HB_sAg) was prepared by treating purified HB_sAg (0 5 mg ml^{-1}) with an equal volume of 0 4 M 2-mercaptoethanol for 3 h at 37 °C followed by iodoacetamide in the dark at 4 °C for 1 h Purified HB_sAg was labelled with ^{125}I (carrier-free, Radiochemical Centre, UK) using chloramine-T as an oxidising agent[7], the specific activity was 27–35 μCi μg^{-1}

Four mice from each of the three groups (BALB/c, nu/+ and nu/nu) were injected subcutaneously in four sites adjacent to lymph nodes with 20 0 μg HB_sAg in 0 4 ml FCA The FCA (Difco) contained 0 5 mg ml^{-1} of *Mycobacterium butyricum*, and was supplemented with 4 mg ml^{-1} of *M tuberculosis* (H 37 RA, Difco) In addition four mice from each group were injected similarly with 20 0 μg RA-HB_sAg in 0 4 ml FCA After 18 d all 24 mice received an intracutaneous injection of 10 0 μg HB_sAg in saline in the left hind footpad as a challenge for a DTH response The next day the mice were killed, bled by cardiac puncture, and the spleen was removed and placed in Eisen's balanced salt solution The left hind footpad was amputated and placed in formalin for fixation before preparing sections for histological examination

Serum was tested under code, for antibody to HB_sAg by a haemagglutination assay[8] and for HB_sAg by a solid-phase radioimmunoassay (AUSRIA™)[9] A suspension of 1×10^7 single cells from each spleen was mixed with 1 0 μg ^{125}I-HB_sAg and tested for antigen-binding lymphocytes (ABL)[10] The slides were examined under code for ABL and scored as previously described[11], cells with 5–25 grains above background were scored as lightly labelled, and those with more than 25 grains as heavily labelled DTH reactions were assessed only microscopically, with histological sections of the foot-pads being examined under code The basis for scoring the intensity of DTH reactions was the degree of infiltration of cells of mononuclear type, for example 1+ represented minimal and mostly perivascular infiltration, and 4+ represented massive and diffuse infiltration throughout the section The results are shown in Table 1

In BALB/c mice and in heterozygotes the native HB_sAg induced high titres of antibody to HB_sAg Concurrent titrations on native sera and sera treated with 2-mercaptoethanol

Table 1 Immune response to HB$_s$Ag and RA-HB$_s$Ag in athymic *nu/nu*, heterozygote and normal BALB/c mice

Groups of mice (four per group)	Immunised with	DTH response to HB$_s$Ag*	Mean ABL per 1,000 lymphocytes†			Antibody to HB$_s$Ag (geometric mean titre)‡
			H	L	Total‡	
nu/nu	Native HB$_s$Ag	−, −, +, 2+	0 9	1 9	2 8	0
nu/nu	RA-HB$_s$Ag	+, +, 2+, 3+	0 2	1 7	1 9	0
nu/+	Native HB$_s$Ag	2+, 2+, 3+, 3+	5 5	12 0	17 5	75
nu/+	RA-HB$_s$Ag	2+, 3+, 4+, 4+	2 3	5 5	7 8	45
BALB/c (+/+)	Native HB$_s$Ag	2+, 4+, 4+, 4+	3 9	12 2	16 1	75
BALB/c (+/+)	RA-HB$_s$Ag	3+, 4+, 4+, 4+	2 9	9 6	12 5	53

*Presence and degree of DTH response to HB$_s$Ag were assessed by histological evidence of mononuclear cell infiltration 24 h after intracutaneous challenge, neutrophil infiltration was negligible in all sections
†Antigen binding lymphocytes per 1,000 spleen lymphocytes, H, heavily binding and L, lightly binding (see text) As controls, counts of splenic ABL for HB$_s$Ag in non-immunised *nu/nu*, *nu/+* and BALB/c mice were respectively 0 9, 2 6 and 1 6
‡Differences were significant (*t* test) between group *nu/nu* and other groups for counts of ABL (*P* < 0 005) and antibody (*P* < 0 02)

gave comparable results, indicating that the class of antibody to HB$_s$Ag was IgG Moreover, there were high counts of ABL in the spleen, and a pronounced DTH reaction in the skin Immunisation with RA-HB$_s$Ag gave comparable results for antibody, ABL, and DTH On the other hand, the immune response to HB$_s$Ag and RA-HB$_s$Ag in athymic *nu/nu* mice was weak or absent, as judged by no detectable antibody, minimally raised counts of ABL in the spleen, and lower DTH responses Tests for HB$_s$Ag in serum were uniformly negative

The above findings indicate that in mice, HB$_s$Ag elicits strong DTH responses, and is highly thymic-dependent with regard to requirement for T-cell help for a humoral antibody response The presence in athymic *nu/nu* mice of ABL in the spleen is consistent with the interpretation[12] that such ABL are B cells Although RA-HB$_s$Ag induced only DTH but no humoral immune response in guinea pigs[2], in mice it induced both types, this observation supports the finding[13] that the immune response to RA-HB$_s$Ag varies in different species Thus, it could be suggested that the carrier state for HB$_s$Ag in man is akin to a state of tolerance consequent on failure of T-cell recognition of immunogenic components of this antigen

Human lymphocytes recognise mouse alloantigens

H-2 LD antigens[1] of the mouse major histocompatibility complex and the lymphocyte-activating determinants of the *Mls* (ref 2) locus induce vigorous lymphocyte proliferation and enhance generation of cytotoxic effector cells in allogeneic combinations (ref 3 and D J Schendel, and F H Bach, unpublished) These antigens do not serve well as targets for cell-mediated lympholysis (CML)—a function which in the mouse is performed by the classical H-2 determinants, the SD antigens[4,5] A similar differential function of LD and SD antigens is found in human allograft reactions *in vitro*[6]

Although the polymorphism of the LD antigens clearly is extensive, it is possible that the difference between the LD alleles of two animals of the same species is only a few amino acid substitutions and not enough to allow effective recognition by cytotoxic effector cells It might be expected that with increasing phylogenetic distance there would be a greater difference between the LD alleles of two animals, such that effector cells sensitised against the LD antigens from another species might show positive cytotoxicity towards these antigens

Using human lymphocytes immunised *in vitro* against mouse spleen cells, we confirmed that xenogeneic effector cells are specifically cytotoxic to target cells of the same H-2 type as the sensitising strain[7,8] and found no evidence of differential recognition of any non-H-2 target[9] (see also Fig 1 and Table 1) In this report we describe the fine specificity of H-2 target antigens in xenogeneic combinations The major conclusion is that in xenogeneic as in allogeneic combinations, cytotoxicity is mainly directed towards the H-2 SD antigens, whereas the LD antigens do not function as targets, or do so only poorly

The H-2 complex is divided into four regions K, I, S and D, genes of the K and D regions (H-2K and H-2D loci) determine the H-2 SD antigens, the strong LD antigens are products of genes in the I region Human lymphocytes were sensitised to each of the four strains B10 A(4R), B10 A(2R), AQR, and B10 T(6R), abbreviated 4R, 2R, AQR, and 6R, respectively, and their cytotoxic potential was measured on target cells from each strain The genetic constitution of these strains enables us to assay the importance of the K and D regions versus the I and S regions as targets for cytotoxic effector cells (Fig 2) If the SD antigens of the K and D regions are the prime targets for xenogeneic as for allogeneic effector cells, and the LD antigens do not serve well in this capacity, we would expect that human lymphocytes sensitised to 4R and 2R are equally and highly cytotoxic to targets of these strains and give little or no killing on target cells from AQR and 6R, as a corollary, effectors sensitised to AQR or 6R would give equal and high killing on targets of these two strains and only low killing on targets from 4R or 2R As Fig 1 shows, this is clearly the case

We have carried out nine experiments of this type One was excluded because there was no cytotoxicity on any target and

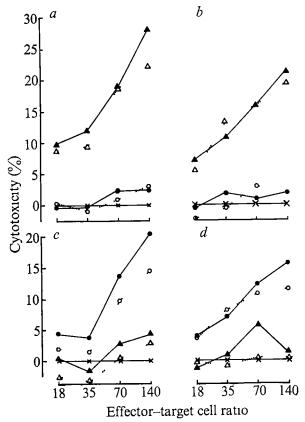
* Activated with LPS (three experiments) or PHA (five) The results have never indicated a difference between the two kinds of targets, and they have been pooled
† Cytotoxicity (%) with 140 (one experiment), 80 (one), or 70 (six) effector cells per target cell Where several ratios were tested in one experiment, 70 1 was used in this analysis
‡ Wilcoxon's signed rank test (one-tailed)
§ Four experiments with each strain gave the same results and have been pooled
‖ Autologous controls Seven different donors were used


Fig. 1 Human effector cells cause specific ^{51}Cr-release from mouse target cells carrying the same H-2 SD antigens as the sensitising strain Targets *a*, 4R, *b*, 2R, *c*, AQR, *d*, 6R Human lymphocytes (12×10⁶) from donor H, purified by Ficoll–Hypaque flotation[10], were cultured with mitomycin C-treated[11] stimulating cells, 24×10⁶ autologous lymphocytes, Hm, or 35× 10⁶ mouse spleen cells, in upright Falcon No 3013 flasks in RPMI 1640 with 7 5% heat-inactivated foetal calf serum, penicillin, and streptomycin After culture for 6 d at 37 °C in 5% CO₂ in humidified air and change of 25% of the medium on days 2 and 4, the viable cells were recovered and mixed at the indicated ratios with 10⁴ ^{51}Cr-labelled target cells and incubated for 3 h according to Alter *et al*[4] The target cells were mouse spleen cells stimulated 2 d previously with LPS

the remaining eight are summarised in Table 1 Two features in particular should be noted First, human lymphocytes sensitised against the I and S regions of the target do not give significantly higher cytotoxicity than lymphocytes sensitised to a different H-2 haplotype (lines 3 and 4, lines 8 and 9) Second, equal killing is obtained when the effector cells are sensitised to the whole H-2 complex or only to the K and D regions of the target (lines 1 and 2, lines 6 and 7) We have obtained similar results on target cells stimulated with LPS (presumably B cells[13]) and PHA (presumably T cells[13]), suggesting that the failure to detect cytotoxicity directed against products of the I and S regions is not an artefact resulting from the tissue distribution of these antigens Table 1 also shows that there is very little difference between the killing by effector cells sensitised to the non-H-2 antigens of the target and by non-sensitised, cultured cells (lines 4 and 5, lines 9 and 10) If species-specific antigens exist in the man–mouse combination, they must, therefore, play a very minor role for cytotoxicity

In conclusion, we have shown that of all the antigens expressed on a mouse lymphocyte surface, human effector cells primarily recognise products of the H-2 K and D regions, presumably the SD antigens themselves, which only constitute a few per cent of all surface proteins[14]

The narrow specificity of cytotoxic effector cells for SD antigens in an allogeneic combination does not seem, therefore, to be the result of a limitation in the number of antigenic determinants which can be recognised, since it is possible to get good cytotoxicity to any number of new determinants presented by xenogeneic cells or generated by chemically modifying syngeneic cells[15] But in both situations it is primarily the products of the H-2 K and D regions which function as targets This suggests that there are important biological

Fig 2 H-2 haplotypes of the strains used in this study 1R and 2R are identical for all the marker loci of H-2 and probably only differ for a chromosomal segment between S and D They have therefore been used equally in these experiments 4R, 1R/2R, and 6R are congenic resistant partners carrying different H-2 haplotypes on the same B10 background AQR was backcrossed four times to C57BL/10 before it was established as an inbred line, it therefore carries a considerable portion of the B10 genome, and studies have shown that it is the H-2 complex of AQR which is most important in allograft reactions with B10 congenic strains[1] All the strains are as a first approximation considered identical except for their H-2 complexes The pairs 4R-1R/2R and AQR-6R are SD-identical, but differ in the I and S regions, whereas 1R/2R-AQR are SD-different but identical for the I and S regions

requirements for target antigens, such as their chemical nature, their density on the cell surface[16] or rate of turnover, which are best fulfilled by the SD antigens These findings raise the question whether tumour-specific antigens can be recognised by cytotoxic effector cells unless they are associated with or modify the SD antigens of the major histocompatibility complex

Properdin factor B and histocompatibility loci linked in the rhesus monkey

IN man, mouse, monkey and dog the major genetic loci for serologically defined (SD) and mixed lymphocyte reacting (MLR) histocompatibility determinants comprise a closely linked gene complex—the major histocompatibility complex (MHC)—on a single chromosome[1-4] Genes controlling immune response in mice are located within the MHC[3] and preliminary data for the rhesus monkey suggest that this species also has these genes within or adjacent to the MHC[5,6] The preservation of the gross structure of this chromosome

region during a long period of mammalian evolution is of considerable biological interest In addition, the demonstration in the mouse of genetic linkage between MHC and resistance to virus infection[7] and leukaemogenesis[8] and the recognition of association between certain HL-A haplotypes and susceptibility to disease in the human indicates that the MHC may be an area of potentially great practical significance in addition to its role in transplantation

Genetic polymorphism of properdin factor B[9] is linked to HL-A in man[10], and the recognition of factor B polymorphism in the rhesus monkey[11] provided the opportunity to test for such linkage in this species Our results suggest close linkage between the *Bf* (factor B) locus and various genetic systems known to be located in the MHC or RhL-A complex of rhesus monkeys[12,13]

Animals studied were part of the breeding colony of the Primate Center TNO, Rijswijk Sera from 76 members of 22 full sibships, which had been sired by one of four males were investigated RhL-A(SD) haplotypes (there are two closely linked SD loci) were determined on the 22 mothers and four fathers (who were unselected and, as far as can be determined, unrelated) and the 76 progeny as previously described[14] Bf phenotypes were determined[11] without knowledge of SD haplotypes in the 76 progeny, three male and 20 female parents Two common Bf types (Bf F and Bf S) and four rare types (Bf G1, Bf G2, Bf S1 and Bf S2) have been recognised[14] and all except Bf G2 and Bf S2 were encountered in these pedigrees Three of the six matings of male No 381 (Bf SS) were uninformative two with a homozygous female and one with a female of unknown type which produced three homozygous progeny Data from the 22 sibships examined are presented in Table 1 Nineteen informative matings include those where maternal or paternal Bf types were deducible from data of multiple offspring In these matings at least one parent was heterozygous for *Bf* genes and the data showed that where a particular *Bf* gene could be followed from parent to offspring it was accompanied by the same RhL-A(SD) haplotype The preliminary assumption made from this observation is that the *Bf* and SD loci lie close together on the same chromosome, that is they are linked If this is the case, chromosomal crossing over between *Bf* and SD loci during meiosis would disrupt this pattern of linkage (if an odd number of crossovers occurred), producing recombinants There were only two certain recombinants, both involving maternal chromosomes In the mating male No 598×female No 832, the gene *Bf^s* of the female was accompanied by the SD d haplotype in AD and BM and its absence with the c haplotype in CN In DS it appeared with the c, however, indicating that DS represented a maternal recombinant In the mating male No 599×female No 493, AX was a maternal recombinant

Lod (logarithm of the odds) scores were calculated in informative families by standard techniques[15] The lod score in males was 10 1 for a recombination fraction (θ) of zero and in females had a maximum value of 5 6 (θ = 0 04) so that the probability of linkage is very high In the total population the maximum lod score was 15 1 (θ = 0 02) and the odds in favour of linkage as opposed to a chance association exceed 10^13 to 1 Corrections for prior probabilities have not been included Three of the four males were heterozygotes for Bf and the most likely phase (whether, in a given animal, specific SD and *Bf* genes are on the same or different chromosomes) can therefore be deduced in one mating Lod scores in males would be even higher if this information were taken into account So far no paternal recombinants have been detected but a higher incidence in females is frequently found in linkage analysis[16] Since the most likely recombination fraction in the pooled data is 0 02, this, if correct, would indicate a map distance of 2 centimorgans between *Bf* and the region coding for serologically defined antigens of RhL-A No evidence for linkage disequilibrium has been found in these studies

In each of two matings with male No 599, one paternal recombination between first and second SD series of RhL-A

was encountered[12] In each case, the Bf type accompanied the first segregant series SD type, suggesting that the Bf locus lies on the first series side of the complex Unfortunately, matings in which recombination occurred between the SD region and the major MLR locus of RhL-A were uninformative for Bf linkage MLR, however, probably also maps on the side of the first RhL-A(SD) locus [17] and if this is confirmed, the following reasoning can be applied AX is a maternal recombinant (Table 1), being of different Bf type but SD identical to her siblings CK and DM In MLR, AX also fails to stimulate or be stimulated by her siblings, indicating lack of recombination between SD and the major MLR loci[17] DS has also been shown not to be a recombinant between the SD and major MLR loci These observations can best be explained by placing the MLR locus between Bf and SD or by placing SD between Bf and MLR Since both Bf and MLR seem to be on the first segregant series side of the rhesus SD complex, the former situation (Fig 1) is the more likely Preliminary data in humans (Ch Rittner, personal communication) indicate that MLR is between SD and Bf in this species

In the mating male No 598 × female No 834, EK has been found to be a recombinant between SD and Ir-GA (a gene controlling immune responsiveness to the linear synthetic polymer of *l*-glutamic acid and *l*-alanine)[6,18] Since EK does not show recombination between Bf and RhL-A(SD), it seems that either the Bf locus lies between SD and Ir-GA or the SD region lies between Bf and Ir-GA A possible situation, suggested by available data, is summarised by Fig 1

The HL-A complex of humans lies on the sixth autosome[19,20] and includes the LA and FOUR series (SD) which are closely linked to MLR, Bf, as well as to PGM₃[16], ME1 and IPO-B[19] There may also be a human Ir (immune response) region in the MHC A region showing striking homology to the human MHC exists in the rhesus monkey, and appears to have been conserved through much of mammalian evolution Bf, apparently closely associated with the MHC, will provide a convenient reference marker for other linkages

This work was supported by grants from the US Public Health Service We thank Miss Lillian Watson for technical assistance and Dr Park S Gerald for invaluable discussion

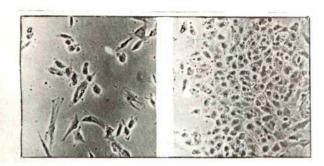
Follicle stimulating hormone enhances attachment of rat testis cells in culture


EXTENSIVE *in vivo* experiments indicate that mammalian spermatogenesis is under the regulation of pituitary gonadotrophins. The cellular sites and mechanisms by which spermatogenesis is regulated by gonadotrophic hormones, however, are poorly understood. Means has shown *in vivo* that follicle stimulating hormone (FSH) stimulates several cellular processes[1,2]. So far, however, no one has shown an *in vitro* effect of FSH on the testis. Several reports have indicated that hormones or hormone mediators alter cell properties in culture. In particular, testosterone was found to cause morphological changes in CHO cells[3] and cyclic adenosine 3′,5′-monophosphate has been shown to affect the adhesive properties of L-929 (ref. 4) and BHK (ref. 5) cells. We have been studying the growth of testis cells from the 10-d-old rat in culture and report here our observations on the stimulation of testicular cell attachment to culture dishes by follicle stimulating hormone.

Cells from 14 testes were dissociated by continuous agitation in 0.1% trypsin (Gibco, 1:250) for 50 min in a trypsinising flask. The tissue-free supernatant was collected at 10-min intervals and diluted with 8% foetal calf serum (1:1). Cells were collected by centrifugation at 1,000g for 10 min and suspended in NCTC-135 media (Gibco) containing 10% foetal calf serum.

Isolated testis cells (5×10^5 per dish) were incubated for 24 h in 35-mm dishes (Falcon) in 2 ml of NCTC-135 with foetal calf serum, (10%), penicillin (100 U ml^{-1}), and streptomycin (100 μg ml^{-1}) at 31.5 °C in an air–CO$_2$ atmosphere (95:5). Culture dishes contained either FSH (NIH-FSH-S$_8$), human chorionic gonadotrophin (HCG, Ayerst 531 U mg^{-1}), or bovine serum albumin (BSA). In dishes without FSH, individual fibroblast-like cells were seen on the bottom of the dish (Fig. 1*a*) whereas in the dishes containing FSH, colonies containing round, tightly-packed cells were seen (Fig. 1*b*).

After incubation, the dishes were washed twice with 2 ml of phosphate buffered saline to remove unattached cells, fixed for 12 h in 10% formalin, and stained for 5 min in haema-

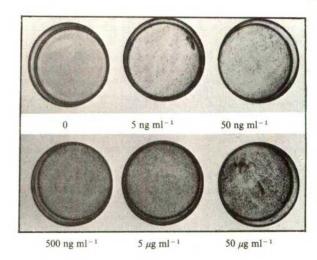

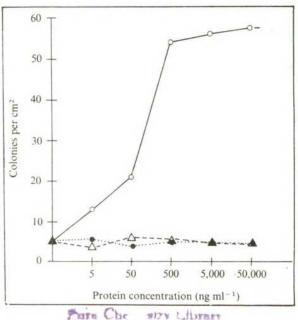

Fig. 2 Photograph of haematoxylin-stained colonies in dishes treated with various concentrations of FSH after 24 h in culture.

toxylin. Examination of stained colonies on the bottom of the dish indicated a dose-dependent (0–50 μg ml^{-1}) stimulation of colony number by FSH (Fig. 2).

To examine more closely the effect of FSH on colony formation, cultures were treated with FSH, HCG or BSA at 5–50,000 ng ml^{-1}; triplicate points were run at each dose in three experiments. Stained dishes were then placed on a 4×4-cm grid and the colonies in 5-cm^2 areas chosen from a random number table were counted at $\times 6$ magnification under a dissecting microscope. Colony counts are summarised in Fig. 3, and show a clear dose-dependent effect of FSH ($P < 0.01$, analysis of variance) on colony number while HCG and BSA had no significant effect. Furthermore, in subsequent experiments, HCG had no effect on colony number at doses up to 5 mg ml^{-1} (2,655 IU).

In the same experiment the effect of the various treatments on the size (number of cells) of the colonies was determined.

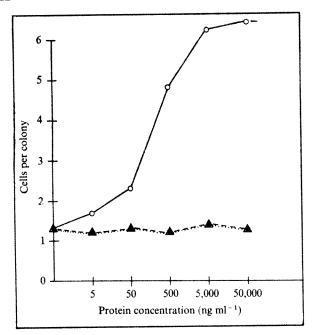
Fig. 3 The effect of FSH (○), HCG (●) and BSA (△) on colony density after 24 h in culture. Dishes were stained with haematoxylin and the colonies in 5 cm^2 chosen at random on the bottom of the dish were counted. The average of the five determinations for three dishes represented one experimental value. The points are an average of the three experiments.


Fig. 4 The effect of FSH (○), HCG (●) and BSA (△) on colony size after 24 h in culture. Dishes were stained with haematoxylin and cells per 100 colonies were counted at ×200. The average number of cells per colony for three dishes represented one experimental value. The points are the average of three experiments. Note: △ and ● are superimposed.

Cells were counted at ×200 magnification on 100 colonies on the bottom of the dish. As with colony density, colony size increased with FSH but not with BSA or HCG (Fig. 4). As before, the effect of FSH was dose-dependent and analysis of variance indicated a highly significant treatment effect ($P < 0.01$).

The results indicate that FSH has a stimulatory effect on some testicular cell in culture. Our preparation of testes cells from the 10-d-old rat contained more than 60% preleptotene spermatocytes; however, these cells do not attach to culture dishes[6] and therefore do not seem to have been the cells stimulated with FSH. Extensive electron microscopic examination of the cells in colonies indicated that they were not germinal cells and were a single cell type; however, an exact identification of the cell type involved would be premature at this time.

Our observation of an action of FSH on a testicular cell *in vitro* agrees with the observations that FSH (1) stimulates RNA synthesis[1] and protein kinase activity[2] and (2) is involved in the initiation of spermatogenesis[7] in the rat testis *in vivo*. The observation that HCG does not stimulate colony formation suggests that the *in vitro* effect may be, like the *in vivo* effect, hormone specific. These findings demonstrate an action of FSH on a discrete testicular cell *in vitro* and should provide new insight into hormonal and cellular interactions involved in spermatogenesis.

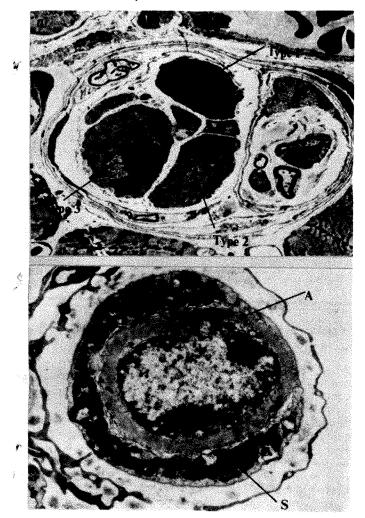
Ultrastructure of muscle spindles in dystrophic mice

ALTHOUGH the pathological changes in muscular dystrophy are commonly attributed to a primary abnormality of the muscle fibres, there is evidence to suggests that mucular dystrophy may be attributable to a neuronal abnormality[1]. This has become known as the 'neural hypothesis'. Dystrophic mice (Bar Harbor 129 REJ *dy/dy*) provide a useful model of muscular dystrophy for experimental study. In spite of the early onset of abnormal reflexes in muscular dystrophy, the richly innervated sensory organs, muscle spindles, have received relatively little attention[2,3]. Optical microscopical studies have indicated that spindles in dystrophic mouse muscles are essentially unaffected[4], although in some human diseases they seem to undergo minor changes[5]. This study was undertaken to establish whether there are ultrastructural changes in spindles of dystrophic mice which are detectable only by electron microscopy.


In dystrophic muscle each spindle was found to possess a prominent periaxial space containing a characteristic flocculent precipitate. The periaxial space was bounded by a capsule containing up to six layers of perineural epithelial cells. Each perineural epithelial cell contained numerous pinocytotic vesicles. The capsule enclosed the muscle fibres of the spindle for most of their lengths except close to their insertions into perimysium. Capillaries were never seen to penetrate the capsule and enter the periaxial space.

The dystrophic spindles contained an average of three to eight intrafusal fibres. No spindle contained less than three intrafusal fibres. Nuclear bag fibres contained up to three nuclei and a peripheral rim of myofilaments in each equatorial cross section and could be clearly differentiated from the narrower and shorter nuclear chain fibres, which contained singly occurring central nuclei. Both types of intrafusal fibre contained numerous myofilaments in their polar regions. Nuclear bag fibres tended to contain confluent masses of myofilaments interspaced with occasionally occurring mitochondria of variable size. In a few nuclear bag fibres the mitochondria were of more regular size and more evenly dispersed throughout the fibre cross section. These two types of intrafusal fibre correspond to those designated types 2 and 3 in other species[7]. Nuclear chain fibres contained groups of myofilaments which formed discrete myofibrils often separated by numerous mitochondria. In both nuclear bag and nuclear chain fibres the number of myofilaments was markedly reduced in equatorial compared with polar regions. Dilated terminal cisternae of the triads typical of those found in other species[8] were also found.

Satellite cells were found lying between the basement membrane of the intrafusal fibres and their plasma membranes. They seemed inactive because their relatively small amounts of cytoplasm contained few ribosomes and a little rough endoplasmic reticulum. All the intrafusal fibres examined received a direct sensory innervation without intervening basement membrane. Two motor-nerve endings were also observed. Their primary synaptic clefts contained a continuous layer of basement membrane which extended into the relatively few secondary synaptic clefts that occurred.

None of the spindles in dystrophic muscles was seen to contain any ultrastructural abnormality and did not differ significantly from the spindles in the control muscles. These findings have important implications for the 'neurogenic hypothesis' of muscular dystrophy. If that hypothesis is true then changes in the richly innervated intrafusal fibres may be expected. Consequently, at least a modification of the hypothesis must be proposed. Several possibilities exist; for example, either there is a selective sparing of the sensory or γ-motor supply of

Fig. 1 *a*, Transverse section across the polar region of a muscle spindle in a clinically dystrophic mouse. Three types of intrafusal fibre can be differentiated. Type 1 fibres (nuclear chain) contain many large mitochondria; type 2 fibres (nuclear bag) contain intermediate numbers of evenly scattered mitochondria; type 3 fibres (nuclear bag) contain a few small mitochondria. ($\times 2,300$). *b*, Transverse section across the equatorial region of the nuclear chain (type 1) fibre seen in (*a*). A primary sensory ending (S) contains numerous mitochindria and partly encircles the intrafusal fibre. The cross sectional area (A) which contains myofilaments in this region of the fibre is much smaller than in the polar regions. ($\times 12,000$). Specimens of soleus and extensor digitorum longus muscles were obtained from six clinically affected Bar Harbor 129 REJ *dy/dy* dystrophic mice and from six nonlittermate controls, and prepared for electron microscopy as described previously[6]. Eleven spindles were found in dystrophic muscle and eight in control muscle. Ultrathin sections were cut from these spindles at intervals of 25–50 μm along most of their lengths. A few spindles were also examined in longitudinally cut sections.

the spindles or, alternatively, the intrafusal fibres may have acquired a high resistance to the supposed neurogenic influence. In support of the latter, in many human muscle diseases, apart from an apparent disuse atrophy, the intrafusal muscle fibres usually seem to be relatively unaffected[9,10]. Although the relevance of such findings in dystrophic mice to the pathogenesis of human muscular dystrophy is uncertain, studies on human dystrophic spindles could be of considerable interest.

This work was carried out with the aid of grants from the MRC and SRC.

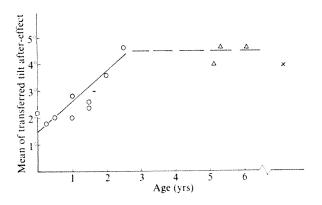
Squint and the development of binocularity in humans

IN the past ten years it has been shown that binocularity[1], orientation sensitivity[2,3], ocular dominance[4] and disparity[5] of cortical neurones can be modified by experimental procedures in kittens during the sensitive period (3–14 weeks of age).

In 4-week-old kittens which had one eye closed for 6 d the percentage of binocular cells decreased to 9% from 80–90% in normal controls, but closing one eye for 2 months in 4-month-old kittens did not affect the relative number of binocular and monocular cells[6]. In humans, according to clinical experience, binocular vision is not fully established at birth and develops to full maturity during the first four to five years of life[7].

If neurones of the visual cortex need to be excited by identical or nearly identical stimuli from both eyes during the critical period in order to develop binocularity, a squint during this period should result in a smaller number of cells than normal with binocular input. Since binocular neurones of the visual cortex are an essential prerequisite for binocular single vision and depth perception[8], a lack of such cells will result in a failure of real binocular single vision after correction of the squint. This is also supported by clinical observations which indicate that the later a squint is acquired the more likely it is that binocular vision will be restored after a successful operation[9].

We have tried to correlate these clinical observations with quantitative measurements of interocular transfer in children whose squint had developed at different ages but was corrected by surgery. This was done with the assumption that interocular transfer may be a reliable indicator for the binocular input to visual cortical neurones. A simple test of this kind is the interocular transfer of the tilt after-effect described by Gibson[10]. If a subject fixates a grating tilted 10° anticlockwise away from the vertical for some minutes, he will make a systematic clockwise error when asked to adjust the same grating in the vertical position. The same systematic error is found, though to a smaller degree, if one eye is trained and then adjustment of the grating is done with the other, untrained eye (binocular transfer). Patients with strabismus have a smaller after-effect transferred from one eye to the other than subjects with normal vision[11].

Twelve children, 5.10 to 15.2 years old, served as subjects. Nine of them (mean age 9.8 yr) had been patients of the Göttingen eye hospital and had suffered from strabismus concomitans convergens alternans in early life. They had been operated on at the age of 3–5 yr (mean 4.1 yr). Preoperation squinting angle was between 12° and 40° (mean 23°). Binocular interaction was tested on the synoptophor, visual acuity with the Pflüger-hook. The Worth test and the Maddox cross test were also applied. The Gibson transfer phenomenon was then tested on the synoptophor. Three children with normal vision (mean age 5.9 yr) served as control subjects.


A vertical light bar on a black ground was adjusted five times for each eye and the angular error measured. This was of the order of $\pm 0.5°$. The subject then adapted monocularly for 2.5 min to a grating orientated 10° anticlockwise to the vertical. The bar had the same width as the lines of the grating. Immediately after this adaptation period the single bar, set at 5° clockwise to the vertical was shown to the untrained eye. The experimenter slowly rotated the single line and asked the subject to say 'stop' when the line appeared vertical to him. Normal children indi-

cated that the bar appeared vertical when it was still tilted about 4–5° from the normal. This value will be called transferred tilt after-effect (TTA). After readaptation for 45 s the test was repeated twice for each eye. The typical error between successive measurements was less than ±0.3°.

The age at which the squint first appeared was noted in the hospital records and the parents were also asked. Figure 1 shows that the TTA is smallest (1–2°) in children who had a squint from birth. It increases steadily the later the squint started. A child who had started squinting at the age of 2.6 yr showed no difference in TTA compared with subjects with normal vision. The TTA values shown on the ordinate of Fig. 1 are the means of the TTA values from the right to the left and from the left to the right eye.

Only 3 children were used as controls. Their TTA values were the same as those known for normal subjects in other investigations[12], so that further controls were not necessary. Ophthalmological assessment of binocularity closely corresponded to these results. The children who had started squinting at birth had simultaneous perception only (stage 1 of binocularity). Those who had acquired their squint at 0.6–1 yr could fuse images (stage 2), and those whose squint began at 1.6 yr or later could perceive depth (stage 3).

Fig. 1 Binocular transfer of tilt after-effect in operated strabismic children, whose squint developed at different ages. Abscissa: ○, age of onset of squint in patients; △, age of control children at which the measurement was done. Ordinate: mean error of adjustment of vertical line with one eye after exposure of the other eye to a grating tilted 10° away from the vertical for some minutes (transfer of tilt after-effect). ×, Control values from Campbell and Maffei[12].

Thus the later a squint began in the child the higher was his mean interocular transfer angle, and the better his binocular vision. If the squint started by the age of approximately 2.6 yr, normal interocular transfer was possible. These findings indicate that at an age of about 2.6 yr, binocular functions of the visual cortex as measured with the TTA are well enough established to be restored by correction of a squint. The age of about 2–2.6 yr may therefore be considered the end of the critical period for the development of binocular vision in humans.

The fact that the interocular transfer has never been found to be zero could indicate either that at least some binocular cortical neuronal connections develop independently of binocular vision during early life time, or that a post-operation training effect took place. Orthoptistic training is given to children until they are nine years old.

The good correspondence between the TTA results and the clinical assessment of binocularity suggests that the TTA is a good indicator of binocular functioning of the visual cortex. It may be directly related to the number of binocular units in the visual cortex as also suggested by earlier investigations[11,13]. As it is a simple test it could be included in clinical testing of binocular functions.

Visual acuity development coincides with the sensitive period in kittens

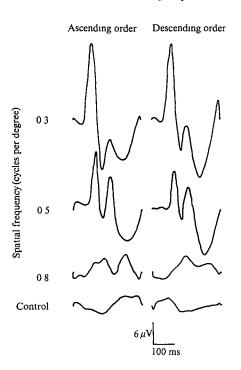
AT about ten days of age when a kitten's eyes open, synaptic connections of its visual system are partly laid down[1]. They are completely developed during the sensitive period[2] which lasts from about three weeks of age to three months. During this period of plasticity the formation and modification of synaptic connections respond to features in the visual environment[3-6]. Both the original and subsequently developed connections may be disrupted or modified by environmental factors during the sensitive or critical period with a sensitivity that peaks at about the fourth week and gradually drops off[2].

Conventional (psychophysical) visual acuity as well as its electrophysiological acuity correlate, obtained by pattern-dependent visual evoked potentials, must also develop in the kitten as a result of the organisation of synaptic connections. (Visual evoked potential acuity measurements are based on electrical processing in the visual cortex, although it is possible that they may reflect retinal and geniculate processing resolution before cortical processing takes place.) Our goal was to measure visual acuity in cats and kittens of various ages to determine the time course of its development.

Visual evoked potential acuity measurements were made on nine kittens and three adult cats, all raised in a normal visual environment. The data were obtained from the two eyes separately in each of four kittens and in one eye in the rest of the kittens and cats, providing fifteen data points in all. A horizontal rather than longitudinal time study was dictated because stable electrodes were difficult to maintain through the thin, growing skull of the kittens. Following the method of Rose *et al.*[7], stainless steel screw electrodes were positioned just through the skull over the visual cortex and, with dental acrylic cement, were encased in a small electric connector on the head. The implantation of electrodes yielded excellent potentials with a much better signal to noise ratio than did surface electrodes.

The responses were evoked by the virtually instantaneous reversal of the light and dark stripes of a bar grating pattern by an optical electromechanical shaker. A constant temporal frequency of 0.5 Hz was used with a variable bar width (spatial frequency). During recordings the animals were quiescent under general anaesthesia (sodium pentobarbitol) and a contact lens protected the optical quality of the cornea. It is clear that the optical quality of the eye of the very young kitten is inferior to that of the adult. But on the basis of ophthalmoscopic observation we feel that it is unlikely that optical factors limit the acuity determined for the younger animals. The eye was aligned to the screen by finding the optic disc ophthalmoscopically and projecting it on to the screen. Retinoscopy and trial lenses provided

an optical correction to the screen at 57 cm which covered a 40° visual angle The target had 80% contrast and a luminance of 24 cd m⁻²

For each size or spatial frequency of grating, 100 responses were recorded and averaged on a PAR Waveform Eductor to provide a good signal to noise ratio (Fig 1) Measurements were begun at 23 days of age, well after the hyaloid artery disappeared and the optical media were clear The amplitude of the evoked response was found to be a function of the spatial frequency of the pattern, confirming Berkley and Watkins[8] Visual acuity was taken as the highest spatial frequency for which a clear electrical response was present Spatial frequency thresholds for each animal were plotted on a log–log scale as a function of age (Fig 2, solid curve)


The points on the curve are, in principle, slightly above threshold because a clear though minimum response was used as the criterion At the next higher step of spatial frequency no response could be observed, so the exact threshold cannot be above these points which are represented by the dashed curve of Fig 2 This curve is at or slightly below threshold and is the limit of the maximum possible error in the minimum threshold as determined by this method

Grating resolution of the adult cats fell between 3 and 5 cycles per degree which is similar to that found by Berkley and Watkins[8] and by Campbell et al[9] using related evoked potential methods, and by Muir and Mitchell[10] using a standard psychophysical method Recently Blake et al[11] using conditioned suppression were able to approach 6 cycles per degree Wassle[12] found a comparable value for the optical upper spatial frequency cut-off using two parallel slits for the cat's eye, calculated at 4 to 5 arcmin or 6 cycles per degree Pure optical values would be expected to be the same or higher than the psychophysical acuity value of 3 to 5 cycles per degree These values seem low when compared with those of the human eye, the cat's optical system, however, is poorer[10] and its retina lacks a fovea centralis

It is clear from the trend of the curve that from 23 days of age, development of visual acuity in the cat is exceedingly rapid, and is virtually complete by 100 d At 23 d of age acuity was only 0 3 cycles per degree or 20/2000 Snellen Ten days later the acuity had improved to 1 cycle per degree or 20/600, an

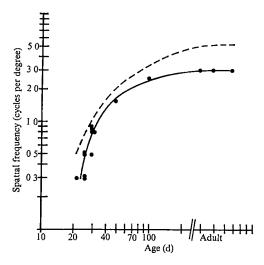
Fig 1 Pattern evoked potentials from stimulation of the right eye of a 31-d-old kitten Measurements were recorded for different fineness of bar gratings (spatial frequencies) in ascending and then descending order The control was a static projection of the 0 3 cycles per degree pattern


Fig. 2 The highest spatial frequency for which an evoked potential was present is graphed as a function of age (closed circles) A curve has been fitted by eye to these points (solid line) The dashed line joins the next higher spatial frequencies for which no pattern evoked potentials were present and is a measure of the maximum error Age scale for adult cats is in yr

enormous increase Between 33 d and 100 d the acuity approached the adult level of 3 cycles per degree, or 20/200

The optical media may become slightly clearer during the third to sixth week which could make a curve representing synaptic development slightly less steep Fig 2 may also be described as follows It " begins suddenly near the start of the fourth week, at about the time a kitten begins to use its eyes, and persists until some time between the sixth and eighth weeks, it then begins to decline, disappearing ultimately around the end of the third month " This is Hubel and Wiesel's description[2] of the sensitive period for changes in ocular dominance which fit our data Their descriptive data have been plotted by Blakemore[13] While other functions of the visual system may have somewhat different sensitive periods, it seems likely that all other functions fit within the limits of that described above for ocular dominance

Because the normal development of acuity takes place during the sensitive period, our findings support the hypothesis that this development may be used as a measure of the visual sensitive period A similar but non-invasive method (that is, using electrodes on the skin rather than on the brain) can be used to investigate the visual development of the human infant in order to study the human visual sensitive period and its time course

Functional and neurochemical correlates of potentiation of striatal asymmetry by callosal section

AFTER lesions have been made in one side of the nigro-striatal system, rats have been found to rotate when administered drugs which release dopamine (such as amphetamines) or activate dopamine receptors (such as apomorphine) in the corpus striatum (see for example refs 1 and 2) Because this circling effect is specific to the nigro-striatal system[3] and because it has been established that rats consistently rotate contralateral to the more active striatum (for example ref 4), the lesion–rotation paradigm is now commonly used as a model for the study of nigro-striatal function Studies[5,6] in our laboratory have shown that rats without lesions also rotate when administered doses of the same drugs larger than those administered to lesioned rats As in lesioned rats, the direction of rotation is consistent for normal rats, when tested on several different occasions with the same dose of the same drug, some rats consistently rotate to the right and others rotate to the left This suggested that normal rats have an intrinsic asymmetry between left and right sides of the nigro-striatal system which is accentuated by drugs This functional asymmetry corresponds to a chemical asymmetry[7] the dopamine contents of normal left and right

Table 1 Effect of callosal section on rotation induced by (+)-amphetamine (1 0 mg kg⁻¹)

	Mean net rotations ± s e per 1 h	
Group	Preoperative	Postoperative
Callosal	48 2±14 6	97 7±12 2*
Sham	46 8±14 5	49 0±15 1

*Significantly different from preoperative value at $P < 0 01$, paired t test

striata were found to differ by 10–15% After administration of (+)-amphetamine, the dopamine contents of left and right striata were found to differ by 25% Moreover, in response to (+)-amphetamine, rats consistently rotated contralateral to the side containing the most dopamine This normal asymmetry suggests an inter-hemispheric mechanism that maintains or regulates the asymmetry Mensah and Deadwyler[8] demonstrated in rats a pathway between left and right caudate nuclei coursing through the ventral corpus callosum It seemed plausible that this pathway may be part of the mechanism maintaining striatal asymmetry We have now found that the striatal asymmetry is potentiated, both functionally and chemically, by callosal section

Twelve naive female Sprague–Dawley rats about 3 months old (approximately 250 g) were placed individually in a roto-meter modified[9] after that described by Ungerstedt and Arbuthnott[10] After 15 min each rat was injected intraperitoneally with (+)-amphetamine sulphate (1 0 mg kg⁻¹) Rotations were recorded automatically on a printout counter during the 15 min before and 60 min after injection Rotations to the left

or right during the pre- and post-injection periods were totalled separately and the net positive rotational difference (that is rotations in the dominant direction minus rotations in the opposite direction) was determined for each rat Approximately 3 h after testing, six rats were subjected to section of the anterior corpus callosum (from 0 5 mm posterior to bregma to the frontal pole) using procedures developed by Teitelbaum[11] Sham surgery was performed on the other six rats One week later, all rats were retested in the rotometer with the same dose of (+)-amphetamine All rats were then killed and perfused with 10% formalin, brains were removed and immersed in formalin for at least a week, after which sections (40 nm stained with Luxol blue and cresyl violet) were made and histological examination was conducted In all six rats of the experimental group, the anterior corpus callosum was severed as intended, except for slight cortical damage in one rat, there was no damage to other structures

Table 1 shows that whereas the sham-operated group made approximately the same number of rotations in both test sessions, the callosal-sectioned group made about twice as many rotations in the second session as in the first For all 12 rats, the direction of rotation was the same during both sessions Callosal section, therefore, only potentiated a normal bias

For the neurochemical experiment, six rats were again subjected to section of the anterior corpus callosum and six received sham surgery A week after surgery, each rat was killed by decapitation, its brain was removed and the left and right striata were dissected Each striatum was initially homo-genised by a Tissumizer in 4 0 ml of acetonitrile containing 0 2 μg of propionylcholine as an internal standard for analysis of acetylcholine The homogeniser was washed with an additional 3 0 ml of acetonitrile Homogenates were combined and centrifuged at 2,500 r p m for 10 min The acetonitrile phase was removed and assayed for acetylcholine by pyrolysis-gas chromatography[12] The pellet was resuspended in 5 0 ml of 0 4 N perchloric acid containing 0 1 ml of 10% EDTA, homogenised in a Teflon-glass homogeniser and then centrifuged at 15,000 r p m for 20 min in a refrigerated centrifuge Striatal dopamine was determined in the extract by a spectrofluorometric method[13]

Table 2 shows that callosal section had no effect on mean levels of striatal dopamine and acetylcholine The callosal section, however, enhanced a striatal dopamine asymmetry and induced a striatal acetylcholine asymmetry In the sham-operated group, there was a significant difference in dopamine content between striata, confirming previous work[7,14], and no significant difference in striatal acetylcholine content In the callosal-sectioned group, striatal dopamine asymmetry was approximately twice as great as in the sham-operated group, and an asymmetry in striatal acetylcholine content was significant Moreover, in the callosal-sectioned group, the striatal acetylcholine asymmetry was in the opposite direction to the striatal dopamine asymmetry, that is, for each rat, the side containing more dopamine had less acetylcholine In addition, for the latter group, the striatal dopamine asymmetry (H/L ratio) was inversely correlated with the striatal acetyl-

Table 2 Effects of callosal section on mean unilateral striatal dopamine and acetylcholine levels (μg g⁻¹)*

	Group	Left	Right	High	Low	Mean ratio (H/L)	
Striatal dopamine±s e	Callosal	6 87±0 51	6 57±0 49	7 67±0 44†	5 77±0 43	1 33±0 07‡	
	Sham	6 73±0 39	6 56±0 53	7 11±0 46†	6 18±0 38	1 15±0 04	
Striatal acetylcholine ±s e	Callosal	5 13±0 47	4 70±0 41	5 35±0 40†	4 48±0 41	1 19±0 05‡	
	Sham	4 82±0 32	4 65±0 23	4 94±0 34	4 53±0 25	1 08±0 04	

*Mean dopamine and acetylcholine were computed in two ways left side against right side, and side containing higher level against side containing lower level In addition, the mean high side/low side (H/L) ratio was also computed
†High side significantly different from low side (t tests, $P < 0 05$–$0 01$)
‡Callosal-sectioned significantly different from sham-operated (t test, $P < 0 05$)

Jline asymmetry ($r = -0\,92$, significant at $P < 0\,01$, t test), ere was no significant correlation for the comparable measurements in the sham-operated group ($r = 0\,21$)

/ These results support the initial hypothesis that a callosal pathway serves to regulate or maintain a set degree of balance or imbalance between the two striata After section of this pathway, the asymmetry is potentiated, both behaviourally and neurochemically The reciprocal relationship between the dopamine and acetylcholine asymmetries in the callosal-sectioned group is consistent with recent ideas concerning relationships between central cholinergic and dopaminergic mechanisms[15] If the normal asymmetry in striatal function is related to spatial preferences, as previous studies suggest[14,16], then different levels of activity in the intercaudate callosal pathway, as affected by reciprocal dopaminergic and cholinergic mechanisms, may be responsible for normal variations in sidedness among different animals

Distribution of butanol molecules along bullfrog olfactory mucosa

ALTHOUGH electrophysiological[1] and gas chromatographic[2] studies have indicated that odorant molecules drawn into the intact frog olfactory sac establish a concentration gradient along the olfactory mucosa, conclusive evidence for such gradients requires a direct determination of how the molecules are actually distributed This requirement is met here by labelling butanol molecules with tritium and directly mapping their sorption along the mucosa

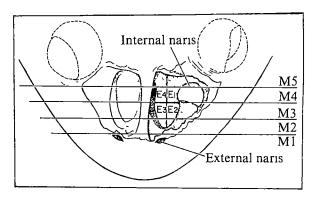
Bullfrogs (*Rana catesbeiana*) anaesthetised with urethane were mounted in a headholder and kept in a hood designed for use with radioactive gases The concentration (measured in partial pressure) of the tritiated butanol was controlled by a flow dilution olfactometer[1], from which the tritiated butanol was delivered to the frog's intact olfactory sac through a Teflon cannula placed in the external naris The stimulus was drawn into the sac as an artificially produced sniff of controlled flow rate This was accomplished using the negative pressure developed by a Harvard withdrawal pump which was connected to a Teflon cannula placed in the internal naris and secured there by a dental moulding material The stimulus


Fig 1 The relationship of the dorsal surface and eminentia sections to the intact olfactory sac of the bullfrog Immediately after the stimulus was presented, the frog was quick-frozen in liquid nitrogen This minimised any further movement of odorant molecules which could have resulted from diffusion and/or desorption With the animal frozen solid, a No 3 jeweller's saw was used to remove, in one piece, the dorsal, lateral, and septal walls of the olfactory sac To further section this piece and at the same time prevent its thawing, the piece was mounted in a specially constructed mitre box which could be maintained at a temperature below 0 °C In this way the dorsal surface could be sawed into five sections perpendicular to the long axis of the olfactory sac's surface These five sections were designated M1 to M5 with M1 being the section cut just caudal to the external naris and M4 being that part of the dorsal surface mucosa overhanging the internal naris When the dorsal, lateral, and septal walls of the olfactory sac were removed, its ventral surface (which contains the eminentia olfactoria) remained attached to the frozen carcass The eminentia was then cut into four sections designated E1 to E4 and each section was then removed from the animal All these sections (M1 to M5 and E1 to E4) were individually dissolved in tissue solubiliser and counted in a liquid scintillation system The number of disintegrations per minute for each mucosal section is an index of the total number of butanol molecules attracted to it The long black lines running the length of the figure refer to the dorsal surface, which is removed in this drawing E1 to E4 are indicated by the thicker crossed lines drawn along the surface of the eminentia

volume was controlled by the duration of the artificially produced sniff since, at a constant flow rate, duration determines volume Labelled molecules not adhering to the mucosal surface were collected in a toluene trap placed in the Teflon line between the internal naris and the withdrawal pump The animal was then frozen and sectioned (Fig 1)

The first column of Table 1 shows the distribution of butanol molecules resulting from the artificially produced sniff in which the partial pressure of the stimulus was 0 36 mmHg, the flow rate 16 ml min^{-1}, the duration 1 56 s, and the volume 0 42 ml

There is an obvious decreasing gradient of butanol molecules from the section which contains the external naris (M1) to that section overhanging the internal naris (M4), and the gradient is rather steep There is also a gradient, though less steep, rostro-caudally along the eminentia It is possible, however, that these gradients may simply reflect differences in the surface areas To correct for these differences, the percentage of the molecules recovered in each section was divided by the mean surface area for that particular section Correcting for surface area does not reduce these gradients (Table 1), indeed, the dorsal surface gradient is now even steeper

The comparatively small number of molecules sorbed by the eminentia compared with the dorsal surface is surprising This is perhaps caused by the poor location of the eminentia for the attraction of chemicals, which, like butanol, are heavily sorbed near the entrance to the olfactory sac, a region into which the eminentia does not even protrude Such observations raise questions concerning the role of different regions of the mucosa

If the gradient of odorant molecules along the mucosa has an effect on the processing of information by the olfactory system, the stability of these gradients as the stimulus intensity is varied becomes an important consideration[2] Therefore, holding volume and flow rate constant at the above levels, we compared

Table 1 Mucosal distribution of butanol molecules

Section	Total molecules recovered (%)	Mean surface area (mm²)*	Total molecules recovered (% mm⁻²)	Mean of all concentr % total molecules reco
Dorsal Surface				
M1 (most rostral)	84 38±1 29	4 5±0 1	18 75	84 59±1 98
M2	5 81±1 41	14 2±0 3	0 41	6 46±1 77

E4 (caudomedial)	0 11±0 05	4 2±0 2	0 03	0 16±0 11
Not Sorbed	0 51±0 41	—	—	1 05±0 63
Number of animals	8	4		30

*Means based on four animals (comparable in weight to those used first two columns) which had not received any radioactive stimulus and were frozen and cut as described in the legend to Fig 1

Results (%) represent the number of molecules found in each section compared to the total number of molecules recovered Mean ± s d for that particular section taken from eight animals

the mucosal distribution patterns of butanol molecules established by five different partial pressures 0 06, 0 36, 0 62, 0 92, and 6 78 mmHg At least four animals were run at each partial pressure

Although the absolute number of butanol molecules recovered from each mucosal section increased with partial pressure, the relative number of molecules from section to section remained constant That is, an analysis of variance showed no significant differences among the percentages of the total number of molecules recovered from each section as a function of partial pressure Therefore, the results for each partial pressure are not presented individually, but are instead represented by mean values (last column, Table 1)

The fact that butanol establishes a steep concentration gradient and that this gradient remains unchanged throughout a wide range of concentration explains Mozell's earlier electro-physiological data[1] He showed that over a two log unit range of partial pressures butanol consistently produced measurable responses on the olfactory nerve branch supplying a region of the dorsal mucosa near the external naris, whereas the same butanol concentrations usually produced no measurable response on the nerve branch supplying the mucosal region overhanging the internal naris Mozell's interpretation of these data, namely, a rather steep mucosal concentration gradient, has now been directly and graphically confirmed by our radio-isotope study Only at the highest partial pressure obtainable at ambient temperature did Mozell observe significant activity on the internal naris nerve branch In terms of our study this would suggest that the saturated vapour, although still distributed along the mucosa in the same relative proportions, now provides a large enough absolute number of molecules at the M4 region to yield a measurable electrophysiological response

We do not mean to infer, however, that all odorants will have the same mucosal concentration gradient as butanol Indeed, from previous chromatographic[2] and electrophysiological[1] studies we predict that odorants with mucosal retention times[2] shorter than butanol, would, in a given sniff, have a less steep gradient Likewise, those odorants with long retention times might well show a gradient even steeper than that reported here

In summary, a butanol odorant stimulus results in the establishment of a concentration gradient along the intact olfactory sac and this gradient remains constant within a rather broad range of stimulus intensities This is what Mozell[2] predicted was necessary if a 'chromatographic-like' differentiation were one of the mechanisms basic to odorant discrimination Even if these distributions are not basic to olfactory discrimination themselves, they could be fundamental to any process which actually underlies olfactory discrimination For example, selectively tuned receptors along the flow path would be reached by different concentrations of the same odorant Therefore, this

initial distribution of the molecules along the olfactory receptor sheet is likely to be of central importance to our full understanding of both quality and intensity discrimination

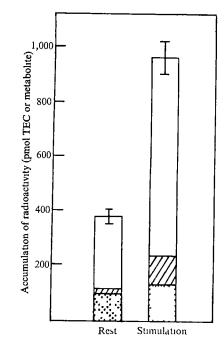
Triethylcholine as a precursor to a cholinergic false transmitter

A false transmitter is a substance that is stored and released by a nerve terminal instead of its normal transmitter Several false transmitters have been demonstrated at adrenergic synapses[1], but there has been no report of the synthesis, storage and release of a false transmitter at cholinergic synapses It has been suggested that the triethyl analogue of choline (2-hydroxyethyl-triethylammonium iodide, TEC) might form a cholinergic false transmitter, in vitro studies have shown that it can be accumulated by tissues that take up choline[2], and that choline acetyltransferase can acetylate TEC (refs 3 and 4) Nothing is known, however, about the specificity of the processes associated with storage and release of acetylcholine in intact tissue The possibility that TEC can form a false transmitter was studied in the present experiments The results demonstrate the uptake of TEC, its acetylation, and the release of acetyl-TEC by the superior cervical ganglion of the cat


To measure the uptake and metabolism of TEC, ganglia were perfused[5,6] for 60 min with Krebs solution (mM NaCl, 120, KCl, 4 6, CaCl₂, 2 4, NaHCO₃, 25, KH₂PO₄, 1 2, MgSO₄ 7H₂O, 1 2, glucose, 9 9) containing ¹⁴C-TEC (*N*-ethyl labelled, 8 6 mCi mmol⁻¹, 10⁻⁵ M), in some experiments the preganglionic nerve was stimulated throughout (20 Hz, 0 3 ms, supramaximal voltage) Ganglia were removed, extracted with trichloroacetic acid (TCA, 10% w/v), and the TCA was removed with ether (initial experiments showed that TCA extracted almost all of the radioactivity accumulated by ganglia, <5% was extracted with phospholipids) The fate of TEC accumulated by ganglia was determined by shaking the aqueous

extract with tetraphenylboron in heptanone[7] (10 mg ml⁻¹), phosphoryl-TEC remained in the aqueous layer, but acetyl-TEC, and unchanged TEC were extracted into the organic phase from which they were recovered into hydrochloric acid (1 N, HCl) The HCl was removed by evaporation under reduced pressure, and the residue was incubated (30 °C for 30 min) with choline kinase (prepared from brewer's yeast, incubation mixture contained choline kinase 3 mg per ml protein, and (mM) ATP, 8 3, MgCl₂, 12 5, glycyl-glycine, 83, pH 8 5), TEC, but not acetyl-TEC, was converted to phosphoryl-TEC which was separated from the acetyl-TEC by extracting the latter into heptanone containing tetraphenylboron The breakdown of acetyl-TEC during these procedures was <5% In stimulated ganglia, 13 7±1 3% (mean±s e) of the accumulated radioactivity was phosphoryl-TEC, 10 6± 2 2% (102 pmol) was acetyl-TEC, and the rest was unchanged TEC The identity of these metabolites was confirmed by thin-layer chromatography In non-stimulated ganglia, total uptake of radioactivity was only 41% of that by stimulated ganglia (Fig 1), and less than 4% (<15 pmol) of the accumulated radioactivity was acetyl-TEC Thus, nerve stimulation increased the synthesis of acetyl-TEC, and also increased the uptake of TEC This extra TEC also accumulated in stimulated ganglia when synaptic transmission was blocked by tubocurarine (3×10⁻⁵ M) and therefore, it probably entered preganglionic terminals

In 13 experiments, ganglia were perfused first with ¹⁴C-TEC during preganglionic nerve stimulation (60 min), stimulation was then stopped, and perfusion was continued with TEC-free medium containing eserine sulphate (3×10⁻⁵ M), after washing out the radioactivity for 30 min, the preganglionic nerve was again stimulated to test the release of accumulated radioactivity In all experiments, nerve stimulation increased the release of radioactivity from ganglia (Fig 2a) In other experiments, the ganglion was not stimulated during exposure to TEC, little, if any, radioactivity was released from these ganglia during subsequent nerve stimulation (Fig 2b) This suggested that acetyl-TEC, not unchanged TEC, was released by nerve stimulation, and this was confirmed by treating the samples collected before and during nerve stimulation with choline kinase (see above) Radioactivity collected at rest was un-

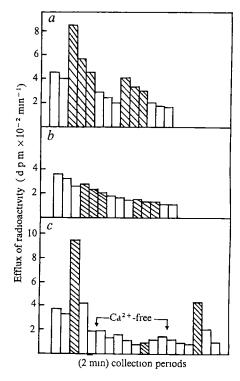
Fig 1 Accumulation of radioactivity by cat superior cervical ganglia Ganglia were perfused (60 min) with Krebs solution containing ¹⁴C-TEC (10⁻⁵ M) at rest or during stimulation (20 Hz) of the preganglionic nerve Unshaded columns represent unchanged TEC pmol, mean±s e), hatched areas represent acetyl-TEC, stippled areas represent phosphoryl-TEC


Fig 2 The effect of preganglionic nerve stimulation (20 Hz during collection periods indicated by the hatched columns) on the efflux of radioactivity from cat superior cervical ganglia perfused with Krebs solution containing eserine (3×10⁻⁵ M) The ganglia had previously been perfused for 60 min with Krebs solution containing ¹⁴C-TEC (10⁻⁵ M) during preganglionic nerve stimulation (a and c) or during rest (b), and then (all experiments) for 30 min (no stimulation) with TEC-free medium containing eserine In (c) perfusion was switched to a calcium-free medium (containing 10⁻⁴ M EGTA) during the time indicated by the arrows

changed TEC, and the extra radioactivity released during nerve stimulation was all acetyl-TEC The amount of acetyl-TEC released at the onset of the test period of stimulation was 19 1±2 9 pmol min⁻¹ (estimated from the extra radioactivity collected in the first 2 min of stimulation), this represents the release per minute of about 19% of the ganglionic content of acetyl-TEC, which suggests that acetyl-TEC is at least as available for release by nerve impulses as is acetylcholine under similar experimental conditions[8] The release of acetylcholine from nerve terminals is known to depend on the presence of calcium, and in two experiments, the release of acetyl-TEC by nerve stimulation was tested before, during and after perfusion with a calcium-free medium (containing 10⁻⁴ M EGTA) The release of acetyl-TEC was calcium-dependent (Fig 2c)

The present experiments show that TEC is taken up by cholinergic nerve terminals, that it is acetylated, and that acetyl-TEC can be released by nerve impulses in a manner similar to the release of the normal neurotransmitter Acetyl-TEC is pharmacologically inactive on cholinergic receptors[9], TEC, therefore, forms a false but inactive cholinergic transmitter

Immunoreactive thyrotrophin releasing factor in gastropod circumoesophageal ganglia

REPORTS have indicated that thyrotrophin releasing factor (TRF) is stored in extrahypothalamic as well as hypothalamic brain regions of many vertebrates from the primitive larval lamprey to the more advanced mammals[1–4] Although TRF is found in the brain of many poikilotherms, administration of synthetic TRF (pGlu-His-ProNH₂) to these animals does not activate thyroid gland function[5–7] Thus, it has been proposed that, in these animals, TRF modulates synaptic transmission rather than releasing thyrotrophin (thyroid stimulating hormone)[1] Furthermore, the administration of TRF to hypophysectomised rodents potentiates the effect of the L-dopa on behaviour[8], thus supporting the hypothesis that TRF modulates monoaminergic transmission in higher vertebrates as well Further support for a role of TRF in synaptic transmission is the finding that administration of the synthetic tripeptide leads to an increase in noradrenaline turnover in rat brain[9–11] Because these reports imply first, that TRF may influence mono-aminergic transmission and second, that, in lower vertebrates, this role of TRF may be more important than that of regulating TSH release, we have investigated whether TRF is present in invertebrates which do not produce thyroid hormones but exhibit monoaminergic neurotransmission We found immunoreactive TRF in the circumoesophageal ganglia of various gastropods Species studied were the landsnail *Mesodon roemeri* (Connecticut Valley Biological Supply Co , Massachusetts), *Planorbis corneus* (Mogul Ed Corp , Wisconsin), *Helesoma trivolbis* and *Viviparus malleatus* (Ann Arbor Biological Center, Michigan)

The circumoesophageal ganglia were removed and freed of excess connective tissue under a dissecting microscope The ganglia were frozen immediately and tissues from several animals were pooled After thawing, they were homogenised in 100 μl of distilled water, and proteins were precipitated with 1 0 ml of absolute methanol After refrigeration overnight, the homogenate was centrifuged at 15,000g for 5 min and the protein concentration of the pellet was determined according to the technique of Lowry et al[12] The methanolic phase was dried under nitrogen and resuspended in phosphate buffer for radioimmunoassay of TRF The presence of immunoreactive TRF was determined by the method of Jackson and Reichlin[1] or by a modification of the method of Jeffcoate et al[13], to be described in detail elsewhere Both assays showed minimal crossreactivities with TRF breakdown products and structurally related small peptides The TRF determination in both assays, although carried out with different antibodies, were in good agreement (for example, 125 pg mg⁻¹ protein compared with 150 pg mg⁻¹ protein for a pool of ganglia)

Table 1 shows that TRF was present in various gastropods from the most primitive species examined (*V malleatus*) to the more advanced pulmonates (*H trivolbis, P corneus, M roemeri*) There was more TRF in circumoesophageal ganglia from the landsnail *Mesodon roemeri* than that in those from water snails (mean value of 308 pg mg⁻¹ protein compared with a pooled mean value of 44 5 pg mg⁻¹ protein) The amount of TRF in pooled snail ganglia was less than has been reported for hypothalamic tissue of various vertebrates[1], but was within the range of values reported for cerebral cortical tissues (20 pg mg⁻¹ protein in the rat to 4,500 pg mg⁻¹ protein in the tadpole[1]) Although not shown in Table 1, immunoreactive TRF was present in extracts from *Mesodon roemeri* after the methanolic extracts from the circumoesophageal ganglia had been purified on a column of Sephadex SP C-25 according to the method of McKelvy[13] This indicates that the immunoreactive material found in crude methanolic extracts from these animals is the tripeptide pGlu-His-ProNH₂ In further support of the identity of the immunoreactive material as TRF is the fact that the immunoreactive material from snail ganglia and synthetic TRF showed parallel dilution curves in the radioimmunoassay systems used

Thus immunoreactive TRF is present in various gastropod species This supports the evidence obtained from mammals that this molecule has a role in modulating neurotransmission, and suggests that this function evolved before that of controlling the release of thyroid stimulating hormone

Possible placental origin of ACTH in normal human pregnancy

IT is well known that the free fraction of plasma cortisol is increased in pregnancy[1], but it has not been established whether this is a result of maternal pituitary or placental adrenocorticotrophic hormone (ACTH) secretion Maternal plasma ACTH levels in human pregnancy have been variously reported as elevated[2], or depressed[3], but there is no information on the relationship between ACTH levels and the stage of gestation We now report that maternal ACTH levels increase progressively throughout pregnancy, that urinary free cortisol levels are raised and show resistance to suppression by dexamethasone

and we present evidence suggesting that ACTH may be produced by the placenta

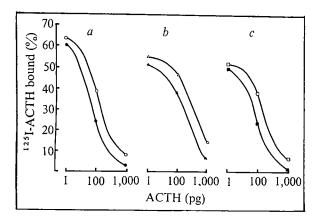
A total of 82 heparinised blood samples were collected between 0900 and 1100 from normal, pregnant women attending an antenatal clinic All samples were separated immediately at 4 °C and stored at −20 °C until assayed and all measurements were made within three weeks of sample collection Plasma ACTH was determined by radioimmunoassay after extraction on to porous glass[4] Highly purified human ACTH was used as standard and for iodination Three antisera were used, one directed against the N-terminal part of the biologically active amino acids 1–24 of the ACTH molecule (extended N-terminal antiserum), a second specific for amino acids 13–18 of the molecule (middle N-terminal antiserum), and the third against the biologically inactive C-terminus (C-terminal antiserum) The specificities of these antisera have been described in detail elswhere[4-6] Only the extended N-terminal antiserum was used to measure plasma ACTH, all three were used to measure ACTH in placental extracts


Fig. 1 Serial dilutions of a placental extract compared with dilutions of standard purified human ACTH using ^{125}I-ACTH, and N-terminal antiserum (*a*), and middle N-terminal antiserum (*b*), and C-terminal antiserum (*c*) ●, ▲, ■, standards, ○, △, □, placental extracts

Freshly collected placentas from normal deliveries were trimmed of cord and membranes and washed with 8 l of ice cold 4% saline Approximately 100 g of tissue was extracted in HCl-acetone (2 5 97 5 v/v)[7], ACTH was determined by radioimmunoassay in serial dilutions of these extracts In one extract, ACTH levels were also determined by cytochemical bioassay[8]

Excretion of free cortisol in the urine was measured by a competitive protein binding assay[9] The assay was modified for pregnancy urine by the addition of a preliminary wash with an equal volume of petroleum ether to remove progesterone which otherwise interferes in the assay This procedure removes 95% of ^{14}C-progesterone, but only 2% of the ^{3}H-cortisol[10] Determinations were made in 24 normal women, in 16 patients with pituitary-dependent Cushing's syndrome and in six women during the last trimester of normal pregnancy before and after the oral, administration of dexamethasone (2 mg d^{-1} for 3 d)

/ **Table 1** ACTH concentrations in human placentas measured by two radioimmunoassays

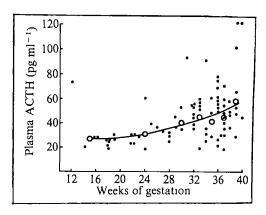
1 2	1 0	
21 3	13 1	


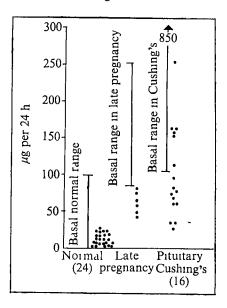


Fig 2 Maternal plasma ACTH levels in normal pregnancy Individual levels are shown (●) together with the mean levels (○) estimated after logarithmic transformation of grouped data (10–20 weeks, 21–27 weeks, 28–31 weeks, 32–33 weeks, 34–35 weeks, 36–37 weeks, 38–40 weeks) (Note the occurrence of a few very high levels which may have been caused by unrecognised stress during sample collection)

Plasma and placental extracts gave inhibition parallel to that of the standard (Fig 1) There was a progressive rise in plasma ACTH levels throughout pregnancy (Fig 2), although most lay within the normal range (<10–80 pg ml^{-1}) The placental content of ACTH ranged from 1 0 to 21 3 ng per g wet weight tissue (Table 1)

Following dexamethasone, normal subjects showed suppression of urinary free cortisol to less than 30 μg d^{-1} (Fig 3) Pregnant women, however, showed resistance to suppression, urinary free cortisol levels during dexamethasone administration were similar to those observed in some with pituitary-dependent Cushing's disease

These results agree with those of Genazzani and his colleagues[2], in showing elevated plasma ACTH levels during normal pregnancy, although, in contrast to these workers, the ACTH in maternal plasma shows parallel inhibition in our radioimmunoassay We have also shown a progressive rise in circulating ACTH concentrations throughout the second and third trimesters The discrepancy between these results and those of Mukherjee and Swyer[3], who found decreased levels, may be attributed to technical factors, since they did not use a plasma extraction step Other observations on maternal ACTH levels in human pregnancy cannot be strictly compared with

Fig 3 Urinary free cortisol levels before (vertical bars) and after (●) dexamethasone administration in normal women, women in the last trimester of pregnancy and patients with Cushing's disease

the findings discussed here because the samples were collected at the time of Caesarean section[11] or vaginal delivery[12,13]

The source of the increasing plasma ACTH levels may be the placenta or the maternal pituitary gland We have shown that urinary free cortisol levels in women in late pregnancy are resistant to dexamethasone suppression, a situation comparable with that observed in Cushing's disease This suggests that a component of maternal ACTH in pregnancy is not of pituitary origin The present studies, in agreement with those of Genazzani[2], and others[14-16] demonstrate high concentrations of ACTH in the human placenta Although content does not necessarily reflect either synthesis or release, these levels are comparable with those observed in tumours associated with ectopic ACTH secretion[17] and are much higher than could be accounted for by the content of sequestered blood This observation, together with the progressive increase in circulating levels during pregnancy and the elevated urinary free cortisol concentrations, suggests placental release of ACTH which is autonomous and not subject to feedback control

These studies were supported by the Medical Research Council We thank Dr J Girard for the gift of the middle ACTH antiserum

Phosphorylase and glycerol production activated by cold in diapausing silkmoth pupae

THE accumulation of glycerol in overwintering insects, first shown in eggs of the silkworm, *Bombyx mori*[1], and pupae of certain saturniid silkmoths[2], is now known in many species Although not all cold-resistant insects contain high levels of glycerol, and the mechanisms of tolerance to cold are not fully understood, it is accepted that naturally produced glycerol can act as an antifreeze and contribute to protection against cold injury[3-5]

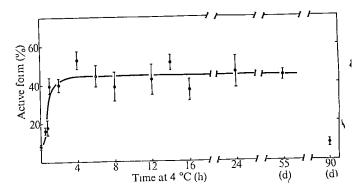
In certain insects, such as adult carpenter ants (*Camponotus pennsylvanicus*[6]) and Alaskan carabid beetles (*Pterostichus brevicornis*[5]), production of glycerol depends on exposure to cold In diapausing pupae of the silkmoth (*Hyalophora cecropia*) some glycerol is produced at 25 °C, but the rate of production is greatly increased at 6 °C (ref 7) Table 1 shows that haemolymph glycerol reaches about 250 mM at 25 °C and 500–600 mM after 1 month at 4 °C Glycerol is formed chiefly at the expense of glycogen[7], and enzymes forming an appropriate pathway occur in insect tissue glycogen phosphorylase[9], the glycolytic pathway to dihydroxyacetone phosphate, α-glycerophosphate dehydrogenase[10,11] and α-glycerophosphatase[12,13] Accordingly, cold might be expected to activate one or more steps in this sequence We have now demonstrated this


Fig. 1 Conversion of fat body phosphorylase to the active form after transfer of cecropia pupae from 25 °C to 4 °C Pieces of fat body were removed within 45 s and frozen between aluminium plates on dry ice The frozen tissue (about 100 mg) was homogenised in 1 3 ml of buffer (20 mM triethanolamine acetate, pH 7 0, containing 5 mM EDTA and 20 mM NaF) The homogenate was centrifuged twice at 10,000g for 10 min, and 25 or 50 μl of the supernatant was used for enzyme assay A coupled spectrophotometric assay[15] was performed in a Gilford 2400S spectrophotometer A rate was established in the absence of 5′-AMP, for active phosphorylase, then 2 mM 5′-AMP was added and a new rate was determined for total phosphorylase Values are means ±s e m from 3–10 determinations on individual pupae The initial level of about 8% active form is higher than that of less than 1% previously found by a different assay method[9], and recent experiments (L T Wimer, R Z and G R W, unpublished), show a systematic difference between the two assays, the reason for which is not known

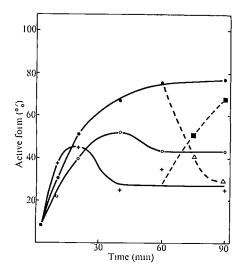
We found in the fat body, which is the site of the major glycogen reserves in diapausing cecropia silkmoth pupae, activation of glycogen phosphorylase by cold that seems to play a role in the control of glycerol formation Phosphorylase in this tissue occurs in active and inactive forms, the latter (like muscle phosphorylase b) being activated by 5′-adenosine monophosphate[9,14] In fat body excised quickly from pupae stored at 25 °C, usually less than 10% of the phosphorylase was in the active form, but when pupae were placed at 4 °C, the active fraction increased rapidly to about 45% (Fig 1) After 3 months of storage at 4 °C, this activation had been reversed Similar effects of temperature were observed with fat body tissue *in vitro* (Fig 2) When pupal fat body was placed in Ringer solution, phosphorylase was converted partially to the active form

Table 1 Increase in glycerol content in haemolymph of cecropia silkmoth pupae after storage at 4 °C

Age of pupae (d)	Unchilled (25 °C) Glycerol (mM)	Chilled Days at 4 °C	Chilled Glycerol (mM)
30	147±9 (5)	5 5	171±13 (5)
70	278±35 (3)	30	490±80 (3)
90	225±54 (3)	40	679±57 (3)
110		50	512±50 (4)
110	205±27 (3)	60	540±46 (3)
110		70	438±45 (3)

Haemolymph samples were deproteinised with ethanol, and glycerol was determined with chromotropic acid[8] Means and standard errors, with numbers of samples in parentheses, are shown


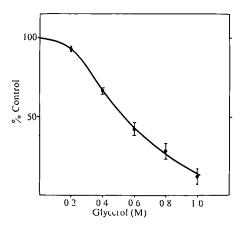


Fig 2 Changes in degree of activation of phosphorylase in fat body after incubation of the tissue in Ringer solution at different temperatures Fat body was removed quickly from diapausing pupae, rinsed very gently and divided into small pieces (about 100 mg), and each was placed in a small beaker with 2 ml of lepidopteran Ringer solution[16] at the temperature shown At the times indicated, the tissue was frozen between aluminium plates on dry ice Phosphorylase was then prepared and assayed as described in Fig 1 ●, 0 °C, ■ 0 °C after transfer; O, 15 °C; +, 25 °C; △, 25 °C after transfer.

(see ref 9), at 25 °C this activation was reversed after 20–40 min, but at 0 °C it continued, to produce up to 80% active enzyme at 90 min Incubation at 15 °C yielded an intermediate curve Transfer from 25 °C to 0 °C, or from 0 °C to 25 °C, after 60 min showed the effect of temperature to be reversible

Since the total level of phosphorylase did not change during these experiments, the activity changes probably reflected conversion of enzyme forms by phosphorylase kinase and phosphatase, respectively Both these activities have been demonstrated in soluble supernatant preparations under appropriate conditions, but in such preparations phosphorylase activation was not enhanced by cold The possible similar effects in other animal tissues, are being investigated

The association of changes in phosphorylase activity in cecropia silkmoth pupae with glycerol production is sup-

ported by our observation that the activation of phosphorylase in fat body at 0 °C is inhibited by addition of glycerol to the bathing Ringer solution (Fig 3) The level of glycerol giving 50% inhibition (about 0 5 M) is often attained in haemolymph *in vivo* This is suggestive of a regulatory feedback

These observations indicate that glycogenolysis in diapausing cecropia silkmoth pupae is controlled in part by the influence of both environmental temperature and the level of glycerol in the haemolymph on the phosphorylase system The specific conversion of carbohydrate to glycerol, however, is probably controlled at another step A regulatory role has been suggested[7] for α-glycerophosphatase and has recently received support[13] An effect of cold on this enzymatic step might account for the observation[17] that *Galleria* larvae contained elevated inorganic phosphate and decreased α-glycerophosphate after chilling at 0 °C

This work was supported by the US National Institutes of Health and the National Research Council of Canada R Z was supported by the Deutsche Forschungsgemeinschaft We thank Tom Mueller for help

Fig 3 Influence of glycerol on the activation of phosphorylase in fat body *in vitro* Pieces of fat body (about 100 mg) from a single diapausing pupa were incubated in 2 ml of Ringer containing different concentrations of glycerol at 0 °C After 60 min the fat body was treated and phosphorylase was assayed as described under Fig 1 The values are expressed as percentage of the increase shown by the control (60 min in Ringer with glycerol) Each value is the mean ± s e m of four determinations on different animals

Chromatographic demonstration of mineralocorticoid-specific receptors in rat kidney

THE binding of a drug with its specific macromolecular receptor(s) seems to constitute the first step whereby a number of pharmacological agents initiate a variety of intra and intercellular processes Aldosterone is the principal mineralocorticoid in mammals regulating ion transport in the kidney, and some extrarenal targets, but at higher concentrations it also exhibits glucocorticoid-specific properties[1] From studies on displaceable binding to protein ligands alone, it is not possible to affirm the physicochemical nature and homogeneity of a 'specific' mineralocorticoid receptor that is thought to be essential for the steroid function and said to exist in the toad bladder[2] and rat kidney[3] Techniques have been established for the characterisation and partial purification of corticosterone receptors in rat liver[4,5] These have now been adapted to demonstrate aldosterone-specific binding proteins present in rat kidney but absent from the liver

Figure 1 shows that aldosterone was bound to three sorts of proteins in rat kidney cytosol The first of these (I) was eluted with the low ionic (0 001 M) prewash on the DE-52 column and seemed to be the most abundant, the second (II) eluted at 0 006 M phosphate and was one-third as radioactive as the first, the third (III) component exhibited nearly the same concentration as the second but came off only at ionic strengths of 0 018 or more One or more of these could constitute the specific mineralocorticoid receptor(s) When a similar separation

was attempted with kidney cytosol equilibrated at 10^{-8} M corticosterone (Fig 2) there was only a faint indication of the first peak, the component in the 0 006 M PO_4 region was totally wanting, whereas nearly all of the radioactivity eluted between 0 02–0 06 M concentration of the phosphate From a series of other experiments, 5×10^{-9} M aldosterone was actually more effective than a high concentration (10^{-7} M) of corticosterone in revealing the components that peak in the 0 001 M and 0 006 M PO_4 regions (although 10^{-8} M aldosterone seemed to be required to saturate these macromolecules) In addition, the elution profile demonstrates that the first peak in the prewash does not represent free radioactivity or an artefact of the washing procedure[8] Although peaks I and II (Fig 1) may be explained as polymerised or aggregated forms of the mineralocorticoid receptor, this would be an unlikely postulate for peak III, in view of results shown in Figs 2 and 3

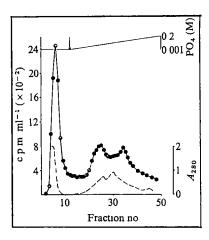
Mammalian kidney is endowed with gluconeogenic potential and is reported to possess macromolecules with high affinity for glucocorticoids[3] Peak III (Fig 1), which has the same elution position as the corticosterone peak in Fig 2, could therefore represent such receptors, or transcortin, or both When kidney cytosol equilibrated with 10^{-7} M ^{3}H-corticosterone was cochromatographed with ^{14}C-corticosterone bound to serum transcortin, a shoulder of radioactivity coming off at 0 018–0 02 M was masked by a much larger peak coeluting with serum transcortin at 0 06 M phosphate (Fig 3) Separation was sharper in the absence of serum and these peaks almost certainly represent the glucocorticoid receptors and transcortin, respectively, whereas peak III (Fig 1) and the peak in Fig 2 would seem to be a mixture of both of these components


Fig. 1 Ion-exchange separation of aldosterone-binding proteins in rat kidney Male Wistar rats (150–200 g) were bilaterally adrenalectomised at least 48 h before use, exanguinated under light ether anaesthesia, and perfused with the initial buffer by aortic cannulation The excised organs were homogenised in an equal volume of the same buffer and the 105,000g supernatant fraction (6 ml) was equilibrated for 60 min at 4 °C with the desired concentration of labelled steroid (aldosterone, 10^{-8} M) The free radioactivity was then removed by additional incubation in presence of 100 mg ml^{-1} cell sap of activated charcoal (Sigma C-5260) for 10 min and centrifugation at 3,000g The supernatant was then passed through glass wool to remove traces of carbon and then charged on to the column The chromatography on DEAE-cellulose-52 (column 1×25 cm) was performed as described previously[4-6] The column was equilibrated with 0 001 M sodium phosphate, pH 7 5 Aliquots (1 ml) were mixed with 10 ml Unisolve (Koch Light) and counted in a Packard Tricarb Liquid Scintillation Spectrometer with corrections for quenching, spilling and background[7] After passage of 60–70 ml of the initial buffer (fraction volume 6–7 ml), protein was eluted (at arrow) with a linear gradient of 60 ml 0 001 M and 60 ml 0 2 M Na phosphate, at a flow rate of 60 ml h^{-1} (fraction volume approximately 3 ml) All manipulations were carried out at 4 °C 1,2,^{3}H-aldosterone (lot 1172, 55 Ci mmol^{-1}), 1,2,^{3}H-corticosterone (batch 57072, 26 Ci mM^{-1}) and 4,^{14}C-corticosterone (lot 467–248, 57 mCi mmol^{-1}), (Saclay, France) were diluted in ethanol, which was evaporated in the incubation vessel before equilibration All other chemicals were high purity reagent grade

Dotted line, A_{280} values, continuous line, radioactivity

Fig 2 Absence of corticosterone binding to mineralocorticoid specific receptors in rat kidney All details as in legend to Fig 1 except that the kidney cytosol (5 ml) was equilibrated with 10^{-8} M ^{3}H-corticosterone and loaded on the resin

Since mammalian liver is not the principal site of ion regulation, it is believed to be devoid of mineralocorticoid receptors[1,3] Figure 4 shows that the 0 006 M region had no radioactivity when liver cytosol equilibrated with 10^{-7} M ^{3}H-aldosterone was chromatographed under the conditions described above Competitive binding, followed by chromatography, further established that liver glucocorticoid receptors elute as a more abundant species in the 0 001 M prewash and a less abundant peak in the 0 018 region of the phosphate gradient (although the latter may also contain some residual, intracellular transcortin) and it is to these macromolecules that aldosterone seems to be bound (Fig 4)

These results thus provide chromatographic evidence that, as the principal ion regulator, the kidney is endowed with mineralocorticoid-specific receptors which are physicochemically distinct from the glucocorticoid binders, are present as readily distinguishable subpopulations within the cell and are wanting in the liver (having no active role in physiological ion regulation) Furthermore, they seem to be saturated at those endogenous, physiological concentrations at which binding of corticosterone

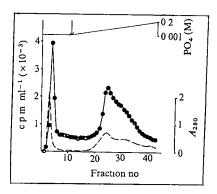
Fig. 3 Binding of corticosterone to glucocorticoid receptors and to transcortin Kidney cytosol (3 ml) and blood serum (2 ml) were saturated with 10^{-7} M ^{3}H-corticosterone and 0 25 µCi ^{14}C-corticosterone, respectively, and then treated with charcoal to remove free radioactivity After 60 ml prewash with 0 001 M phosphate buffer, elution was carried out (at arrow) with 60 ml each of 0 002 M and 0 2 M phosphate (fraction volume 4 ml) at a flow rate of 60 ml h^{-1} ●^{3}H, O, ^{14}C


Fig 4 Absence of mineralocorticoid-specific receptors in rat liver All details as in legend to Fig 1 except that liver cytosol (5 ml) was equilibrated with 10^{-7} M ^{3}H-aldosterone and charged on the column

is still markedly dose dependent, and this is compatible with the fixed time assay value of KD_{37} °C 5×10^{-10} M (refs 1 and 3) Glucocorticoid specific receptors seem to be identical in the two organs, both with respect to the tenfold higher KD values and saturation with 10^{-7} M steroid, in keeping with levels circulating *in vivo*[1,3].

Purification of the receptor proteins is required to establish unequivocal affinity constants Nevertheless, the techniques described here may profitably be used to understand the mechanism of corticoid hormone action by analysis of receptor function in other organs, the stereospecificity of aldosterone binding in the presence of various agonists and antagonists of the steroid, possible qualitative differences in the relative abundance of the different subpopulations of steroid binders in various stages of differentiation, hypo or hyperfunction, and the relationship between the glucocorticoid and the mineralocorticoid receptors in diverse tissues

I thank Monique Philippe for assistance and numerous colleagues for discussions

Molecular structure of membrane-bound rhodopsin

WE have results which suggest a structure for the membrane-bound sensory protein, rhodopsin This structure has novel features which are of considerable biological interest

The transduction of light energy into neural signals is mediated in all known visual systems by a common type of visual pigment consisting of the 11-*cis* isomer of a retinaldehyde chromophore conjugated to some form of the protein opsin Photoisomerisation of a single molecule of the photopigment in a vertebrate photoreceptor cell can initiate a chain of events leading to excitation of that cell Although the primary events of the sequence are not known, it is widely suspected that they include a change in photopigment structure that causes release of some transmitter substance[1-3]

We looked for structure changes in rhodopsin-containing disk membranes using hydrogen–tritium exchange techniques[4,5]

Evidence for structure change has previously been limited to rhodopsin in detergent solutions[6-10] and some of these changes have been specifically shown not to occur *in situ*[10,11] Figure 1 shows that changes do occur in the membrane-bound protein following illumination The data in Fig 1 measure only the slowest 25 % of the exchanging protein hydrogens

To study the much larger fraction of protein hydrogens that exchange more rapidly, different exchange conditions must be used Figure 2 shows data obtained at lower pH where the intrinsic exchange rate of peptide hydrogens is 250 times slower Disk membranes from cattle and frog gave similar results While about 0 4 hydrogens per peptide group exchange rather slowly and trace out a series of slower and slower rates, a larger number, $\sim$ 0 7 hydrogens, form a clearly distinguishable and much faster kinetic class Surprisingly, the exchange rate of the fast phase is experimentally identical to that previously found for peptide group hydrogens that are freely exposed to bulk solvent water

The factors controlling the hydrogen exchange behaviour of free peptides have been calibrated in studies with small molecules[12] and homopolypeptides[13] Peptide exchange rates are a strong function of pH and temperature and vary to a minor extent depending on nearest neighbour side chains The calibrations obtained for these factors have been tested against hydrogen exchange data for the free peptides in a random chain heteropolypeptide, oxidised ribonuclease[12], in the globular protein, myoglobin[12,14], in the fibrous protein, collagen[15], and, by use of nuclear magnetic resonance techniques, for specific protons in the cyclic oligopeptide, angiotensin[16] In all these cases, the free peptide rates were well behaved and precisely predictable Under the conditions of Fig 2, free peptides are expected to have half times ranging generally from 30 to 60 s, and this is found for the fast phase in Fig 2

The possibility that protons from other sources might contribute significantly to these curves was considered in some detail The data in Fig 2 measure a total of 1 1 $\pm$ 0 1 exchanging hydrogens per peptide group This corresponds closely to the 1 12 $\pm$ 0 17 peptide and primary amide hydrogens expected on the basis of composition data for rod outer segment membranes[17-20] Moreover, experiments were carried out which excluded protons from phospholipids and protein side chains (These results will be detailed elsewhere) Thus the data in Figs 1 and 2 represent protein hydrogens

The data show that close to two-thirds of the peptide hydrogens in disk membranes are hydrogen bonded to solvent water Most of these must come from rhodopsin itself, since rhodopsin accounted for $\sim$ 85 % of the protein in our preparations, in agreement with the value established for uncontaminated rod outer segments[21-23] Thus we conclude that at least 60 % of rhodopsin's peptide hydrogens are freely exposed and hydrogen bonded to water This seems especially remarkable when it is considered that rhodopsin is an intrinsic membrane protein, and also that the more familiar water soluble proteins that have been studied by either hydrogen exchange or X-ray diffraction or both all have only 30 $\pm$ 10 % of their peptide groups hydrogen bonded to solvent water Some results for other membrane systems also indicate that their proteins, like typical soluble proteins, have only a small fraction of fast, freely exposed peptides (see ref 24 for sarcoplasmic reticulum and unpublished results of G Gabor and S W E for erythrocyte ghosts)

Rhodopsin's structure then must be quite unusual In addition to the large number of freely exposed peptide groups, a second restriction on possible structural models for rhodopsin is provided by its large complement of apolar residues Many of these are presumed to be in contact with the lipid hydrocarbon chains since the protein can be separated from the membrane only through the use of detergents The general, non-committal resolution of these apparently contradictory requirements seems to be that a good part of rhodopsin's polypeptide chain must be arranged at a lipid–water interface with many of its apolar side chains contacting lipid hydrocarbons and many of its peptide group protons in water

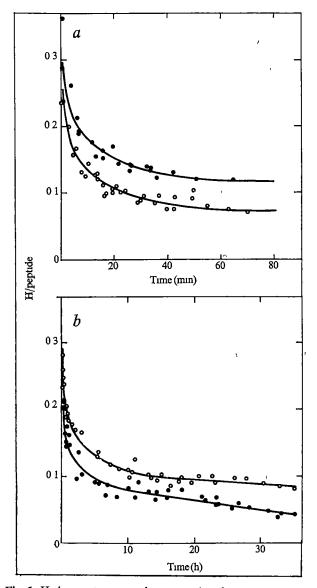
Several considerations argue against the surface of the membrane bilayer This surface could not provide the required apolar contacts, the highly polar phospholipid head groups are there Rhodopsin is thought to penetrate into and perhaps through the membrane, as suggested by fluorescence transfer experiments[25], by the pattern of protease sensitivity of the membrane-bound protein[26,27] and by freeze-fracture studies


Fig 1 Hydrogen–tritium exchange-out data for disk membrane suspensions at pH 7 7, 0 °C The frog (a) and cattle (b) disk membrane preparations used had ratios A_{280}/A_{500} of 2 2–2 5 after purification on discontinuous sucrose gradients Exchangeable hydrogen sites were labelled to equilibrium with tritium in darkness by exchanging-in for 50–60 h at 0 °C in Ringer buffer with added tritiated water Exchange-out was initiated (zero time) by passing a sample of the suspension through a Sephadex column to remove the free tritiated water Subsequent separations allowed measurement of the amount of tritium still remaining bound as a function of exchange-out time, and the data were computed and plotted in terms of mol of original hydrogen as yet unexchanged per mol of peptide group present a, Disk membranes from frogs were either dark-adapted (●) or irradiated with white light at 0 °C for several minutes starting at zero time of the exchange-out experiment (○) When disk membranes from cattle were so treated (except that irradiation was with light of λ > 540 nm) no changes in exchange behaviour developed relative to the dark control b, Exchange-out of cattle disk membranes in the dark-adapted state (●) is compared with that of disk membranes containing opsin (○) Here the rhodopsin was converted to opsin by bleaching in white light and then incubating the disk membrane suspension for 45 min at 35 °C The suspensions were recooled to 0 °C before beginning exchange-out We do not know if the difference in response between cattle and frog disks represents a difference in the intermediates formed or in their kinetics of formation

of native photoreceptor membranes[28] Also against such a model is the consideration that this placement of the polypeptide chain seems to have little potential for function

A more compelling though still quite general possibility is that a good portion, perhaps 50%, of the polypeptide chain is arranged so that it forms the surface of an aqueous channel into the membrane In order to traverse a considerable fraction of the lipid bilayer and also contain enough bulk water to satisfy the requirement for hydrogen bonding to peptides at its surface, the channel would have to be of the order of 10–15 Å in diameter Analogous arrangements may be considered if two or more monomers cooperate to enclose the aqueous space[28]

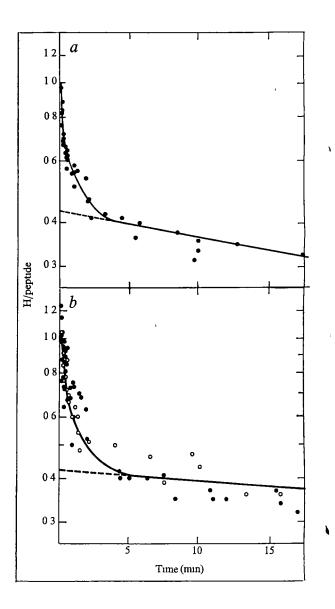
The changes in hydrogen exchange behaviour found on illumination involve the slowly exchanging, internally bonded hydrogens corresponding to structured regions of polypeptide The free peptide region of the curve is unaffected by light (Fig 2) This matches the obvious expectation that the retinaldehyde chromophore is held within a structured part of the molecule, and is consistent with the supposition that this structure may act as a plug that closes off the rhodopsin channel in the dark but becomes distorted after illumination to


Fig 2 Exchange-out data for frog (a) and cattle (b) disk membranes at pH 5 3 and 0 °C Data from dark-adapted (●) and opsin-containing disks (○) are shown In both curves, 0 4 H/peptide group are slow and 0 7 form a faster kinetic class exchanging at just the free-peptide rate ●

allow the rapid escape of some transmitter substance contained within the disk membrane

Photoreactivation of herpes simplex virus in human fibroblasts

When DNA is treated with ultraviolet light (220–300 nm) cyclobutyl pyrimidine dimers are produced between adjacent pyrimidines on a strand of DNA[1] These dimers are a major cause of mutations and death in simple organisms after ultraviolet-irradiation[1], and they have been implicated in the induction of skin cancer in man[2,3] An important tool for assessing the deleterious effects of dimers is the photoreactivation test the photoreactivating enzyme repairs DNA by the specific and exclusive monomerisation of dimers in a light-dependent (> 300 nm) reaction[4,5] If ultraviolet biological damage can be reversed by true photoenzymatic repair, then dimers have a major role in the production of that damage[6] For the test to assess the role of ultraviolet-induced dimers in human carcinogenesis at least three criteria must be met (1) human cells must possess a functional photoreactivating enzyme, (2) this enzyme must be able to monomerise dimers in DNA, and (3) the enzyme must be able to restore biological activity to ultraviolet-irradiated DNA It has been shown that human cells meet the first two criteria[7,8], we now show that human photoreactivating enzyme in fibroblasts can restore infectivity to ultraviolet-irradiated herpes simplex virus (HSV)

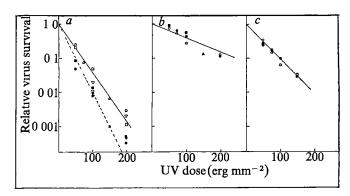
We exposed HSV in phosphate-buffered saline solution[9] to increasing doses of ultraviolet light from a low pressure mercury arc The ultraviolet-irradiated HSV was then titred on normal fibroblasts or those from patients with xeroderma pigmentosum, a rare genetic disease characterised by development of neoplasia in skin exposed to high levels of sunlight[3] It has been found that different cell lines derived from patients with


Fig 1 Photoreactivation of HSV in Jay Tim cells *a*, Jay Tim, *b*, HESM, *c*, XP-1, stocks of the F strain of HSV were grown and their titre was determined as before[9] Samples containing between 10^6 and 10^7 plaque forming units (PFU) of HSV in 1 ml of phosphate-buffered saline containing 0 1% glucose (PBS-glucose) were irradiated for various times with a 15-W GE germicidal lamp, ultraviolet dose was measured with a Jagger metre[13] calibrated with a Hewlett-Packard thermopile Immediately after irradiation the virus stocks were diluted with PBS-glucose and overlayed on fibroblasts in 25-cm² plastic tissue culture flasks at 37 °C Xeroderma pigmentosum cell lines were obtained from the American Type Culture Collection and normal human embryonic skin and muscle fibroblasts (HESM cells) were obtained from Flow Laboratories The growth and maintenance of these cells in Dulbecco's modified Eagle's MEM with 20% foetal calf serum has been described[8] Appropriate dilutions of virus were allowed to adsorb to the cells for 60 min in PBS-glucose and then the cells were overlaid with medium 199 containing 2% foetal calf serum and 0 4% human immune serum globulin The infected cells were either illuminated for 6 h with a 60-W yellow incandescent bulb at an average distance of 25 cm in an incubator at 37 °C or were kept in the dark by wrapping in aluminium foil Plaques were allowed to develop for 48 h and visualised by staining the infected cells with 2% crystal violet in 20% ethanol Virus survival was calculated from the relative plaque titres obtained by diluting unirradiated HSV and carrying out a parallel infection in illuminated or dark cells The open symbols represent titres on photoreactivated cells and the closed symbols represent titres on cells kept in the dark The different symbols represent different experiments The ultraviolet-dose curves on HESM cells were carried out in parallel with those on Jay Tim cells

xeroderma pigmentosum vary in both their levels of photoreactivating enzyme and the excision repair pathway[3,8] The ultraviolet-irradiated virus stocks were titrated on a xeroderma pigmentosum cell line lacking excision repair but possessing photoreactivating enzyme (Jay Tim) (Table 1) Infected cells were exposed to photoreactivating light for 6 h, duplicate cultures were kept in the dark and plaques were allowed to develop (Fig 1) Figure 1*a* demonstrates that virus exposed to 150 erg mm⁻² of ultraviolet light and plated in the dark on Jay Tim cells showed an apparent drop in titre by a factor of 1,000, in contrast, the titre of this virus was only reduced by a factor of 150 when cells were illuminated with photoreactivating light Since human photoreactivating enzyme has an action spectrum that extends beyond 600 nm (ref 16), we used a 60-W yellow incandescent light as our photoreactivating source to minimise damaging wavelengths in white incandescent light In the experiment shown in Fig 1*b* photoreactivation of HSV could not be detected when the virus was titred on normal human fibroblasts (HESM cells) containing both excision repair and photoreactivating enzyme (Table 2) The difficulties in detecting photoreactivation in excision-proficient cells have been discussed by Harm et al[10] The apparent drop in HSV titre at a given ultraviolet dose was considerably greater with xeroderma pigmentosum cells compared with normal fibroblasts This result is in agreement with previous reports on the effect of excision repair on ultraviolet-damaged HSV[11,12]

If the increased light-dependent survival of the HSV in Jay Tim cells is true photoenzymatic repair, cells which lack photoreactivating enzyme should show no effect of light on virus survival XP-1 cells contain neither appreciable excision

Table 1 DNA repair activity in normal and xeroderma fibroblasts

Cell line	Unscheduled synthesis (% of normal)	Photoreactivating enzyme activity (U)	Photoreactivating enzyme activity (% of normal)
Human embryonic skin and muscle	100*	627†	100
Jay Tim (XP12BE)	<2*	227†	36 3
XP-1 (XP1LO)	<2*	2 93	<1
Wo Mec (XP4BE)	100*	58 2	10 8

*See ref 3 for a complete discussion of unscheduled synthesis
†Photoreactivating enzyme activity was determined by the method of Sutherland and Chamberlin[14], protein was determined by the Lowry method[15] using bovine serum albumin as a standard Units of enzyme activity are pmol $mg^{-1} h^{-1}$

repair capacity nor photoreactivating enzyme activity (Table 1) HSV treated with 100 erg mm^{-2} showed a tenfold decrease in virus titre on XP-1 cells whether the cells were treated with photoreactivating light or kept in the dark (Fig 1c) In comparison, when cells were treated with white light from a 60-W bulb for 24 h after infection, the inactivated virus showed a 50-fold decrease in apparent titre. This was presumably the result of further damage to the infected cells by inactivating radiation present in the white light

We tested the contribution of photoprotection[13] to increased virus survival as follows Jay Tim cells were illuminated with photoreactivating light for 8 h before infection and then kept in the dark for plaque development We detected no appreciable difference in virus titre compared with unilluminated cells At a dose of 200 erg mm^{-2} we found the titre of the virus reduced more than 500-fold in both cases We therefore conclude that photoprotection does not contribute to the increased survival of HSV in Jay Tim cells treated with photoreactivating light We can also exclude any differences in the efficiency of plaque formation of HSV on xeroderma pigmentosum cell lines compared with normal human fibroblasts as a contributor to our observed results Several experiments with both types of cells kept in the dark yielded virus titres within 10% of each other when unirradiated HSV was used

Table 2 Effect of HSV infection on photoreactivity enzyme activity

Cells	Infected with 10 PFU per cell HSV*	Photoreactivating enzyme activity (% of line 1)
Human embryonic skin and muscle	No	100
Human embryonic skin and muscle	Yes	68 5
Wo Mec	No	10
Wo Mec	Yes	8 15

*Infection was carried out as described in Fig 1 Cells were overlaid with Medium 199 containing 2% foetal calf serum and harvested at 7 h after infection

These results show that the increased survival of HSV is caused by true photoreactivation It was considered possible, however, that such photoreactivation could be the result of the induction of an HSV specific enzyme after infection rather than to a human enzyme To exclude this possibility we assayed photoreactivating enzyme levels in HESM cells and in a xeroderma pigmentosum line (Wo Mec) with a low level of photoreactivating enzyme but normal levels of excision repair activity (Table 1) The data in Table 2 show that there is no increase in the photoreactivating enzyme level in HSV-infected HESM cells Thus virus infection does not increase photoreactivating activity *per se* In the Wo Mec cells there was no increase in enzyme activity after HSV infection (Table 2) This cell line should be an extremely sensitive indicator of appearance of any photoreactivating enzyme synthesised *de novo* provided there is normal expression of the HSV genome We have determined the yield of infectious virus from xeroderma pigmentosum

lines When the cells were kept in the dark we could obtain as much as 5–10 plaque forming units (PFU) of infectious virus per infected cell compared with a yield of 10–30 PFU per infected cells with HESM cells Such results, together with the efficiency of plaque formation of HSV on xeroderma pigmentosum cell lines, demonstrate that there is normal expression of HSV gene products during the infection of these cells We conclude, therefore that all the photoreactivation observed in the infected cells is caused by the presence of the human enzyme

We have demonstrated that the photoreactivating enzyme in human cells repairs UV-damaged DNA and restores its biological activity This demonstration confirms the biological significance of the human photoreactivating enzyme It is thus valid to use the photoreactivating test in evaluating the contribution of pyrimidine dimers in UV-induced human skin cancers

Cyclic AMP and the production of sex pili by *E. coli* K-12 carrying derepressed sex factors

THE filamentous appendages, known as sex pili, determined by F-like and I-like sex factors in enterobacteria, have an essential function in conjugation[1] But neither the exact nature of their function, nor their mode of formation is yet known The number of sex pili ordinarily seen in cultures of *Escherichia coli* K-12 carrying derepressed F-like or I-like sex factors[2] (where pilus production is not limited by specific repression) seldom exceeds an average of 1–2 per bacterium With I-like pili, however, the numbers can be increased 50-fold or more by exposing the bacteria to either antiserum reacting with the pili[3], or vigorous washing[4]

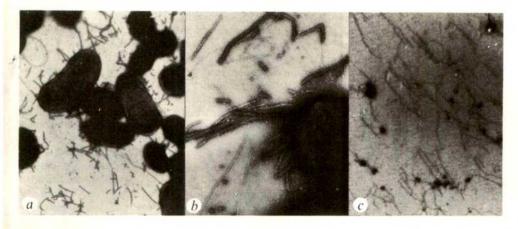
Liquid cultures of strains of *E coli* K-12 producing sex pili due to a derepressed sex factor are commonly granular in appearance[5,6] Therefore, when very large clumps of bacteria visible to the naked eye were seen with a particular strain, M878, carrying the derepressed I-like sex factor, I*drd*16 (ref 7), this suggested that M878 was forming exceptionally large numbers of the sex pili determined by I*drd*16 The parent of strain M878 was PP78*cya crp*[8] (deficient in adenyl cyclase[8] and cyclic AMP receptor protein[9]), the tentative interpretation was,


Fig. 1 *a, b*, Samples of a broth culture of strain 5336*cya crp*⁺ carrying R538I*drd*2, grown without cyclic AMP, showing numerous I-like sex pili, distinguished from F pili and common pili by attachment of specific antibody, as described by Lawn and Meynell[6]. Samples were fixed with 0.5% formalin before adding antiserum to avoid the possibility of an increase in pilus production caused by the antibody itself[3]. Comparison with the sample in *c*, which was treated with F pilus antiserum, shows that large numbers of I-like pili were indeed also present when they had not reacted with the antibody (*a*, ×7,700; *b*, ×23,760; *c*, ×16,280).
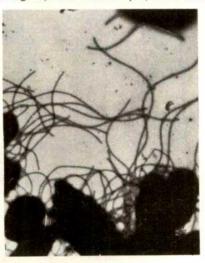

therefore, that the unusual behaviour of strain M878 was caused by the *cya crp* mutations. PP78 was derived from strain 1100 (*cya*⁺ *crp*⁺) (ref. 8) which, in turn, was derived from HfrH*thi*, strain 3000 (ref. 10). In addition to carrying I*drd*16, M878 had been made E1ʳ (resistant to colicin E1-K30) and carried ColE1-K30 (ref. 11). The *cya*⁺ *crp*⁺ control strain (M889) for M878 was, therefore, strain 1100 made E1ʳ and carrying ColE1-K30 and I*drd*16.

When cultures of M878*cya crp* were examined by electron microscopy, at least 100-fold more I-like sex pili were seen, mainly loose and scattered over the specimen grid, compared to cultures of the control strain, M889*cya*⁺ *crp*⁺. Since M878 and M889 both originated from HfrH, they were expected to form F pili, common pili and flagella, as well as I-like pili. However, only I-like pili were more numerous in M878 than M889. F pili and common pili were equally frequent in either strain but only a very rare flagellum was seen with M878. This confirms Yokota and Gots[12] who showed that cyclic AMP is required for flagella formation but that its absence does not decrease the numbers of F pili.

Similar results were obtained with two derepressed I-like R factors, R538I*drd*2 and R64*drd*11, after their transfer to strain PP78*cya crp* E1ˢ Col⁻.

To test whether increased formation of I-like sex pili resulted from the *cya* or the *crp* mutation, R538I*drd*2 and R64*drd*11 were transferred to the following strains: 5333*cya*⁺ *crp*⁹, 5336*cya*⁺ *crp*⁺ (ref. 8) (from strain 1100); CA8306*cya crp*⁺ (from HfrH, strain 3000); and WZ25*cya*⁺*crp* F⁻ (ref. 13). In each case, large numbers of I-like sex pili were formed. Thus the products of both the *cya* and the *crp* genes were involved in restraint of pilus formation and their effect was not confined to strain M878, originally tested.

Fig. 2 Sample from a broth culture of strain CA8306*cya crp*⁺ carrying R538I*drd*2, grown with 0.33 mM cyclic AMP. Large numbers of flagella, but no I-like sex pili, can be seen (×10,000).

The effect of the *cya* mutation on synthesis of catabolite-sensitive enzymes is reversed by adding cyclic AMP to the growth medium[8]. Strain 5336*cya* or strain CA8306*cya* carrying R538I*drd*2 were grown either with or without 0.33 mM cyclic AMP. The two strains behaved identically; without cyclic AMP, the cultures showed many I-like pili but only a rare flagellum (Fig. 1*a,b,c*); with cyclic AMP, they showed few I-like pili (considerably less than one per ten bacteria) but many more flagella than were observed in *cya*⁺ *crp*⁺ strains whether cyclic AMP was present or not (Fig. 2). Also, the bacterial bodies differed: with cyclic AMP, they had their usual bacillary shape, but without cyclic AMP, they were almost coccal. The numbers of F pili or common pili were not significantly affected.

In our experience, F is not typical of derepressed F-like sex factors inasmuch as it causes relatively few sex pili to be formed. The effect of cyclic AMP was, therefore, tested on four derepressed F-like R factors (two *o*ᶜ, R538F*drd*1 and R124*drd*2; and two *i*⁻, R1*drd*19 and R136*drd*M1: refs 14, 15) in strain 5336*cya crp*⁺. With all four R factors, about 10 times more F-like sex pili were present in cultures grown without cyclic AMP. The contrast was less striking than with I-like factors because more pili were formed when cyclic AMP was present.

We have, as yet, no clear indication of the level at which cyclic AMP acts in restraining sex pilus production. The effect of the *cya crp* mutations could be on pilus protein synthesis or its polymerisation into morphological pili. The fact that the cyclic AMP receptor protein is also required may indicate that, as with other prokaryotic functions where cyclic AMP is involved, cyclic AMP acts at the level of transcription[16]. It is notable that the effect of cyclic AMP and its receptor protein on pilus production is negative rather than positive. But the *cya* or *crp* mutations need not directly affect transcription of genes involved in pilus production, but may act indirectly through some more general effect on the bacterial cell envelope[17]. Some authors have suggested the possibility that pilus protein may be present as a constituent of the bacterial membrane when a sex factor is present (for example ref. 18). The bacteria of the *cya crp* strain, PP78, had an altered shape and, in conditions where they carried an I-like sex factor and produced large numbers of sex pili, the bacteria were lysed by low concentrations of sodium dodecyl sulphate (SDS) (~ 1%) which in the case of *cya*⁺ *crp*⁺ bacteria[6] only dissolved the sex pili without affecting the viability, microscopic appearance or motility of the bacteria. Neither did the same concentrations of SDS affect *cya crp* bacteria not carrying an I-like sex factor (K. Flint, unpublished).

Washing with broth or phosphate-buffered saline increases the number of sex pili[4] and removes intracellular cyclic AMP[19]. If the effect on pilus production caused by washing was a result of removal of cyclic AMP, it might be abolished by adding cyclic AMP to the wash medium. This could not be shown, however, despite repeated attempts. Samples of the strain, W945(R538 I*drd*2), with which the effect of washing was originally demonstrated, were washed with broth containing up to 3 mM cyclic AMP neutralised with NaOH, after growth in the same medium,

but the number of pili produced was similar to control preparations grown and washed with medium without cyclic AMP.

Even where a structural component has been identified in bacterial conjugation, as with the sex pili determined by F-like and I-like sex factors, a major difficulty in its study up to now has been its isolation in sufficient quantity. This difficulty should be overcome to a considerable extent by the greatly increased numbers of pili produced by *cya crp* mutant bacteria, as described here. Furthermore, several additional categories of sex factor exist for which a structural component corresponding to the sex pili of the F-like and I-like classes has not yet been demonstrated[20]. If such a structure were similarly produced in greater than normal amounts in *cya crp* mutant bacteria, the use of such bacteria may increase the likelihood of its identification.

Strains 1100, 5333, 5336 and PP78 were provided by Dr I. Pastan, strain CA8306 by Dr J. Beckwith and strain WZ25 by Dr S. Baumberg. The authors thank the Medical Research Council for financial support.

Synthesis of ribosomal RNA during sporulation in *Bacillus subtilis*

SPORULATION in *Bacillus subtilis* is associated with specific changes in RNA metabolism required for the expression of sporulation genes. Although net RNA synthesis stops abruptly at the end of logarithmic growth (T_0), active turnover and differential transcription of the genome have been demonstrated[1-3]. Losick and Sonnenshein[4] suggested that modifications of RNA polymerase may play a primary role in the regulation of gene expression during the sporulation process. The expression of ribosomal RNA genes during this period has been subject to conflicting reports[1,5-7]. The reported turn-off of these genes at the onset of sporulation[5,6] has not been observed in similar experiments[7]. The latter, and the reported changes in template specificity of RNA polymerase[4,8] were shown to be strongly dependent on the nature of the sporulation medium and to a lesser extent on the phenotype (*sp+* or *sp-*) of the strain[7,8]. We have analysed the pattern of synthesis and turnover of stable RNA components in *B. subtilis* induced to sporulate in the highly defined resuspension medium, SM (ref. 9). We report that rRNA synthesis does continue during sporulation, although at a reduced rate, resulting in the gradual replacement of vegetative rRNA components by similar newly synthesised sporulation species.

To label the stable RNA components during vegetative growth. *B. subtilis* strain *A26*, a uracil auxotroph, was cultured

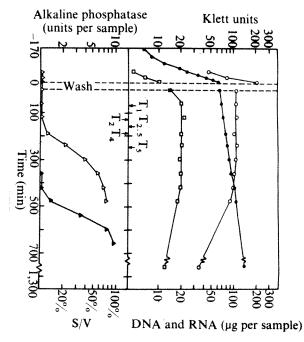
in a synthetic medium containing ³H-uridine. These cells were centrifuged, resuspended in SM medium and samples were withdrawn at various times for a second labelling with ³²P-phosphate. Figure 1 illustrates the periods of labelling and some typical events connected with sporulation which were examined here, that is, nucleic acid synthesis, formation of alkaline phosphatase and heat-resistant cells. The appearance of these events are characteristic of cells sporulating in SM medium[9]. RNAs were extracted[14] in the presence of 2 mg ml⁻¹ bentonite[15] with 1% sodium lauryl sulphate added to protect the lysates from the new sporulation nucleases[16,17]. To evaluate the distribution of the labels among the RNA species and to eliminate the extraneous ³²P-labelled material known for its nonspecific binding to nitrocellulose membranes, the RNA preparations were first fractionated on methylated albumin-Kieselguhr (MAK) columns[18]. Figure 2 illustrates a typical MAK profile of an RNA sample taken from stage T_2 and cochromatographed with vegetative marker. The bulk of the ³H-labelled species chromatographed as stable RNA components with the expected 2 : 1 ratio of label in the 23S and 16S peaks, whereas the ³²P-labelled species had a ratio nearer to 1 : 1 indicating the presence of mRNA in addition to the stable RNAs. The profile also shows the efficient separation of the nonspecific ³²P-labelled material and low molecular weight species from the bulk RNA which eluted only after the application of the salt gradient. We calculated that in the RNAs from stages T_1, $T_{2.5}$, T_5, 15%, 30% and 60% of the ³H-label eluted as low molecular weight RNA, respectively. This change


Fig. 1 Sporulation of *B. subtilis* in SM resuspension medium. A uracil auxotroph strain (*A26u⁻, sp+*) was grown in the presence of 5,6-³H-uridine (10 μCi ml⁻¹; specific activity 46.2 Ci mmol⁻¹, New England Nuclear) and 15 μg ml⁻¹ of unlabelled uridine. Turbidity (●) during growth was monitored by a Klett colorimeter using a 66 filter. At a Klett of 44, 100 μg ml⁻¹ of unlabelled uridine was added for a chase period of 20 min, the cells then were resuspended in SM medium containing 15 μg uridine ml⁻¹ for 20 h. Throughout the experiment, duplicate samples (9.5 ml) were removed and precipitated with cold TCA (final concentration 5%) and fractionated according to the Schmidt-Thannhauser procedure[10]. RNA (□) was determined by the orcinol reaction[11]; and DNA (○) by the diphenylamine reaction[12]. For the estimation of alkaline phosphatase activity (△), 5 ml samples were removed and treated according to Torriani[13]. Spores were estimated by viable counts before (V) and after heating (S) for 10 min at 80 °C and is expressed as sporulation frequency (▲, S/V × 100). At the indicated times after resuspension (T_1, T_2, $T_{2.5}$, T_4, and T_5), 200 ml samples were removed and labelled with ³²P-phosphate (33-70 μCi ml⁻¹) for 30 min followed by rapid chilling with an equal volume of frozen media.

Table 1 Hybridisation-competition behaviour of vegetative rRNA of *B subtilis*

Expt no	DNA Preparation no	Strand	DNA/RNA input ratio	Unlabelled rRNA competitor*	Complexed after RNase (c p m)†	³H-RNA hybridised (%)	DNA (H) or (L) hybridised (%)
1	I	H	50 1	—	1,650	36 6	0 73
		H	50 1	50 × (V)	18	0 4	
2	I	H	75 1	—	2,215	49 1	0 67

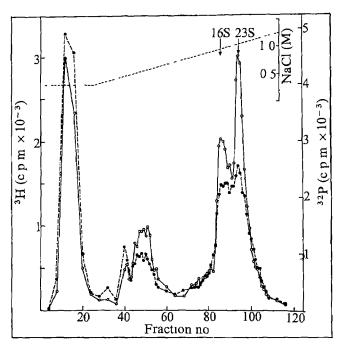
3	II	H	200 1	—	4,490	99 7	0 50
		H	200 1	100 × (V)	43	1 0	
		H	200 1	100 × (S)	167	3 7	
4	II	L	95 1	—	2	0 04	0 0005

* Unlabelled messenger-free rRNA from vegetative (V) cells was extracted after treatment with rifampicin (30 µg ml⁻¹) for 20 min Similarly, unlabelled RNA from sporulating (S) cells at stage $T_{2\,5}$ was extracted after treatment with rifampicin (100 µg ml⁻¹) for 40 min

† Each reaction mixture contained 0 17 µg ³H-rRNA (specific activity, 26,500 c p m µg⁻¹) MAK-fractionated H or L strands, 6 × SSC in a total volume of 1 60, 1 28, 0 68 and 3 0 ml for experiments 1, 2, 3 and 4, respectively The reactions were incubated at 67 °C for 18 h and treated as described previously[18,19]

represented a turnover rate during sporulation of 12% h⁻¹ Similar calculations were not carried out with the ³²P-labelled RNAs because of the high content of extraneous phosphate

We have previously shown that in *B subtilis* 16 and 23S rRNA, all soluble RNA (4 plus 5S) and 80-90% of pulse-labelled RNA synthesised by vegetative cells hybridise to the H strand of DNA[18,19] Ribosomal cistrons account for only a small portion of the *B subtilis* genome[20] but their transcription products constitute more than 95% of the total cellular contents[20] The use of MAK-fractionated L and H strands of *B subtilis* DNA enabled us to achieve nearly quantitative hybridisation of stable and pulse-labelled RNAs (refs 18 and 19) The hybridisation properties of MAK-fractionated H strands to vegetative ³H-labelled rRNA are summarised in Table 1 The results shown confirm the following earlier observations none of the rRNA hybridised to the L strand, maximum hybridisation (99 7% input) was achieved at DNA/RNA ratios


of 200 1, 0 25-0 37% *B subtilis* DNA hybridised with rRNA, addition of excess (50-100×) unlabelled messenger-free rRNA from vegetative or sporulating cells competed entirely with the available DNA sites The proportion of rRNA transcripts in the radioactive RNAs was determined by similar competition assays using the same H-strand preparations and the same unlabelled rRNAs as competitors The results in Table 2 are presented as a comparison between two pulse-labelled log-phase RNAs (experiments 1 and 2) and two independent sets of double labelled sporulation RNAs (experiments 3 and 4) Hybridisation competition of the double-labelled RNAs showed that 97-98% of the vegetative ³H-RNA that hybridised to the H strand was rRNA, whereas the ³²P-labelled sporulation RNAs were composed of both ribosomal and messenger species The proportion of rRNA in the various ³²P-labelled RNAs was characteristic to the sporulation stage and related to the overall rate of RNA synthesis One hour

* Log (3) and Log (8) are log-phase cells grown in minimal salts[28] or in SM growth medium and pulse-labelled with ³H-uridine (44 or 17 µCi ml⁻¹) for a period of 3 and 8 min, respectively In experiments 3 and 4 the same amount of ³H-uridine (10 µCi ml⁻¹) was used, and the amount of ³²P-phosphate as µCi ml⁻¹ was 33 for T_1, $T_{2\,5}$ and T_5, 65 for T_2 and 70 for T_4

† The same H strand preparations described in Table 1 were used here, preparation I in experiment 3 and preparation II in 1, 2, and 4,

‡ The various reaction mixtures contained the following amounts of RNA in µg experiments 1 and 2, 0 06 and 0 35 (specific activities (c p m µg⁻¹), 55, 200 and 4,630, respectively), experiment 3, 2 87 (specific activity (c p m µg⁻¹) of ³H and ³²P, 7, 270 and 476) 0 83 (6,500 and 1,955) and 1 68 (7,160 and 900) for T_1, $T_{2\,5}$ and T_5, respectively), experiment 4, 0 5 (5,130 and 2,162) 0 5 (4,400 and 5 110) for T_2 and T_4 respectively The reaction mixture contained the appropriate amounts of MAK-fractionated H strand, 6×SSC in a total volume of 0 68 for experiments 1, 2, and 4 and 3 0 ml for experiment 3 The reactions were incubated at 67 °C for 18 h and treated as described previously[18,19]

Fig. 2 Chromatography of double-labelled RNA ^3H (O), ^{32}P (●) from sporulation stage $T_{2\,0}$ on a MAK column Isolated labelled RNA (0 1 mg, specific activity as c p m µg^{-1} of 5,130 and 2,160 for ^3H and ^{32}P, respectively) mixed with unlabelled marker RNA (1 06 mg) from vegetative cells, was applied to a MAK column (1 9 × 8 0 cm) and eluted using a linear salt gradient between 0 3 and 1 4 M NaCl in 50mM sodium phosphate, pH 6 7 (total volume, 600 ml) Fractions (4 ml) were collected and 1 0 ml samples were mixed with 3 0 ml scintillation mixture[27] The arrows indicate the peak absorbance (A_{260}) of the unlabelled 16S and 23S marker RNA Recovery of the unlabelled RNA (% input) total, 90 7, peak 1 (fractions 1–24), 9 2, 4S + 5S RNA (fractions 36–60), 14 3, and 16S + 23S RNA (fractions 72–105), 67 2

after resuspension in the sporulation medium (T_1), only 28 % of the ^{32}P-labelled RNA that hybridised to the H strand contained rRNA sequences, whereas at later stages, $T_{2-2\,5}$ and T_{4-5}, 66% and 78% of the ^{32}P label consisted of rRNA The latter values are comparable to the fraction of rRNA measured in pulse-label RNAs from vegetative bacteria (see experiments 1 and 2, Table 2)

We interpret the initial reduction in the labelling of rRNA at stage T_1 as being comparable to the temporary retardation of RNA synthesis and accumulation observed during a carbon-source step-down or amino acid deprivation of both relaxed and stringent bacteria[22,23] The SM resuspension medium[9] used here represents such a typical shift-down condition, which resulted in the characteristic decrease in the rate of RNA synthesis and more significantly in an RNA preparation that exhibited a smaller proportion of the label in rRNA As soon as the cells adjusted to the resuspension medium, the rate of RNA synthesis, particularly that of rRNA, increased When the pattern of RNA synthesis is studied in two commonly used sporulation media, the modified Schaeffer medium[24,25], or the Sonenshein and Roscoe medium[26] containing high levels of amino acids and glucose, this initial decrease in the rate of RNA synthesis was not observed[3] Instead, incorporation of radio-active precursors into RNA during 1-min pulse periods revealed a reproducible pattern of three periods of high rates of RNA synthesis at stages 0 to I, III and IV, the latter two were also observed in the SM medium used here (ref 3 and D T and R R, unpublished) We conclude that during the periods of increased RNA synthesis in sporulating *B subtilis* a substantial portion (65–80%) of the transcripts are copies of stable RNA genes The initial decrease in the rate and extent of rRNA synthesis which occurs only in certain media is not unique to sporulation, but rather represents the response of cells to growth rate transitions or to their entry into stationary phase This response involves the preferential restriction of rRNA transcrip-

tion until the cells become committed to sporulation or simply cease growing and remain stationary until lysis ensues We are currently investigating the transcription of rRNA cistrons during stationary phase of asporageneous mutants of *B subtilis*

This work was supported by the National Institute of General Medical Sciences and the City University of New York Faculty Research Award

Note added in proof Pero *et al*, (*Spore*, VI (in the press)) report that in *B subtilis* sporulating in 121B medium[26] only 10% of a 3-min pulse-labelled RNA (T_2) represented ribosomal RNA

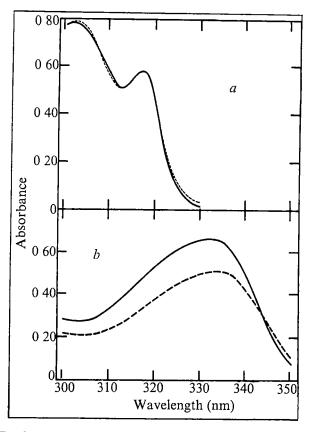
Mefloquine, a clinically useful quinolinemethanol antimalarial which does not significantly bind to DNA

We report that mefloquine (2,8-bis-(trifluoromethyl)-α-(2-piperidyl)-4-quinolinemethanol[1], see Fig 1) clinically useful against drug-resistant *Plasmodium falciparum* malaria (G M Trenholme, unpublished), does not significantly bind to calf thymus DNA This constitutes the first reported case of an active compound in the quinoline–acridine class of antimalarials which does not strongly bind to DNA by intercalation

Investigations of the binding of acridine derivatives to DNA have provided information both on DNA structure and on the manner in which the complex of the dye with DNA can affect physiological functions Lerma[2], for example, tested the intercalation theory, using quinacrine, and Hahn[3] has carried out detailed spectroscopic investigations on the interaction of this compound with DNA An entire group of antimalarial compounds has been termed the quinoline–acridine class by Pinder[4] These compounds consist of a planar aromatic ring system with a positively charged side chain attached, and are typified by the quinolines, chloroquine and quinine, and the acridine, quinacrine Considerable evidence has accumulated that these three antimalarial compounds form an intercalated complex with DNA in vitro and can inhibit bacterial DNA and RNA synthesis by formation of an in vivo complex with DNA (ref 5) This has lead to a theory that the antimalarial action of these compound results from such a complex in the malarial parasite[5] Some controversy over this theory has arisen[6-8] but alternative postulations for the mode of action of these compounds ar


somewhat qualitative at present Recent synthetic efforts to find compounds which have good activity against chloroquine-resistant strains of malaria have resulted in a large number of compounds which can be used to study the postulated modes of drug action[9,10] As part of a continuing investigation of DNA interaction with antimalarials of the quinoline-acridine type, we initiated a DNA binding study of some new compounds which may be considered members of this class[11,12] This report extends our studies to include quinoline methanols

One method for determining whether an aromatic compound forms a complex with DNA is to follow shifts induced in its electronic absorption spectrum on the addition of DNA Figure 2 shows the ultraviolet spectra of mefloquine and quinine in the presence and absence of DNA The spectrum of quinine shows the familiar hypochromism and a shift of absorption maxima to longer wavelengths typical of compounds that bind to DNA, whereas that of mefloquine undergoes no significant change Thermal denaturation profiles conducted at a DNA phosphate and mefloquine concentration of 10^{-4} M changed DNA T_m by less than one degree The lack of significant change in T_m at this rather high ratio of compound to DNA phosphate also indicates at most a very weak interaction between mefloquine and DNA

Fig 1 Structure of mefloquine The sample used in these studies gave NMR, infrared, ultraviolet and melting point data in accord with published values

To quantify the mefloquine interaction with DNA, equilibrium dialysis studies were conducted using the buffer described in Fig 2, 2 × 10⁻⁴ M DNA phosphate, and mefloquine concentrations from 3 5 × 10⁻⁵ to 7 5 × 10⁻⁵ M (final concentration of unbound mefloquine after equilibration) The amount of mefloquine bound varied from approximately 3 5% to 6% of the total amount added and was too low for a Scatchard binding analysis Some estimation of the possible range of the binding constant is possible, however, if the number of mefloquine molecules bound per DNA phosphate is arbitrarily fixed For example, if one molecule binds for every DNA phosphate (electroneutrality) then the equilibrium constant can range from 400 to 700 If one molecule binds to every five nucleotides (mefloquine/DNA phosphate = 0 2), then the binding constant must be between 2,000 and 3,700 This is quite small compared with the range of 10⁵ to 10⁷ typically obtained for the binding equilibrium constant of drugs, the mode of action of which is known to involve binding to DNA A more detailed equilibrium dialysis study is impossible because of the limitations imposed on DNA concentration by the Donnan effect (at low ionic strength) and on the mefloquine concentration by the limitations of spectrophotometric determination of concentration

Almost any positively charged compound will become associated with DNA in a weak electrostatic complex as the ionic strength is reduced to low values To determine whether the weak binding observed with mefloquine is such an external electrostatic association or an intercalated complex, viscometric titrations have been carried out using methods described previously[12] The titration curves for two intercalating com-

Fig. 2 Effect of DNA on the absorption spectra of mefloquine and quinine *a*, Mefloquine hydrochloride 2 × 10⁻⁴ M (————), mefloquine hydrochloride 2 × 10⁻⁴ M plus DNA 10⁻³ M (—————), *b*, quinine hydrochloride 2 × 10⁻⁴ M (————), quinine hydrochloride 2 × 10⁻⁴ M plus DNA 10⁻³ M (—————) Solutions were prepared in 7 5 × 10⁻³ M NaH₂PO₄ and 10⁻³ M EDTA (standard buffer) adjusted to *p*H 7 with NaOH to yield an ionic strength of 0 019 Calf thymus DNA (Miles, Lot 36–155), which was used in spectrophotometric, viscometric, and thermal denaturation experiments, was dissolved in standard buffer and an extinction coefficient of 6,600/mol DNA phosphate (at 260 nm) used to calculate DNA concentration Drug stock solutions were prepared in standard buffer and diluted to the desired concentration before absorption measurements Difference spectra were recorded in 1-cm lightpath quartz cuvettes on a Beckman Acta V spectrophotometer We have found that mefloquine obeys Beer's law over a concentration range considerably larger than used in these studies, suggesting that aggregation of the drug is not a problem in these conditions and cannot account for the lack of intercalation with calf thymus DNA

pounds, a naphthothiophene methanol[12] and quinine, the structures of which are related to mefloquine, are shown in Fig 3 together with the result for mefloquine Both the compounds which intercalate cause a definite enhancement of DNA viscosity in contrast to mefloquine which causes a modest decrease in viscosity The latter result indicates that mefloquine does not intercalate, but could bind weakly to the DNA phosphate groups through an electrostatic interaction in a manner analogous to aliphatic amines and diamines[2,12]

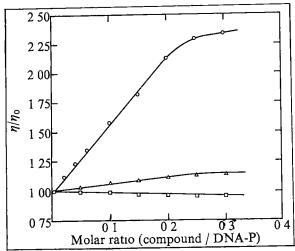
The above results, taken together, strongly indicate that mefloquine does not intercalate with DNA, and when binding does occur at low ionic strength, it is by some weak external mechanism probably governed primarily by electrostatic interaction A compound with the same side chain and ring system(6,8-dichloro-2-phenyl-α-(2-piperidyl)-4-quinolinemethanol) without the trifluoromethyl moieties but with a 2-phenyl group, has been shown to bind strongly to DNA (ref 13) It is known that bulky groups, including trifluoromethyl groups, on aromatic ring systems can hinder intercalation[14,15] Model building experiments with CPK space-filling models indicate that a 2-phenyl substituent can lie in the same plane as the quinoline ring and that the entire aromatic system can intercalate between


Fig 3 Viscometric titration of DNA with mefloquine hydrochloride (□), and quinine hydrochloride (△) The results for 6,8-dichloro-4-(2-N-piperidino-1-hydroxyethyl)naphtho[2,1-*b*] thiophene (○) were taken from reference 12, in which a more detailed procedure is given The ratio of the specific viscosity (η/η_0) of DNA with added compound (η) to DNA alone (η_0) is plotted as a function of the molar ratio of compound to DNA phosphate Viscosities were determined in a 1 2 dilution of the standard buffer with a Cannon-Ubbelohde four bulb dilution viscometer at 25 °C A measured volume of DNA $(2 \times 10^{-4}\text{M})$ was successively titrated with drug stock solutions in a calibrated (μl) syringe, and viscosities were corrected for slight changes in DNA concentration during titration

adjacent DNA pairs Similar experiments with mefloquine, however, suggest that the two trifluoromethyl groups introduce unfavourable steric interactions with DNA bases in an intercalative-type complex Since the binding constants of the smaller quinoline compounds, such as chloroquine[16], are lower than similar larger aromatic compounds, such as quinacrine[3], the unfavourable steric repulsion caused by the trifluoromethyl groups of mefloquine probably overrides the favourable hydrophobic interactions that would be obtained by intercalation Both model building studies and the experimental results described above are consistent with the conclusion that mefloquine cannot bind to DNA by intercalation

This work does not provide direct evidence for the mode of antimalarial action of mefloquine, however, it does indicate that DNA intercalation is not of primary importance and raises important questions about the mode of action of other unstudied compounds in the quinoline–acridine class of antimalarials Identification of cellular receptors other than DNA will be important in understanding the mode of action of mefloquine and perhaps other antimalarials of this class Since synthetic chemists have frequently assumed an intercalative DNA-binding mechanism of action similar to that of chloroquine to design potential antimalarials[17-20], the fact that mefloquine binds very weakly and does not intercalate with calf thymus DNA will be important in this field We are currently studying the interaction of several other quinoline methanol antimalarials with DNA to determine whether DNA binding could be an important part of their mode of action

We thank Drs R E Strube and E A Steck of Walter Reed Army Institute of Research for technical information, encouragement, and samples of mefloquine, and G M Trenholme for allowing us to cite his unpublished results

Crystallisation of troponin-C

TROPONIN is the protein complex that controls the onset of muscular contraction[1-3] It has three subunits[4] troponin T (Tn-T), troponin I (Tn-I) and troponin C (Tn-C) The complex is bound at regular intervals along the thin filaments, which are composed of a double helix of actin monomers and tropomyosin, which runs along the grooves of the actin helix[5-7] Each tropomyosin molecule spans seven actin monomers and one molecule of the troponin complex is bound to each tropomyosin molecule through Tn-T (refs 3 and 6–8) Tn-I binds to actin and Tn-C binds both to Tn-T and Tn-I (refs 3, 4 and 6) In the absence of Ca, Tn-I and Tn-T inhibit contraction by inhibiting the interaction of actin and myosin but in the presence of Ca, Tn-C binds to Ca, the inhibition is reversed and contraction occurs[3] We have been interested in crystallising Tn-C in the hope that an eventual crystal structure determination will be helpful in understanding how Ca binding controls the onset of muscle contraction Here we report the occurrence of a crystalline form of this protein

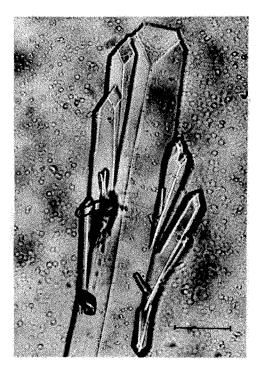
Fig 1 SDS gel electrophoresis *a*, of rabbit troponin (35 μg) and *b*, Tn-C (35 μg) separated by column chromatography (in this example, using DEAE-Sephadex A-50)


Fig. 2 Photomicrograph of crystals of pure rabbit Tn-C photographed in mother liquor with unpolarised, unfiltered light (×20). Bar represents 100 μm.

Rabbit troponin was prepared by the method of Ebashi *et al.*[9]. The three components were separated using column chromatography with either DEAE-Sephadex or A-50 (ref. 4) or Whatman cellulose DE-52 (ref. 6). Sodium dodecyl sulphate (SDS) gel electrophoresis[10] with heavy loadings of Tn-C invariably showed a single band with a molecular weight of 17–18,000 (Fig. 1) and all the Tn-C preparations, when combined with Tn-T and Tn-I, conferred Ca sensitivity on the ATPase of actomyosin.

For crystallisation a 25 mg ml^{-1} solution of protein in 50 mM Tris-HCl 5 mM $MnCl_2$, pH 7.0, was dialysed in Zeppenzauer cells[11] against 35% saturated ammonium sulphate, 5mM $MnCl_2$, 50 mM Na acetate, adjusted to pH 5.0 with concentrated acetic acid. All chemicals were BDH reagent or Analar grade; no other precautions were taken. For dialysis, ordinary Visking tubing was used that had been boiled for 5 min in 0.1% $NaHCO_3$. Crystals (Fig. 2) form within 4–8 weeks and are long bipyramidal tetragonal needles. They often show multiple growths roughly parallel to the long axis, sometimes rotated at either 45° or 90° about the long axis relative to the larger crystal.

Typically, crystals are 0.1 mm long. Occasionally large crystals (0.5 × 0.05 mm) appear and these have been used for preliminary X-ray diffraction studies[12]. The crystals give rise to three-dimensional diffraction patterns which confirms the existence of single crystals. Rotation of the crystals by 90° about the long axis gives rise to superimposable precession photographs. The patterns are weak, however, and generally limited to 8–10 Å resolution, occasionally to 3 Å. The observed reflections may be indexed on an 'I' lattice and there is evidence (G. Dodson, B. B., D. M., and J. P., unpublished) for a 4_1 or 4_3 screw axis parallel to the long dimension of the crystals. Thus at low resolution the crystals seem to be tetragonal with a body centred unit cell of 127 Å × 156 Å. More extensive data will be necessary, however, to confirm and extend these results.

The role of $MnCl_2$ in the crystallisation procedure is obscure. It is known that certain divalent cations such as Mg can compete for at least two Ca sites[12]. For these sites, the Ca-binding constant of troponin is about 5×10^8 mol^{-1} in the absence of Mg, but about 5×10^6 mol^{-1} in the presence of

2 mM Mg. In general, all divalent cations with a crystal radius of 0.8–1.1 Å that can displace Ca are also capable of activating the ATPase of myosin in the presence of troponin-containing thin filaments inhibited by ethyleneglycol-*bis*-(β-aminoethyl ether)N_1N'-tetraacetic acid[13]. Mn is in this size range (0.8 Å) and we have confirmed the result of Konieczny and Weber (unpublished, cited in ref. 13) that Mn is active in stimulating the ATPase to the same extent as Ca. Smaller ions such as Mg, Zn, Co, and Ni are inactive in stimulating the ATPase[13]. These results closely parallel the ability of different ions to induce conformational changes in Tn-C similar to those produced by Ca, as judged by ultraviolet spectroscopy[14].

The conformation and physical properties of Tn-C depend on the degree of saturation with Ca and these changes are evident in the properties of the troponin complex[3,4,6,14,15]. For example, Ca increases the affinity of Tn-C for Tn-I (refs 6 and 15). Similarly, Ca increases the affinity of Tn-C for Tn-T (ref. 6). It is likely that the Ca-dependent conformational changes in troponin Tn-C are involved in the control of the position of tropomyosin with respect to the actin helix[3,8,16,17]. In the presence of Ca, tropomyosin is moved to a position nearer the actin groove and actomyosin formation occurs. The Ca-dependent changes in Tn-C are likely to be the first steps in a series of structural events that constitute the control of muscular contraction. Thus a knowledge of the crystal structure is an important step in understanding this system.

We thank Professor S. V. Perry for a gift of rabbit Tn-C and Professors D. C. Phillips and J. W. S. Pringle for their encouragement.

Release of leukocyte kallikrein mediated by IgE

BRADYKININ is a vasoactive nonapeptide believed to mediate various acute inflammatory conditions[1]. Although its production in plasma is well defined[1], an understanding of its role in disease is hampered by the lack of information about the mechanism by which it can be generated by an immune process or by any stimulus other than clotting. Immune release of a kinin-generating factor from perfused sensitised guinea pig lung has been reported[2,3]. The release is not, however, calcium-dependent and the factor may be a product not of the primary allergic reaction, but of a secondary event[4]. Substantial information is available, however, about the release of other mediators of inflammatory or allergic reactions—histamine, SRS-A, and ECF-A[5]. These are secreted after antigen challenge of basophils

Fig. 1 The release of histamine and TAMe esterase activity from human leukocytes. *a*, Dose–response relationships of antigen-induced release. The precision of the esterase assay is indicated by the standard deviation shown in the release curve caused by rye grass group I antigen (left-hand curve). The other two frames represent *b*, release by highly specific anti-IgE; *c*, kinetics of the release of the esterase (●) and histamine (○).

and mast cells sensitised with IgE antibody[6-7]. The release depends on calcium and temperature, requires energy and is controlled by hormone-receptor interactions which influence the intracellular level of cyclic nucleotides[10-13]. We have now demonstrated the immune release of an enzyme from human leukocytes that hydrolyses *p*-toluene sulphonyl-L-arginine methyl ester (TAMe) and generates bradykinin from citrated human plasma. The release is initiated by the interaction of antigen or anti-IgE with cell-bound IgE[6,14] and seems to be similar in mechanism to the release of histamine and the other mediators of the allergic response.

Human leukocytes from donors allergic to ragweed or grass were separated from the other formed elements of the blood, washed free of serum and suspended in a serum-free Tris-buffered medium containing 0.03% human serum albumin, calcium and magnesium as previously described[10]. The immunological reaction was initiated by addition of antigen or anti-IgE to the cell preparations and the reaction proceeded for 30–45 min in the dose–response studies or for increasing periods in the kinetic studies. At the completion of the reaction, cells were centrifuged and the histamine released into the supernatant as well as that present in samples of untreated cells was determined spectrophotofluorometrically[10]. Arginine esterase activity of the supernate was determined radiochemically using ^{3}H-TAMe, a method which was devised by Beaven *et al.*[15] to measure human urinary kallikrein and modified for determination of prekallikrein[16] and arginine esterase activity in supernatants[17]. The total cellular arginine esterase activity was determined using sonicated samples of untreated cells. Bradykinin was generated by treating citrated human plasma with the supernatant from cells challenged with antigen or anti-IgE and measured by a radioimmunoassay with a sensitivity of 4.0 ng as previously described[18].

The dose–response relationships of the release of histamine and TAMe esterase have been studied with leukocyte preparations from more than 20 allergic individuals challenged with either the purified protein antigens from ragweed (AgE)[19] or grass (Gp I)[20] or with highly specific anti-IgE[21]. Typical dose–response curves are shown in Fig. 1. The precision of the assay for histamine is 5–10% while that for the TAMe esterase is about 3%, as shown in Fig. 1*a*. In general the pattern of the dose response curves for histamine and esterase release were similar, whether release was initiated by antigen (Fig. 1*a*) or anti-IgE (Fig. 1*b*). The absolute percentage of histamine or TAMe esterase released by a leukocyte preparation may differ.

Rates of histamine and esterase release are compared in Fig. 1*c*. The time courses were essentially identical: this was confirmed in eight experiments. Further experiments demonstrated that the reaction did not proceed in the absence of calcium ions or at 4 °C. Moreover, the addition of EDTA or lowering the reaction temperature immediately stopped the release of esterase at any point in the reaction, as described for histamine release[10].

The interaction of the TAMe esterase with the kinin-generating system was studied. Using kaolin as a positive control to generate prekallikrein activator from Hageman factor it was observed that the supernant from antigen-stimulated cells was inactive: no additional TAMe esterase activity was noted after its interaction with plasma. This suggests that the leukocyte enzyme does not function as or cause the production of any prekallikrein activators. It does, however, generate kinin activity from citrated human plasma. In four experiments 30–350 ng of bradykinin was produced after incubation of the esterase with plasma for 20 min; buffer incubation with the same plasma yielded less than 4 ng of bradykinin (the limit of the assay). In a typical experiment the esterase or buffer was incubated with plasma in duplicate and the kinin generated was assayed in quadruplicate. The buffer control was below the limits of detection (< 4 ng) in each case whereas the esterase-treated plasma had 33.4 ± 3.2 ng of bradykinin. Preliminary experiments have shown that the esterase can generate high levels of bradykinin from highly purified kininogen. It would appear, therefore, that the release of the TAMe esterase is associated with kallikrein activity. Whether the two activities are subserved by the same enzyme, however, remains to be ascertained.

The parallelism in dose–response and kinetics of kallikrein and histamine release, as well as the release by anti-IgE, indicates that the kallikrein is derived from human basophils: previous work has demonstrated that basophils constitute the only type of white blood cell that fixes IgE and contains histamine[22]. Phagocytosis by polymorphonuclear leukocytes, induced by latex beads or immune complexes, releases some materials with protease activity but these are not kallikreins[23]. This, therefore, seems to be the first time that the generation of kallikrein from human leukocytes has been observed as a result of a primary immune reaction, and represents an important link between reactions of immediate hypersensitivity and the plasma kinin generating system. The demonstration of the IgE-mediated release of a basophil kallikrein allows us to begin to study the role of this system in the pathogenesis of acute inflammatory responses.

reviews

This book* must fascinate everyone interested in the history of British zoology in the 19th century. It begins with Joseph Banks still in the seat of power, his soirées at 32 Soho Square attended by eminent scientists discussing the latest 'curiosities'. Over his shoulder one has a glimpse of Hans Sloane whose collections, gradually disintegrating, were housed in subterranean excavations, said to resemble the catacombs of Palermo, in Montagu House. The greatest collections remained in possession of the landed gentry and nobility; even those offered to the Government were largely refused because of lack of space in which to keep them. Appointed by patronage, the miserably paid Keepers of Natural History had neither status nor influence.

The gradual changes which led to the organisation of the greatest collections in the world occupied the whole of the Victorian era and were the work of two keepers, John Edward Gray and Albert Gunther, their lives and work here admirably surveyed by the grandson of the latter. The major events are the erection behind Montagu House of the British Museum with the transfer there of the Natural History collections in 1840 and 1841 and the far greater move, in distance and bulk of material, from Bloomsbury to South Kensington in 1882 and 1883.

Born in 1800, the son of a struggling botanist and pharmacist, John Gray proceeded by devious occupations into medicine, to emerge, by virtue of character and ability, as a leading naturalist. Friendship with W. E. Leach, then too briefly at Montagu House, introduced him to Banks and his circle. His first Museum employment, at a daily payment of 15 shillings, was during the keepership of J. G. Children whom he succeeded in 1840. Initially, with his fellow keepers he was subject only to the Principal Librarian with direct access to the Trustees, this changing in 1856 when Richard Owen was appointed superintendant of all the natural history departments.

The spirit of Linnaeus, tempered now by that of Cuvier, prevailed and the great task presented to Gray was

*A Century of Zoology at the British Museum—Through the Lives of Two Keepers. By Albert E. Gunther. Pp. 533+37 photographs. (Dawsons: London, 1975.) £17.30.

The new Coral Room

Recollections of a century

the accumulation of specimens with "the diffusion of instruction and rational amusement". He travelled widely, visiting museums and meeting their directors and staff. Material began to pour in particularly from the colonies; collections of birds were purchased from John Gould, collections of shells from Hugh Cumming. Gradually, the collections came to rival in extent that of the still growing empire, although the Admiralty and Foreign Office were to disregard its claims until the conflict over the *Challenger* collections led to the final deposit of these in the Museum.

The first British Museum catalogues were contained in the suitably named *Naturalist's* (later *Zoologist's*) *Miscellany*, begun in 1790 by Shaw and illustrated by Nodder, then briefly continued by Leach. Gray's achievement was to produce the first adequate catalogues of major groups, starting with the reptiles. But how could a handful of underpaid, badly housed assistants contend with the flood of incoming material? Wallace's complaint to Darwin about the reaction to his claim to have brought 8,000 new species from the Amazon was met with commiseration for their overwhelming task and with a feeling that "too much systematic work and description blunt the faculties".

It was to produce more order out of chaos that the young Albert Gunther, initially a theology student at Tübingen, came to the Museum in 1857 to be led into "A suite of three half subterranean rooms, in which the spirit collection

was stored . . . The floor showed large damp patches. There was no ventilation. Non-inviting rheumaticky quarters at any time. But what did I care?" What indeed?—he regarded this first year working on the great *Catalogue of Fishes* (1859–1870) as the happiest in his life. His later friendship with Alfred Newton at Cambridge bore fruit for the enduring sustenance of all zoologists by the establishment in 1856 of the *Zoological Record*.

Carrying the weight of the Department during Gray's final years of illness, Gunther succeeded him in 1875. His relations with Owen are interesting. Initially very much the protégé, differences developed alongside increased responsibilities, notably in connection with the new Museum at South Kensington for which Owen was fully responsible although the final plans were made without the knowledge of the keepers (or indeed of Owen himself). This is no place to discuss either the architecture or the internal planning of a building into which Gunther had to move specimens for the custody of which he was responsible although "their selection and arrangement was to be left to the Superintendent."

That figure was almost immediately replaced by the first appointed director, William Flower, who also assumed the keepership when Gunther retired in 1895, to be succeeded in this capacity by Sydney Harmer with Tate Regan as a junior member of staff. Here this book ends—not far short of when zoologists of my generation came into the picture.   **C. M. Yonge**

Quantum theory

Quantum Theory of the Solid State. By Joseph Callaway. Part A: Pp. x+1–370+10. Part B: Pp. xiii+371–824. (Academic: New York and London, July 1974.) $29.50; £14.75.

THIS work is in two parts, the first containing an account of the formalism required to study solids and the second concerned with more specific problems. The book is at a level suitable for students with a good background in quantum mechanics and some knowledge of the experimental facts of the solid state.

Part A is divided into four chapters, the first on lattice dynamics being followed by magnetism at a phenomenological level. Chapters 3 and 4 can be viewed together as an introduction to the group theory, followed by the calculational methods needed to find the electron states (and from the symmetry standpoint the phonon states) in periodic crystals. Part B then treats impurities, the effect of external electric and magnetic fields on solids and transport phenomena. In the final chapter there is an introduction to many-body theory.

Professor Callaway, of course, has made important contributions over a wide area of solid state physics and the book reflects his deep understanding of his subject. I wonder, however, a little about his ordering of the material. For, although many-body theory is treated in depth only in the last chapter, on p. 22 we have the creation and annihilation operators, and on p. 41, also in the first chapter, the van Hove correlation function appears in its full quantum mechanical form. Nevertheless, even for the reader who does not struggle too hard with the more advanced detail in Chapter 1, there is a good deal of basic solid state physics concerned with phonons which can be learned from it. The references, which are at the end of each chapter, number about 60 on phonons. Three refer to work later than 1971 but the rest are from 1969 and earlier.

Chapter 2 begins with the Heisenberg Hamiltonian along with some discussion of how the exchange parameters can be calculated from first principles. Molecular field theory is then discussed at some length, followed by an account of antiferromagnetism. The spin wave problem is then tackled using the Heisenberg Hamiltonian, with the dependence of spin waves on an external magnetic field given some attention. The extensive and helpful (though pretty advanced) discussion of spin waves is followed by a discussion of neutron scattering from magnetic crystals. The Ising model is then given

a good deal of prominence, 15 pages or so being devoted to it. Phase transitions in ferromagnets are then treated, at about the same length. The discussion is scholarly, but in my opinion rather more advanced than is consistent with the author's remarks in the preface about the level of students it is written for.

In the chapter on symmetry, one of the nice features is the attention given to crystal field effects. The reader will probably find Chapter 3 on symmetry and Chapter 4 on band theory a good deal easier than the first two chapters. The chapter on energy bands has all the clarity one would expect from such an expert in the field; however, quite a bit of the discussion is available already in good sources. The discussion of the tight-binding method, which Professor Callaway has used to very good effect on the transition metals, is very helpful here. Finally, the central question of the way the crystal potential is to be constructed is discussed from the standpoint of density functional theory; Dirac-Slater exchange theory and gradient corrections to it are summarised.

Part B begins with the impurity problem, Wannier and also *t* matrix methods being dealt with in some detail. A nice account of the optical

theorem is to be found here. Effective mass theory, local moments, the coherent potential approximation and the Kondo effect are other topics treated. A chapter of about 100 pages then follows on crystals in external fields, including optical properties, and magnetic field phenomena, such as low field diamagnetism and the de Haas-van Alphen effect. Transport theory is discussed at length and the last chapter represents a useful introduction to many-body theory. Itinerant electron magnetism is treated in a very clear manner in this chapter, along with Landau Fermi liquid theory. Green's functions and diagrammatic analysis are also developed here.

The only general criticism I would want to level concerns the ordering of the material. The first two chapters might have been better placed after the consideration of symmetry and band theory. More discussion of many-body theory would have been helpful earlier in the book.

Without doubt, this is a valuable addition to the literature which I found very stimulating to read. The problems at the end of each chapter are helpful in assessing one's grasp of the material as one goes along, though some are pretty difficult.

N. H. March

Sound through the sea floor

Physics of Sound in Marine Sediments. Edited by Loyd Hampton. Pp. xii+567. (Plenum: London and New York, 1974.) $39.00.

THIS publication is a collection of 20 papers presented as the proceedings of one of four symposia organised by the Office of Naval Research to review current research activities and to discuss possible future trends in the subject of sound propagation in marine sediments. Edited by Loyd Hampton, the papers describe the research efforts of many of the world's leading authorities on a subject which is of increasing importance as the commercial exploitation of the natural resources that lie on, or beneath, the sea floor continues to expand into less accessible areas.

This collection of papers is presented quite informally and is therefore comprehensible to those not too familiar with all of the aspects of a relatively diverse field. The volume highlights the difficulties involved in obtaining accurate geophysical, acoustic and mechanical data from sediments in their natural environment. Such data have perhaps, not been given sufficient priority in the past, but the advent of large structures that are to be placed on the sea floor may change that situa-

tion. Current static loading tests may soon prove inadequate in solving settlement problems in the high energy environments that exist at sea. A possible alternative may be to consider the interrelationships between the required parameters and such physical properties as sound propagation, electrical resistivity and radioactivity. Acoustic properties will probably prove to be the most useful in this respect because of the fundamental relationships involving mechanical and physical properties of materials. With knowledge of these relationships, acoustic measurements could combine with the normal methods of site investigation which use standard acoustic techniques to provide more accurate interpretation as well as dynamic loading information. Continuous monitoring of the acoustic properties of sediments may also allow the measurement of the long term changes in sediment fabric and of the effects of severe weather conditions on sediment structure.

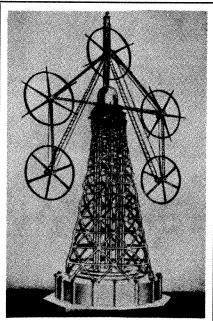
The presentation of the papers is of a general high standard, but as many authors are involved it is often necessary to compare data; this task would have been simplified if a standard set of units had been specified.

Peter G. Simpkin

Wrong word too early

Invertebrate Endocrinology and Hormonal Heterophylly. Edited by Walter J. Burdette. Pp. xviii+438. (Springer: Berlin and New York, 1974.) $21.50.

HETEROPHYLLY, as defined by the Oxford Dictionary, is a botanical term referring to plants having leaves of more than one shape. How then does this relate to invertebrate hormones? In fact, it does not. The editor has given a new meaning to the word, and uses it to describe the effects of hormones from one phylum on individuals of another phylum. From the title one expects to read about hormones from various invertebrate groups. But, in truth, the book considers only insect hormones, and of these, only ecdysone, juvenile hormone, and brain hormone.

The book contains contributions made to a meeting held at Houston early in 1971. Unfortunately, there has been a long delay between the submission of the manuscripts and the appearance of the book in late 1974, and, consequently, it is rare to find a reference later than 1970; in fast moving areas of research, such as juvenile hormone and ecdysone biosynthesis and degradation, many papers are already out of date.


The book is divided into four parts. Part I, "Invertebrate endocrinology", deals with the control of metamorphosis, hormone assays, and hormone biosynthesis and degradation. The section starts promisingly with remarks by Wigglesworth on the use of hormones to probe basic problems in the regulation of growth and differentiation. The following papers include articles that cater to a general audience as well as those with very technical information aimed at the specialist. The series of papers on assay techniques, an example of the latter, are varied in their usefulness. The paper by Bjerke and Roller on juvenile hormone assays provides a broad, critical comparison of the common bioassay systems that were in use at the time. By contrast, the treatments of the brain hormone and ecdysone assays are much more limited in their scope and, accordingly, are of less value.

The second part considers primarily the isolation and distribution of various ecdysones. Since the original report in 1966 by Nakanishi and his coworkers of the presence of ecdysone-like chemicals in plants, the isolation and identification of these substances has, with a few notable exceptions, been carried out by workers in Japan. The articles in this section serve the valuable function of bringing together the data from the Japanese literature on the structure of the known phytoecyd-

sones (37 at the time the paper was written) as well as extensive listings of their plant sources.

Part III comprises six papers on the effects of vertebrate hormones on vertebrate tissues. Except for presumed parallels between the mode of action of these hormones on vertebrates, and that of insect hormones on insects, these papers bear little relationship to the rest of the book and seem to be quite out of place.

Hormonal heterophylly is the subject of the last part. From the various articles, it quickly becomes apparent that the effects of insect hormones on

Wind turbine designed in 1933. It was to have stood 300 metres high and would, according to its designer, have generated 50.000 kW. From *Power From the Wind*, by Palmer Cosslett Putnam. Pp. xii+224. (Van Nostrand Reinhold: New York and London, October 1974.)

vertebrate cells are neither striking nor profound. The effects of ecdysone on the growth of mammalian tumours and on human leucocyte chromosomes are at best slight and are certainly of questionable statistical significance. The insect hormones do cause metabolic changes in mouse liver, but this can scarcely be surprising in a tissue adapted for detoxification of foreign substances. Indeed, the fact that insect hormones have little effect on vertebrate tissues, as documented by the papers dealing with pharmacological screens of these hormones, is a point in their favour. Especially as one day they may be released into the environment as insecticides.

The editor of this volume states that it is the first concerted effort to collect and analyse responses of vertebrate, as well as invertebrate, tissues to insect hormones. In my opinion, it is a premature attempt.   **James W. Truman**

Old bones

Bones for the Archaeologist. By I. W. Cornwall. Revised edition. Pp. 259. (Dent: London, February 1975.) £4.50.

THIS is a revised edition of a volume first published in 1956. The section on conservation has some useful additions, the bibliography and the references have been improved and brought up to date and a very necessary index has been added. The bulk of the text and the illustrations remain the same.

When this book was first published the intention was to help the archaeologist make preliminary identifications of bones from archaeological sites at a time when much data had accumulated in museums awaiting the interest of some specialists from the natural sciences. It demonstrated successfully that most of this work could be done by the archaeologist himself if he was prepared to apply himself to learning the basic necessities of bone analysis. Many archaeologists, who were not entirely artefactually orientated, found it both necessary and relatively easy to add to their competence. There can be little doubt that some improvement in excavation techniques was one of the consequences of the publication of their book, as well as a reduction in the backlog of material awaiting analysis and identification.

The volume contains chapters on zoological classification and nomenclature, bone identification, field work, laboratory work and conservation, the estimation of age, sex and stature, and study and interpetation. For the tiro it even suggests logical methods of procedure. It is easily the best introductory work available at the present time and will guide many newcomers to archaeology to a useful and essentially practical expertise.

On the other hand, the weakest section is that concerned with study and interpretation. There is no clear indication of what purposes underlie the collection of bone specimens nor, in consequence, how bones should be collected on the site to give an adequate sample. It still remains that, in contrast to pollen analysis, data is atrociously collected during excavation by archaeologists with vastly different interests, techniques, knowledge and relevant expertise; there is still no discipline about archaeological collection. In consequence, samples obtained are commonly of minimal value and amenable to valid interpretation only at the coarsest levels. This fact could have been pointed out to advantage at a time when numerical analyses are increasingly fashionable. Excellent teaching as, for the most part, it is, Dr Cornwall's book stays with the vision of some 20 years ago.   **E. S. Higgs**

obituary

John E. Vance, a chemist who worked on processing of ores and the preparation of pure uranium compounds for the Manhattan Project, has died in New York at the age of 69.

Dr Vance was emeritus professor of chemistry at New York University and former head of the department. He joined the faculty in 1948 and retired in 1971. He had previously been associate professor at Yale, where he directed work on quantitative analysis, and crystal growth. In the 1940s, he was appointed by the State Department as senior staff member to Frederick Osborn, representative to the United Nations Atomic Energy Commission. Dr Vance's special concern was drawing up proposals for international control of atomic energy. At various times, he had served the army research office, particularly during the Manhattan Project which developed the atomic bomb in 1942.

Cyril Leslie Oakley, CBE, FRS, the distinguished bacteriologist, died on March 27 at the age of 77.

Professor Oakley graduated from University College, London, in Zoology in 1930 and held the position of experimental pathologist at the Wellcome Research Laboratories from 1934, becoming head of the Immunology and Experimental Pathology Department in 1947. From 1953, he was Brotherton Professor of Bacteriology at the University of Leeds, becoming Professor Emeritus in 1972. His own interests were in the fields of antibody production and bacterial toxins, and looked after those of others as President of the Association of Scientific Workers from 1956–59. Professor Oakley will, however, be primarily remembered as the editor of a number of scientific journals, including *Pathology and Bacteriology* (1956–68), *Medical Microbiology* (1968–71) and *Pathology* (1969–72).

Louis W. McKeehan, professor of physics at Yale from 1927–55, has died in Jamestown, Rhode Island at the age of 87.

After graduating from the University of Minnesota in 1908, Professor McKeehan taught there as an associate professor until the outbreak of war. At Yale, he directed the Sloane Laboratory of Physics and after becoming emeritus professor, he was research associate at the Laboratory of Marine Physics in New Haven and Jamestown. He had a lifelong association with the navy and had been assistant naval attaché in London during World War II and chairman of the scientific advisory board of Operation Crossroads, for the strategic bombing of Japan. His research included discharge in gases, ferromagnetism, submarine mines, slow-motion spheres in gases, scattering of cathode and β rays, and radioactivity.

announcements

Awards

George J. Todaro has been awarded the **Parke, Davis Award** by the American Society for Experimental Pathology for investigation of viral and genetic factors in the cause of cancer, in particular the viral oncogene hypothesis.

H. E. Ganther has been awarded the **Mead Johnson Award** by the American Institute of Nutrition for his work on the essential nutrient selenium.

Appointment

J. G. Williams has been appointed professor of polymer engineering at Imperial College, London.

International meetings

May 28–30. **Frequency control,** Atlantic City (Dr J. R. Vig, US Army Electronics Command, Fort Monmouth, New Jersey 07703).

June 2–5, **Information transfer in eukaryotic cells,** Montreal (Ms D. Mathieu-Thériault, c/o Dr R. Sinclair, Biology Department, McGill University, Box 6070, Montreal H3C 3G1, Canada).

June 7–18, **Solar terrestrial physics,** Colorado (American Geophysical Union, 1909 K Street, NW, Washington, DC 20006).

Miscellaneous

Cancer awards. The Cancer Research Institute Inc., is establishing Annual Awards in Cancer Immunology. The Institute will honour work judged to have been most critical in founding Cancer Immunology as we know it today, whether in reference to basic experimental research or to observations of more immediate clinical significance. Nominations to Mrs Helen C. Nauts, Executive Director, Cancer Research Institute Inc., 1225 Park Avenue, New York, New York 10028 (closing date July 15, 1975).

Cherwell–Simon Lecture. The lecture for 1974–75 will be delivered by E. W. Montroll, Director of the Institute for Fundamental Studies and Albert Einstein Professor of Physics in the University of Rochester, New York, on May 23, at 4.30 pm in the lecture theatre of the university museum. The subject will be 'Some quantitative aspects of social phenomena'.

Taking stock of *Nature's* bread and butter

VERY occasionally we get our leg pulled about the words on our refereeing form. Our standards call for "topicality, brevity and plausibility". "You'll find this paper seductively plausible", purred an author in a letter of transmittal. "Plausible—yes; correct—no", responded a referee. So we went back in some diffidence to Fowler, who generally gets it right—

'**plausible** has moved a long way from its original meaning, "deserving of applause". Applied to a person it is always pejorative; a plausible man is one who obtains a credence he does not deserve. Applied to an argument the word has not travelled so far on the downward path: it may still be used of one that commends itself, though speculative.'

Continue to send us plausible papers. We will do our best not to send them to plausible referees.

● It is no doubt foolish to boast of the turn-round time for manuscripts, but since it forms the basis on which many scientists decide where to publish, here goes. Once a manuscript has been accepted, it will, on average be published within six weeks.

Statistics on the refereeing process are far more variable, of course, as it may take anything from a week upwards to satisfy ourselves and a referee that a paper should or should not be published. Not all papers go to referees. Some of those submitted seem to us more obviously suited to a specialised journal; and after taking appropriate opinions around the office —and often outside—we return such manuscripts as soon as possible. There is little point in seeking a referee's opinion and only then over-ruling it with our own opinion.

Of the remaining manuscripts, we seek a referee's views on all but a tiny fraction. The tiny fraction are not, as is widely believed, those written by very eminent men, but papers on matters where the facts are indisputable and delay would be positively detrimental to the community.

Some authors feel that sending a paper to a distinguished scientist for him to transmit does some good. It doesn't—it only profits the Post Office.

● One of the greatest problems encountered by sub-editors is that of ambiguity. This is exceptionally acute in a journal in which more than half the readers and many of the authors do not have English as their first language. English is undoubtedly an organic language capable of great flexibility and subtlety through the ease with which it handles nouns as adjectives, absorbs new words, possesses many words meaning almost the same thing and so on. Asset though this is, particularly in the spoken language, it does lead to difficulties for the reader—and not only the reader to whom English is a second language.

It is impossible to set down guidelines; ambiguities follow no rulebook. But here are some which may give some idea of the subtleties which readers are sometimes asked to unravel.

Jones is a solid state physicist (or soft rock geologist).

The equipment has provided extensive trouble free operation.

Smith's paper suggests a new concept (to Smith or to the author?)

Since Robinson made the observations, we have confidence in the theory.

Brown's work appeared to resolve the difficulty.

We shall hopefully repeat this work within a month.

The solution boiled momentarily.

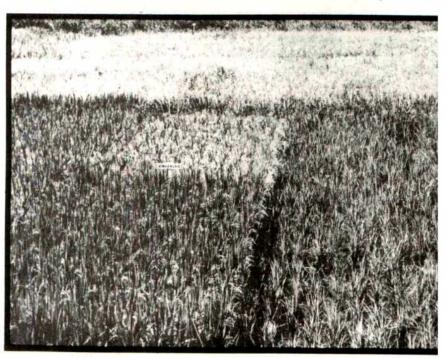
(These last two demonstrate that the generation of ambiguous euphemisms for 'I hope' and 'in a moment' has effectively eliminated two words from the language.)

Some of these examples seem trifling to the English speaker; but the test we try to apply (not always with success) is whether the writing would be clear not only to someone not having English as a first language, but also to someone from a remote discipline reading out of curiosity.

● It is always tricky to know what references are really necessary; to the extent that we attempt at one and the same time to carry large numbers of short scientific reports and also to have them widely accessible we cannot avoid some conflict over the amount of referencing. But on the whole, we prefer relatively few references because anyone who finds interest in a paper outside his own field is presumably going to look and talk further. Particularly vulnerable to the sub-editor's pen are sentences that declare: "There has recently been great interest in this subject[1-11] and much work[12-25] is at present in progress".

● Many people secretly fancy themselves as advertising copywriters and would relish the opportunity to string together compelling but honest words to persuade others to buy cars, read books or (dare we say) to drink a certain brew or smoke a certain cigarette. And yet given an opportunity for self-advertisement, most scientists shy away from compelling but honest words with which to introduce their papers.

Nature has always avoided a summary at the beginning of letters partly for reasons of space, partly in an attempt to retain a certain directness in the reporting of early and often tentative results. But this should not inhibit anyone from writing a short and forthright first paragraph, capable of being understood by almost anyone. On occasions our sub-editors attempt to do this themselves for authors, but the response is often: "Well I didn't quite mean that". Which might, just once in a while, not stem entirely from our dim-wittedness but conceivably from a touch of opacity in the paper itself. □

Updating the Green Revolution


BY DAVID SPURGEON

PERHAPS the most important problem facing agricultural scientists in the decades ahead is how to keep production of staple foods like rice abreast of population increase in the Third World. In Asia alone, something like 5 million tons of rice will have to be produced every year to keep up with the demand. That means that new varieties and agronomic practices must spread, and that new lands must come into production. It also means that pests and flooding must be controlled or their effects minimised and that, in an era of inflation and rising prices, the costs of technological inputs such as fertilisers must be reduced.

One of the chief reasons that the success of the Green Revolution has been limited so far is that the total area in which the new seed varieties and agronomic practices were applied has been small. In the case of rice, the high yielding varieties were semi-dwarf types suitable only for shallow water regions (depth approximately 5–50 cm). These lands constitute only 25–30% of the world's total rice lands and even in these regions, of course, the new varieties are not grown exclusively. The Green Revolution has scarcely touched the other rice-growing areas—the uplands and regions of intermediate and deep water that together comprise 65–70% of the total available rice lands.

The International Rice Research Institute (IRRI) in the Philippines, where the new varieties and technology were developed, is at present working, in collaboration with rice scientists and growers elsewhere, to extend the Green Revolution to the majority of the world's rice-growing areas—and to solve some of the other problems that limit rice production. Some of them feel that rice production could be doubled throughout the world within the next 15 years through such methods. According to Dr Gurdev Kush, head of the IRRI's plant breeding department, the situation is not that gloomy when the available resources are considered. The problem is exploitation of the resources.

The really limiting factors in food production are political, Dr Kush believes, and in addition vast areas of Africa and Latin America have not been exploited. "I'm convinced," he says, "that if there's no major economic upheaval, and provided population control programmes are maintained, we can keep up with demand for the next 15–20 years."

One of the rice-growing sectors of the world being looked at with special interest by IRRI scientists contains the deep water regions, because these are among the most heavily populated anywhere. People have lived for centuries along the deltas of the mighty rivers of Asia—the Ganges, the Brahmaputra, the Godavari, the Irrawaddy, the Cheo Phraya and the Mekong—because of the adequate supply of water and the rich silt deposits.

Often, floating rice is the only food crop that farmers can grow in these areas, but the tall varieties found there are low yielding: for decades they have produced only 1 or 2 tons a hectare. Almost 10% of the rice land in Asia and Africa is planted with floating rices, whereas almost half the total rice land has tall non-floating varieties that are adapted to medium-deep water.

Last summer, the first International Seminar on Deep Water Rice was held at the Bangladesh Rice Research Institute north of Dacca—just after flood waters had destroyed much of that country's rice crop. The disaster served as an object lesson for the group, which surveyed both the flood damage and deep water rice culture from helicopters and boats, noting fields where semi-dwarf and even tall varieties were submerged and killed in fields adjoining flourishing deep water rice.

These floating varieties have developed genetic mechanisms that allow them to grow normally in deep water and to escape flood submergence—their stems elongate (for reasons not understood) as waters rise and their leaves float on the surface. Rice scientists are now incorporating this genetic characteristic into semi-dwarf and intermediate stature rices, hoping to develop high yielding varieties that can survive floods. Several thousand hectares of an IRRI strain known as IR442–2–58 are now being grown in West Bengal, India, where flood water often reach a depth of 1 m. More than 40 other crosses have been made between floating and semi-dwarf types and progeny are being tested in Bangladesh, India, Vietnam, Indonesia and Thailand. The headquarters for the deep water programme is at the Hunter Deep Water Rice Research Centre in Thailand.

"Not many scientists are really experts on deep water rice, despite the extent of the deep water areas and the huge populations they support," says Dr Mohammed Amirul Islam, Director of the BRRI. "This makes it all the more important that attention be focused on the urgent problems of deep water rice."

Other rice types being developed are varieties that will not elongate like floating rices, but will withstand submergence for a few days under flood conditions. These varieties would be useful where flooding is temporary: the floating varieties might lodge (topple over) as floodwaters recede. The need is illustrated by an incident in the Philippines in 1972, where about 230,000 hectares of rice land were flooded in early growth stages for four weeks, causing a crop loss of about $74 million.

Still other varieties of rice are being developed to adapt to the opposite of flood conditions: drought. About 10–15% of the world's rice-growing areas

Rice trials field in the Far East

suffer from insufficient water supply, for example in the uplands. Varieties tolerant to drought are being sought that will, nevertheless, recuperate quickly when the rains come, for areas of varied rainfall. Many regions of the world are too cold for the new varieties yet local rices grow there. Scientists at the IRRI are now gathering seeds from these rices and growing them in ice water to see which ones will survive and then to try to cross breed them.

The IRRI calls this programme of rice improvement the Genetic Evaluation and Utilisation Program (GEU). It brings together not only plant breeders but pathologists, entomologists, soil chemists and agronomists in order to identify and evaluate systematically rice genetically adapted to the most pressing constraints on rice production.

Besides the attributes mentioned, the programme seeks to incorporate these other factors into new high yielding varieties: resistance to insects, resistance to diseases, high protein levels and tolerance to toxic soils. In addition scientists are screening rice varieties to determine which use fertiliser and other agricultural chemicals most efficiently, and how best to deliver the chemicals.

It has been found, for example, that, if fertiliser is incorporated in a kind of mud pellet and placed near the plant's roots, about half the amount of fertiliser normally used will produce the same yield. In other words, the method doubles the efficiency of the chemicals. The difficulty is to package the fertiliser and insecticide together in a suitable way and to persuade industry to produce it.

Some success has already been ac-

hieved with disease and insect resistance. Early this year the IRRI named three early maturing rice varieties (IR 28, 29 and 30) as being resistant to a number of diseases and insects. They are the only known varieties highly resistant to grassy stunt virus disease, a serious problem in many countries. The varieties IR 28 and IR 29 are also resistant to tungro, bacterial blight and blast diseases; IR 30 is resistant to tungro and bacterial blight but moderately susceptible to blast. And all three varieties are resistant to brown plant hoppers and green leaf hoppers and moderately resistant to stem borers.

Furthermore, IR 28 and IR 30 mature in only 105 days and IR 29 in 115 days, compared with about 160 days for traditional tropical varieties and 130 for most high yielding varieties. These short seasons should enable farmers in some areas to adopt multiple cropping systems, thus cutting their risks. Varieties that mature in shorter periods are less likely to be damaged by insects or disease or weather simply because they are in the field for a shorter time. In addition, some farmers might fit in an extra crop this way.

Bad soil conditions prevent farmers from growing rice on millions of hectares. Felix Ponnamperuma, a Ceylonese soil chemist at the IRRI, visited Bombay and found that just 10 miles outside the city there were 100,000 hectares of land ideally suited to rice cultivation yet unusable because of salinity, whereas inside the city people were dying of malnutrition. This is flat, alluvial soil, and there is water throughout the year. There are about 10 million hectares of saline soils in India and Pakistan.

In Indonesia new lands are being opened up, says Dr Ponnamperuma, but they are largely peaty bogs. The country hopes to open up five million hectares in the next 10 years, but they

contain problem soils, and rice does not grow well on them. In all there are about 40 million hectares in the tropics composed of these marsh soils, mostly in South-east Asia.

Scientists now are studying the deficiencies of these soils—deficiencies that include almost all the major nutrients and some trace elements. Even when these elements are added they have found that rice growth is not as good as it should be, probably because of the presence of organic toxins. "So we want to breed varieties adapted to these conditions," says Dr Ponnamperuma. "We are trying to tailor the crop to the soil rather than the reverse."

Problems include acid sulphate soils (in perhaps 15 million hectares on which rice cannot be grown in Vietnam and Thailand); iron toxicity when certain soils are flooded (affecting 10–50 million hectares of rice soils), retarding growth and limiting yield; and zinc deficiency (affecting 500,000 hectares in the Philippines and large areas of Pakistan and India). The IRRI found in the Philippines that zinc deficiency sometimes prevented rice growth altogether, but that dipping seedling roots in zinc oxide and water was the answer. (Only $1 worth of zinc oxide per hectare (1 kilogram) often produced higher yields than 550 kilograms of complete fertiliser). And with zinc oxide seedling dip, any of the modern varieties of rice could produce twice the yield of the local varieties, even without any other fertiliser.

A third of mankind—1,300 million people—depend on rice for more than half their food. Ninety percent of the low income people of the most densely populated regions of the world rely on it, people whose average income is only $80. The efforts of the world's rice scientists will be crucial to their survival in the years ahead. □

Energy in the OECD

G. R. Bainbridge, Professor of Energy Studies and Director of The Energy Centre, University of Newcastle upon Tyne, reflects on the OECD report, Energy Prospects to 1985.

WHEN, in 1972, the council of the OECD initiated an assessment of energy developments and related policies it was anticipating that the projected growth of energy demand in the 24 countries constituting the OECD area would put increasing pressure on low cost energy supplies. It was particularly concerned about future supplies of oil from the Middle East, where 90% of the world's petroleum trade originates and where 55% of the proven natural oil reserves lie.

Moreover the USA, using a third of the 5,000 million tons of oil equivalent world annual energy consumption, was becoming increasingly an oil importer. Indeed only two OECD countries, Canada (trading oil and gas for coal) and Australia (trading coal for oil) have net total energy self sufficiency. So the pressure of oil demand would inevitably have important implications for the economies and policies of most OECD members, 15 of whom are dependent for 70% or more of their energy needs on imports, and only some of whom (the USA, Norway, the Netherlands and UK) could with sustained effort join the select group of those reasonably self sufficient in energy.

The concerted oil export restrictions applied by OPEC towards the end of 1973, followed by a dramatic increase in crude oil prices, came as a shock, emphasising the timeliness of the OECD energy exercise. It was clear that the prospects for a return to an era of relatively cheap energy had "dwindled considerably".

It is not surprising that the OECD assessors found themselves unable to provide probable, or target, projections of energy supply and demand, even for 10 years ahead, while initiatives were and still are being taken by the oil suppliers and consumers almost daily. They made, instead, a brave attempt to present in a qualitative way the principal likely determinants of future development of the energy sector. Increasing gross national production would be expected to require more energy, though perhaps not too much more if the trend towards improved energy-efficient processes, continues

and the likely substitution of capital and labour for more costly energy use occurs.

The price of energy had scarcely before been considered explicitly as a factor influencing energy demand, because prices were low and fairly stable. Now it had become the main one. In obtaining estimates of future energy use, oil prices rising from the early 1973 baseline of $3 (USA 1972 money) a barrel (7 barrels~1 tonne) to $6 and $9 were taken to provide a framework for investigating the implications for other economic factors and to identify possible problems that might confront the policymaker. Without criticism they could have gone even higher with the alternatives. During the period of the exercise, of course, dollar depreciation made those prices selected $3.60, $7.20 and $10.80 by the end of 1974. Inflation is only one of several factors listed in the recent Solemn Declaration of the Sovereigns and Heads of State of the OPEC member countries for consideration by them when adjusting crude oil prices in future.

By comparison with growing gross national product and primary fuel prices the other determinants of energy supply and demand tend to fade into insignificance, particularly in the next worrying decade of readjustment. Measures already taken or planned to improve environmental protection were found to tend to increase energy consumption, albeit by only a few percent. Although some of them have already been relaxed or left in abeyance to ease the energy crisis, efforts towards energy savings, if successful, could enable environmental protection measures to be resumed.

As might be expected the main part of the OECD report concentrates on the prospects for the provision of oil, coal, natural gas, electricity and nuclear power in the near future. The possibility of greater indigenous production within the OECD is considered particularly important, with nuclear fission, North Sea oil and gas, and rejuvenation of coal and its synthetic products being all seen to have useful parts to play.

In order to broaden the options for future choices, and to open up greater possibilities for the diversification of energy supplies, continuing research and development efforts directed towards exploitation of some of the renewable resources are recommended in the report. The contributions from solar energy and further geothermal energy were recognised to be expected in general beyond 1985. Research into the derivation of fuels from towns' wastes and the productions of methanol and hydrogen was also recommended, with thermonuclear fusion as the *pièce de résistance* for the long term. Little was

said of wind and wave power, or ocean thermal gradients, as an energy source, perhaps because the prevailing Southwesterlies and the Gulf Stream have, apparently been veering a little off course of late.

Anyone preparing to read this very informative OECD report should apply initial energy to acquiring a good magnifying glass, as the many and interesting tables in the key chapters 2 (Energy Demand and Supply Projections) and 3 (Economic and Environmental Implications) are printed minutely. Chapter 4, on Energy Conservation, is appropriately of below average length, but that glass is needed again for the vital table which analyses energy conservation possibilities; but the effectively blank four pages immediately preceding the chapter emphasise the scope there is for workers in the energy field to practise what they preach. More than 5% of the 224 pages in Volume 1 carry no significant point and the proportion is higher in Volume 2.

Because of the dominance of US energy consumption (and production) in any overall OECD energy trends, it was correct that the USA should be treated separately. In 1972 the USA was using 50% more primary energy than the 19 European OECD members together, and its indigenous production was three times greater than theirs. Separate consideration of Canada was also useful, for, although it uses only a tenth as much energy as the USA, its surpluses of oil and natural gas will increasingly be directed southwards. Japan (also separately treated) already imports more energy than the USA and in future will continue as a major competitor for the world's oil, coal and natural gas resources—unlike the USA, Japan has little scope for indigenous production and has a higher growth rate for both population and gross national product.

The EEC is included for statistical comparison in some of the tables of the report. The strength of the EEC compared with the OECD European 19 lies in the fact that the smaller grouping contains the major industrial countries, using well over 50% of the primary energy, producing over 70% of the European indigenous fuel supplies and with the better natural potential to improve on that position if pressed. The energy strength of the EEC might have been further improved by Norway, but that country chose through a referendum to opt out; it has indigenous North Sea oil and gas production potential of the same order as the UK, but a very much smaller population already well endowed with hydro-power resources.

The figure summarises historical behaviour and possible alternative trends

of future OECD energy requirements. Had world oil prices not increased, the doubling time for energy consumption would be running at about 15 years, some 4.9% a year. Although the OECD, with present energy consumption running at a little over 3,500 million tons of oil equivalent a year, accounts for about 70% of world usage, the developing countries outside the OECD group will tend to bias world growth to a higher rate and a shorter doubling time. With the oil import price increased by factors of 2 and 3, some energy savings are anticipated to bring OECD growth down to 4.3% a year and 3.8% a year respectively. Then, at 1985, the higher oil prices have depressed energy use (or encouraged desirable energy savings) to the extent of 7% and 12% respectively, on the total. The nuclear, coal and gas proportions are all increased for the higher oil prices, relative to oil.

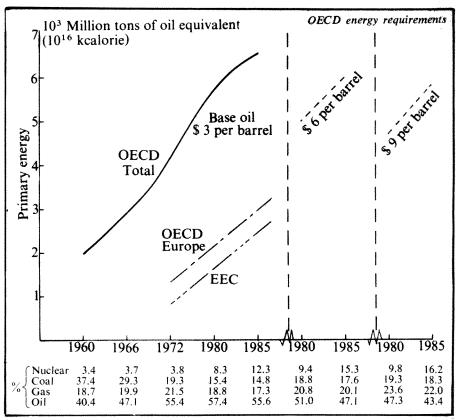
Some of the immediate broad conclusions could have been deduced by intuition almost as easily as from detailed analysis, namely:

● The OECD share of oil is expected to decline to below 50% of total energy requirements from around 55%, though its use is still increasing steadily at 1985 and seems likely to have reached at least 2,800 million tons of oil equivalent a year, compared with 2,000 million tons of oil equivalent a year today. The increment alone is a factor of 4 higher than the anticipated oil yield from the North Sea.

● The natural gas share grows on balance, the percentage increment in Europe compensating for a relative decline in use in the USA. Although the percentage stays around the 22% mark, the annual use almost doubles from 600 to about 1,200 million tonnes of oil equivalent. It should be noted that natural gas is being increasingly supplied into the Eurogas grid from Russia and Holland; soon additional supplies will come north from Africa by undersea pipeline by way of Italy, supplementing present liquid natural gas trans-shipments.

● Nuclear power is expected to play a steadily increasing role, rising (including a small component of hydro) from around 4% of total energy now to some 8 to 10% by 1980 and 12 to 16% by 1985. As might be expected, therefore, the nuclear doubling time is of the order 5 to 7 years, below half that for total energy. This is significant in view of the long lead times for power station construction, and must depend on policy decisions already taken in many countries to press on more quickly with nuclear programmes in view of the higher oil prices.

●

● The use trend for coal is expected to increase again, reversing a steady decline after the Second World War. European coal resources are mainly in Germany (brown) and the UK (black) but the USA still has vast and relatively easily worked coal deposits. It is there and in Australia that the most likely prospect for greatly raising coal production arises, though in Europe an increase of 10 to 20% seems to be a sufficiently challenging and achievable target.


The analysis leading to the projections does not seem to have allowed for the probability that coal and natural gas prices are bound to rise to what the market will bear for these fuels, relative to the oil price, or that nuclear capital costs will escalate because of the effect of increased conventional fuel and labour costs on manufacture. These occurrences will depress the demand for fuels alternative to oil, and the supply of oil may exceed demand sufficiently for selling competition to re-enter the market. The report is right to suggest that, because the energy pattern of the OECD and indeed the world, is a dynamic one, continuing study to achieve a better understanding of it is worthwhile. For example, OECD oil imports in 1980 could easily be 70% higher than now if savings of energy use, substitution of other energy forms and restriction of national product outputs are not effected. Higher oil prices, if sustained, could, however, reduce the extra import demand to below 20% and cause even a reduction of the

amount of imported oil and expenditure on it, ignoring any oil suppliers' price adjustments to optimise their returns.

Actions recommended to OECD members to improve the arrangements for cooperation in energy and related fields, inter-regional (EEC and OECD Europe) and intra-regional (Europe–North America, Europe–Far East) if possible, seem laudable; emergency energy-sharing schemes, promotion of energy trade, energy savings schemes, energy research and development to ensure adequate supplies at reasonable cost all need work. Inflation, and the sorting out of balance of payments problems, are current international problems needing OECD support.

A bringing together of the oil-exporting and oil-importing countries in agreed policies for mutual and world benefit is another area recommended for OECD action, with joint studies of problems to find agreed solutions which will bring greater stability to the energy and money markets. The idea that scientific and technical assistance should flow from countries with the capability towards those that need to develop is one on which OECD and OPEC representatives should be coming close together.

In the UK Parliamentary debate on the EEC energy proposals early in February of this year it was concluded that as trade with our partners becomes more interdependent there is obvious sense in seeking to evolve coordinated energy policies. The OECD report firmly confirms that view. □

international news

EARLY last year, the revelation that Canada's National Research Council (NRC) had for many years served as a cover for the secret gathering of intelligence shocked many Canadians. It also led the then leader of the New Democratic Party, David Lewis, to propose shifting the NRC unit concerned (the so-called Communications Branch) into a more appropriate department, and Prime Minister Trudeau to promise that he would consider the suggestion.

A few weeks ago, the Canadian public learned that the question had indeed been considered: in fact the Communications Branch had been transferred to the Department of National Defence. The information came out in questioning of the Minister of State for Science and Technology, C. M. Drury, in the House of Commons.

But the matter didn't rest there. Questioning of Mr Drury (who, as it happens, is a former president of the Treasury Board) revealed that the budget of the branch could not be identified separately in the estimates, but instead was spread about in such a way as to make it impossible for MPs to find out how much had been spent

More about spying and the NRC

from David Spurgeon, Ottawa

on this sophisticated form of spying (the branch monitors electronics data signals and analyses them).

Mr Drury defended the procedure by saying it was necessary in order to make it difficult for Canada's enemies to learn about the operation. "The counter-intelligence movement . . .", he said, "must, in order to be effective, itself be under cover . . . To take a popular analogy, this is a bit like engaging in a poker game in which one man discloses his hand by putting it on the table and the other keeps his hidden and then proceeds to bet."

Walter Baker, Progressive Conservative MP, Ottawa, was disturbed because, as he said: "Members are to find out about security organisations by accident" (the matter came up in a CBC television programme last year) "and then be denied any opportunity to

ask questions about the scope and purpose of such activities or the amount of money to be spent on them."

It would be comforting to accept assurances that everything being done in the name of security is fit and proper, but recent history in other countries suggested otherwise, he said.

Mr Drury admitted that the need for secrecy presents democracies with a problem, but the problem was not peculiar to Canada. "The problem, from the administrative view, is how to seek [this] parliamentary approval [for security expenditures] without disclosing in a comprehensible and clear way what is being done, and how."

In the past, said Mr Drury, when members of the House felt they must know what was being done, they had been informed *in camera*.

To which Stanley Knowles, New Democratic Party MP from Winnipeg, replied: "The last *in camera* session of this House of Commons that I can remember took place in 1944." Mr Knowles said it is open to the government to keep things secret, but quite a different matter to distribute items through a number of estimates in order to distort the picture given to Parliament of how money is being spent.

The Speaker concluded the session by saying that the "question is extremely important and complex, and I would like to look at it carefully." In view of the fact that Mr Drury had also offered to tell the ministers what was involved *in camera*, "it would perhaps be best to ruminate over the Easter break and see what might develop." □

An interesting footnote was to be found in a series of recently published letters from Dr C. J. Mackenzie, acting president of the NRC from 1939–1943, to General A. G. L. McNaughton, the president, who was on leave of absence as commander of Canada's field forces. (*The Mackenzie-McNaughton Wartime Letters*, edit. by Thistle, M., with introduction and epilogue by Mackenzie, C. J., University of Toronto Press, 1975).

In one of these letters, dated December 6, 1941, Dr Mackenzie said: "There is one very interesting but very secret development which only one or two of us know about. We have organised under the research council a section on cryptography which has succeeded in breaking down codes and cyphers and doing a really good job. It seems an unusual activity for the research council but the intelligence officers of the three services, the Mounted Police and the officers of External Affairs asked me if we could organise such a unit, as they thought we could probably do it easier and keep

it under cover better than in any other way . . . We have an associate committee consisting of the intelligence officers of the three services, the RCMP, a member from External Affairs and myself. We have an expert cryptographer from England and I look after the business arrangements, finances, etc . . . We got into it in the first instance because our facilities were such that we could start a unit in a modest way to see whether or not it was a practicable thing to do.

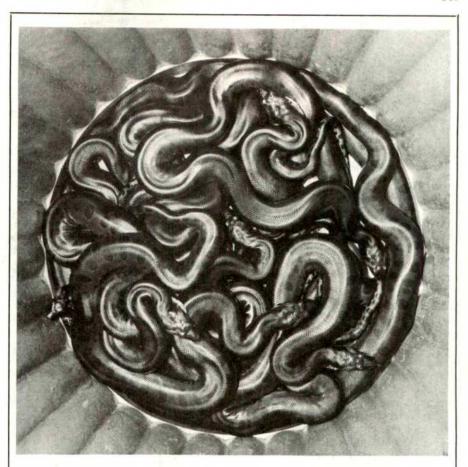
"My feeling was that after we had done the organising and got the staff trained, an official unit could be set up by the government to operate under one of the services or External Affairs. After six months of trial, which a decision had to be made as to how it should continue, all of the members were most insistent that they would prefer it to be carried on under our auspices and that will be done, for a while at least. It is pretty far from research but it is a most important and useful service."

Letter from Japan

from Yoshinobu Kakiuchi, Tokyo

Two new inter-university research institutes, the High Energy Physics Institute and the Institute for Molecular Science, have recently been established in Japan. The first is located at Tsukuba some 35 miles from Tokyo. The place is known as an academic town, the intention being that it should centre on universities and various research institutes. The High Energy Physics Institute was the first institution to be brought into the area, followed by the Pollution Research Institute and the Institute for Inorganic Materials, both of which belong to the

•

Science and Technology Agency. And a new national university (Tsukuba University), based on various new attempts to break with university tradition, has just started activities there.


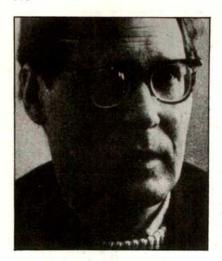
The Institute for Molecular Science is to be located at Okazaki 190 miles to the west of Tokyo, where it is also planned to build two other new institutes devoted to the life sciences.

The idea of the inter-university institute has been nurtured in Japan for some time. Soon after the Second World War, Japanese scientists began to think of establishing forums where they could exchange their ideas and cooperate in research of common interest. Nuclear scientists, for example, wanted to build an accelerator for nuclear research, but the cost seemed too large to be borne by a single university at that time. Therefore, the facility was supposed to be shared by researchers all over Japan. Traditionally, however, the national universities receive money from the government individually, which made it rather difficult to set up facilities to be shared on an entirely equal basis by several of them. The compromise was that institutes should be affiliated to a particular university, which is made responsible for its operation; but the facilities are available to the research scientists outside that university. At present there are more than a dozen of these so-called "institutes for joint use".

The establishment of these institutes raises a series of interesting issues, and naturally there are some difficulties. Universities in the main remain rather closed in structure, and the institutes for joint use are no exception. They usually open their doors only to scientists closely related to the research they cover, and this often causes friction. Of course, it is not impossible to promote inter-institutional joint projects, as is exemplified by the joint programme set up by the Institute for Nuclear Study and the Institute for Solid State Physics, both of which are affiliated to the University of Tokyo. There had been a good deal of spectroscopic work with electron synchrotron radiation in the past, but the spectroscopists involved wanted to build a storage ring to provide increased energy and radiation intensity. The ring has been successfully tested under the supervision of Professor Taizo Sasaki, of the University of Tokyo.

To escape more completely from the university strait-jacket, the idea of inter-university research institutes on a national basis, completely detached from the existing universities but still keeping a university's essential characteristics, were developed.

The Institute for High Energy Physics, for example, was established in 1971, at the recommendation of the

THE picture of young anacondas is taken from the Annual Report of the Zoological Society of London for 1974. In its annual report the Zoo records a rise of expenditure of 16% over last year, mainly on salaries and animal feeding stuffs. Unfortunately this coincided in 1974 with a fall in the number of visitors to both London and Whipsnade. But the numbers picked up again, apparently, after the arrival of the two giant pandas from Peking as a gift from the Chinese government; they arrived last September in a blaze of publicity.


Science Council of Japan, the advisory body to the Prime Minister's Office on scientific affairs. The recommendation was originally made as early as 1962, on the basis of extensive studies of a possible proton synchrotron. The project was investigated in detail and was finally authorised by the Ministry of Education. This synchrotron produces energetic protons in two steps—the booster ring accelerates them to 500 MeV and the main ring (108 m in diameter) brings them up to $8 \sim 12$ GeV. The five-year plan presented to start with is to be modified to a seven-year plan, with an increase in the total budget from about £10 million to about £15 million.

According to Professor Shigeki Suwa, the director of the institute, there has been plenty of cooperation between scientists and engineers in the design and the construction of the accelerator. He also says that the institute is keen to open the way for technicians to achieve better positions in the institute through promotion. A storage ring of the colliding beam type, equipped with super-conducting electromagnets, is still on the drawing board, but is being designed to produce a 70-GeV proton beam. Preliminary testing of the super-conducting wires is progressing satisfactorily.

The building of The Institute for Molecular Science has just been started, and Professor Hiroo Inokuchi, of the University of Tokyo, is now responsible for supervising the preparation of its activities. The setting up of this institute was also recommended by the Science Council of Japan (in 1965) and it is scheduled to cover five major fields of research, ranging from molecular theory to cooperative molecular phenomena.

This institute will be administered along similar lines to the Institute for High Energy Physics, and a development worth mentioning is the establishment of a "technical development section", responsible for the design and development of new research instruments. The original five-year plan for the institute is covered by a total budget of some £6 million. ☐

Sergei Koralev: arrested in December

Moscow scientists under pressure

from Vera Rich, London

THE arrest and harassment of members of the Moscow group of Amnesty International highlights yet again both the involvement of a number of leading Soviet scientists with problems of human rights and the extreme disfavour with which these activities are viewed by the authorities.

Physicist Andrei Tverdokhlebov, the secretary of the group, was arrested in Moscow on April 18, on his way to work. The same day, the Ukrainian science-fiction writer Mykola Rudenko, a postal "associate member" of the group, was arrested in Kiev.

Another prominent member of the group, Dr Sergei Kovalev was arrested last December, as part of a KGB operation against the *samizdat* journal "The Chronicle of the Lithuanian Catholic Church". Dr Kovalev has since been charged with "anti-Soviet agitation and propaganda".

Other members of the Amnesty group, including the Chairman, cyberneticist Valentin Turchin, and Vladimir Albrekht, a mathematician, have had their apartments searched, and documents, including Amnesty material, confiscated.

The Moscow group of Amnesty International was recognised by the International Executive Committee of Amnesty last September. Following the usual procedure, the Secretariat assigned the new group three case-sheets, referring to prisoners of conscience in Sri Lanka, Yugoslavia and Spain respectively. The group as such, had no connection with the internal affairs of the Soviet Union, in accordance with the policy of Amnesty International which does not allow any of its groups to concern itself with prisoners in its own country.

Although certain of the members of the group, have, as private individuals, also been active as regards the defence of human rights within the Soviet Union (Tverdokhlebov and Turchin have, on occasion, been co-signatories to the "open letters" for Dr Andrei Sakharov), it seems clear that it is not only their actions as private individuals, but also the existence of the Amnesty group which has earned official disfavour. The latest reports from Kiev indicate that although Rudenko has been released, his continued freedom is conditional; he has had to sign a promise not to leave Kiev, has been warned that he is awaiting further investigation and trial, and that his Amnesty activities "compound his crime" against the Soviet Union.

A statement from Academician Andrei Sakharov, addressed to the General Secretary of Amnesty International and to the "international public", described the arrests and harassments as "an affront to international public opinion and an attack against legality and democratic and humane principles to which this organisation and its members in the USSR invariably adhere."

Soviet space achievements celebrated

In spite of the recent setbacks to the manned Soyuz programme, Soviet Cosmonautics Day, April 12, was celebrated with the usual progress report on Soviet achievements. Although, on the practical side, the festival was marked only by the launch of that most routine of Soviet spacecraft, a Kosmos (number 726), this deficiency was more than offset by the official and quasi-official speeches.

At a celebration meeting held in the Central Theatre of the Soviet Army in Moscow, Academician Boris M. Petrov spoke of the year's work in tones of unqualified achievement. On such an auspicious day, nothing was said of the problems with the Soyuz–Salyut projects. The stress was entirely on the potentialities of the Salyut programme "for long term experiments in space with human participation".

Special emphasis, too, was placed on the expansion of Soviet participation in international space projects. "Successful cooperation" is at present going forward between the Soviet Union and the USA, France and India, and this cooperation on "major projects" will be extended during 1975 to include Sweden. The Interkosmos (joint COMECON) programme also progresses steadily, the latest satellite in the series being Interkosmos 13.

Within the purely Soviet framework, more than 50 Orbita communications satellites have now been launched, and a new one is planned to bring television to the workers on the Baikal–Amur Railway (one of the present major Soviet prestige engineering projects.

Although the official speeches at such a celebration must, of necessity, be laudatory, Academician Petrov's plaudits are, in fact, substantiated by a year of solid routine achievement. Although the Soyuz setbacks have captured the headlines, valuable preparatory work has gone forward on the Soyuz–Apollo plans (the major difficulty still, apparently, being one of linguistics). The Franco–Soviet "Araks" experiment, operating from magnetically antipodal bases in the Arctic and the Kerguelen Islands, is proceeding steadily with its programme of investigations of the terrestrial magnetic field. Although unfavourable meteorological conditions in the Antarctic have made it impossible, to date, to carry out the main part of the experiment—the injection of electrons into the magnetosphere to create an artificial aurora—some valuable, if routine, observations of the natural aurora have been carried out. Interkosmos 13, with its payload of Czech and Soviet instruments, was likewise devoted especially to magnetospheric and polar ionospheric research, a programme which is also being supported by a team on the drifting ice-flow polar station North Pole 22. A few days after the celebrations, on April 19, the first Indian satellite (named Ariabata after a fifth-century mathematician) was successfully placed in orbit from a Soviet carrier, achieving, *inter alia*, the distinction of being the heaviest first satellite of any country (360 kg).

Cosmonautics Day is, however, not only the time for an annual stocktaking of Soviet space achievements; it is also an occasion for press speculation and "informed" interviews on future plans.

Much of this material is necessary speculative and non-committal. "To prove, for example that there is not and was not life on Mars would be no less important than to find life there", is a typical comment of this type. Nevertheless, from these "supporting" interviews it would seem that long term planners are at least toying with the possibility of recovering soil specimens from the nearer planets. The combination of a Lunokhod-type vehicle with telecontrolled manipulators and a return craft of the Luna-16 type is considered "very promising" for this purpose. And, with an eye to the more distant future, the Institute of Medico-Biological Problems of the Ministry of Health is already working out ecological recycling and life-support systems for eventual long term space flights. ☐

DRINKING water throughout the United States is contaminated with trace amounts of organic chemicals, some of which are suspected carcinogens, according to a survey of drinking-water quality in 79 cities. The survey, carried out by the Environmental Protection Agency (EPA), indicates in particular that chloroform is an almost universal contaminant—it was found in samples of drinking water from all 79 cities, in amounts ranging from 'barely detectable' to 311 parts per billion.

Moreover, a more intensive survey of drinking water in five cities—Miami, Seattle, Ottumwa, Philadelphia and Cincinnati—has turned up evidence of a wide range of chemicals in the water supply. Thirty-five different organic chemicals have been detected in Miami's drinking water, for example, and thirty-six have been found in Philadelphia's.

Just how great a hazard to health those contaminants may be is a matter of some debate, but Russell Train, the Administrator of the EPA, said last week that "even at these low levels, the chemicals are a matter of some concern". The National Academy of Sciences is now evaluating the health hazards, and a special advisory committee has been established by the EPA to help determine national standards for drinking-water supplies.

The EPA survey looked specifically for six different chemicals in drinking water — chloroform, bromodichloromethane, dibromochloromethane, 1, 2,-dichloroethane, bromoform and carbon tetrachloride. Chloroform was the most ubiquitous, but bromodichloromethane and dibromochloromethane were also present in almost all the samples tested.

Officials of the EPA have expressed surprise at the widespread occurrence of the contaminants, and Train summed up the findings thus: "Our basic conclusion . . . is that the problem of organic chemicals in public water supply systems exists throughout the country."

The survey does not identify the sources of the contaminants but there is strong evidence that the chlorination process, which is the most widely used purification method for drinking water, may itself be responsible. A survey of raw, untreated water showed no trace of the six chemicals in 30 of the cities and extremely low concentrations in the other 49. But at least one of the chemicals was present in every sample of treated water that was tested.

The EPA's findings are likely to rekindle the smouldering debate about whether or not there is a safe level of exposure to carcinogens below which no health hazards are encountered. It should be noted, however, that the food and drug laws in the United States are based on the assumption that there is no such no-effect level, since they specify that no chemical which raises cancer in test animals can be added to foodstuffs. The extension of that concept to drinking water would, however, prove difficult, for Train noted last week that although several promising processes for water treatment are being developed, "we simply do not have a single proven method for dealing with all aspects of the organics problem".

The immediate effect of the EPA's

Washington seen

by Colin Norman

findings is likely to be a boom in the market for bottled water, but tests by both the EPA and the Food and Drug Administration have shown in the past that many varieties of bottled water are no 'purer' than tap water.

● The job market for scientists and engineers who have PhD degrees is likely to deteriorate during the next 10 years, according to a survey soon to be released by the National Science Foundation (NSF). According to projections of the likely output from graduate departments of universities in the United States, there will be between 375,000 and 400,000 scientists and engineers with PhDs by 1985, but only about 295,000 are likely to be employed in jobs related to science and engineering.

Those predictions "indicate a trend toward increasing imbalances between supply and utilisation . . . of science and engineering doctorates, possibly in some outright unemployment", the report states. But it adds that although the magnitude of the unemployment is difficult to project, it "is expected to be relatively small since individuals with doctorate education are likely to find some sort of employment—possibly in non-science and engineering activities or in underutilisation of their training".

The NSF's projections indicate that the widest divergence between supply and demand for PhDs is likely to be found in the social sciences, whereas the life sciences are likely to be almost in balance.

A prime reason for the deteriorating job market is the fact that there is expected to be a decrease in enrolment in universities and four-year colleges, which are traditionally the biggest employers of science PhDs. Consequently, the projections indicate that a smaller proportion of PhDs will be engaged in academic research and development in 1985, and that as many as 20% will not be involved with science and engineering at all.

In fact, the projections suggest that almost half of all new job openings for PhD scientists and engineers in the next decade will be in activities unrelated to research and development. The report suggests that such a shift "has major educational implications for institutions as well as for students".

● President Ford has at last signed an executive order to set the seal on the ratification by the United States of the Geneva Protocol, which outlaws the first use in war of chemical weapons. The executive order, which establishes a "national policy" under which the United States has renounced the first use of herbicides and riot control agents in war, had been bottled up for almost three months in the Justice Department, and formal ratification of the protocol by the United States was being held up until Ford signed it. The order, in short, allows the Administration to hang on to its belief that herbicides and riot control agents are not strictly covered by the protocol, but the United States has renounced their first use anyway.

● The Energy Research and Development Administration (ERDA) has backed off from a plan to store radioactive waste material from nuclear power plants in temporary aboveground storage facilities, and has decided that the whole matter requires more study. The move, announced last week by ERDA Administrator Dr Robert Seamans, follows widespread criticism of the plan by a number of environmental organisations. Although the temporary storage scheme has not been dropped entirely, ERDA may well move straight to a permanent disposal operation, consisting of burying the wastes deep in a salt mine. A promising site is under study in New Mexico, but it will take many years to carry out tests there. The original idea was to store the waste material in temporary facilities until a permanent disposal site had been found and tested, and ERDA had asked Congress for $5 million to start constructing the above-ground facilities next year. Seamans said, in a letter to the Joint Committee on Atomic Energy, that no decision would be made until 1976 about how the waste disposal operation should proceed.

Soviet Jews

SIR,—The wave of repressions against Jews seeking permission to emigrate to Israel has recently increased considerably in the USSR.

We scientists, who are being forcibly kept in the USSR against our wills, wish to express our opinion about the present deteriorating situation. We realise that the Soviet authorities now respond to the sympathy and public opinion of the West, and especially of the USA, in terms of what they can gain politically and economically. The Soviet government has found that the West reacts actively to the voices of the persecuted who are deprived of elementary human rights; they therefore try to deprive these people of their voice and to turn them into obedient instruments of Soviet policy.

So the main attack is directed against people whose protests are considered by the authorities to be the most undesirable. Thus Nashpits and Tsitlenok are now charged with participating in a 12-second-long demonstration of protest against the refusal of the Soviet government to issue visas to them. As recently as three years ago such action would have, at the worst, led to 15 days detention for "disturbance of public order".

The other participants in this demonstration were warned that if they set a foot wrong again their fate will be the same as that of Nashpits and Tsitlenok (now sentenced to five years' exile).

The magazine *Jews in the USSR*, created by Professor Voronel and dedicated to the scientific analysis of different aspects of the cultural life of Jews, was claimed at the trial of the writer Vladimir Maramzin to be against the law and anti-Soviet.

Nowadays, also, participants in the scientific seminar founded by Professor Voronel three years ago are persecuted severely.

● The present leader of the seminar, Mark Azbel, was recently told by the KGB that the important thing is not that he is a professor of physics, but that he is a lieutenant in the military reserves and subject to call-up for military service. It is ironic that a man aged 43, who has never been called up, should now, after 2½ years of waiting for a visa and 3 months in hospital, be needed in the military camps.

● Recently Dr Viktor Brailovskii was called to the KGB where he was threatened with the charge of "insulting a policeman" during a demonstration on February 24. But he was not involved in the demonstration.

● Dr Aleksandr Lunts was warned by the KGB that he can be charged as a traitor to the Motherland.

● In Kharkov unknown persons tried to break into the flat of Professor Leonid Gerber.

● Dr Mikhail Shepelev received seven summonses to military offices and a summons to appear before the police for so-called "parasitism" (being unemployed).

● Eltan Finkelshtein has been called to the military offices again and again.

● After being fired from his job, Dr Vainer was ordered to begin work in 15 days. But as it is impossible for a Jewish *refusnik* to obtain work in his profession, he will have to take a menial job.

● Dr Mikhail Mikylinskii and Dr Eugenir Yakir are charged with parasitism as well, in spite of the fact that they were dismissed from their previous jobs.

So, although nobody has been directly charged for participating in the seminar, it now seems too dangerous to be involved in it. And it is the only means of scientific contact for 8 professors, 24 doctors and 18 bachelors of science from eight cities.

The scientists are persecuted for scientific activities as they were in the Middle Ages. This is the true picture of KGB activities to stop the voices of Aliya (the movement for the repatriation of Jews to Israel).

It is hard to predict what will happen if the authorities achieve their aim. If protests cease, the government will be able to say that people no longer want to emigrate.

Whether Russian Jews will play a further part in changing the relationship between the USSR and the USA, and whether they will continue to be repressed is an open question; in any case, if their voices are silenced, the Soviet government would be quite free in its suppression of emigration.

We have too few opportunities for preventing such a sequence of events. We do not know how to convince the Soviet authorities that the humane attitude towards emigration is the only possible way in our time.

It is now abundantly clear that the mass attack against Soviet scientists who participate in Professor Mark Azbel's seminar has been instigated by the KGB in preparation for the 250th anniversary of the Academy of Sciences of the USSR. (The anniversary session was unexpectedly postponed last year because of elections to the Supreme Soviet.)

We are so anxious for scientific contact that we will be happy to speak at and to listen to as many lectures as possible. But such things are impossible, according to KGB logic. So the spirit of the participants in the seminar must be broken before the Anniversary.

We ask all people who are interested in helping the persecuted to help us—to raise their voices in defence of emigration, in defence of our natural human rights.

MARK AZBEL
VENYAMIN FAIN
ILYA PYATETSKII-SHAPIRO
VIKTOR BRAILOVSKY

. . . it is interesting to note that reports from Sweden and Norway state that during the night of March 29–30 last, a heavy rain of ashes or sand took place from the west coast of Norway to the Swedish frontier; the whole of the country was covered with grey dust to such an extent that from a pint of snow more than a tablespoonful of residue was left after the snow had melted. Some chemists of Christiania have examined the ashes, and one of them, Prof. Waage, states that the dust consists of little, irregular, but sharp-edged grains, almost all colourless—some few are of brown colour—and they consist principally of silicates. Acids extract some lime, iron, and alumina from their powder. The professor thinks it likely that the dust originates from an eruption in Iceland. This view is confirmed by a mineralogical investigation made on another sample of the dust at the Christiania University, by Profs. Kjerulf and Fearnley; they recognised the dust to consist of fragments of pumice-stone which is identical with the Hecla pumice-stone. According to Swedish newspapers, some traces of the dust-fall were observed even in the vicinity of Stockholm. Prof. Kjerulf also thinks it highly probable that an eruptiin took place in Iceland. The distance from the Iceland volcanoes to the Swedish frontier is about the same as that from Mount Etna to the Baltic.

news and views

The nucleosome: subunit of mammalian chromatin

from Benjamin Lewin

EACH eukaryotic chromosome contains a very long duplex molecule of DNA, five classes of histone protein whose total weight is about equal to that of the DNA, a lesser weight of a somewhat larger number of nonhistone proteins, and a small amount of RNA. Little evidence has been available to show how these components may be organised at the molecular level, although it has for some time been apparent that DNA and protein form a fibre of regular dimensions which is condensed into the very compact structure of the mitotic chromosome and presumably is relatively less tightly folded into interphase chromatin. Two types of chromosome fibre were identified by DuPraw and Bahr[1] in electron microscopy of chromatin prepared by the critical point drying method (drying on a grid from CO_2); the basic thread folded into the human chromosome seemed to be a fibre of 250–300 Å, which in turn was generated by the folding of a fibre of diameter 50–100 Å. Although critical point drying may alter the dimensions of chromatin organisation, this suggested the general concept of a single continuous fibre folded upon itself many times, with more than one level of organisation.

The existence of a regular repeating unit in both interphase chromatin and metaphase chromosomes of Chinese hamster cells was suggested by Pardon et al.[2,3], whose X-ray diffraction studies suggested the presence of a supercoiled fibre of diameter 100 Å with a pitch of 110–120 Å. By introducing a new method for visualising chromatin structure, Olins and Olins[4] were able to suggest that the chromosome fibre might have the type of structure typical of beads on a string. Following the procedure first developed by Miller and Beatty[5], interphase nuclei of rat thymus

or liver or of chicken erythrocytes were diluted into water; the nuclei swell and break open, the contents are fixed in formalin and then centrifuged on to a grid. Spherical particles, called ν bodies, of about 60–80 Å in diameter can then be seen, connected by a thin (15 Å) filament. Individual ν bodies could be visualised in less stretched region of the fibre; a fibre of greater diameter was generated when the ν bodies were more closely packed together.

Histones

Another line of approach to resolving the structure of chromatin has been developed from analysis of histone properties. Histones are separated on acrylamide gels into five distinct classes, which fall into three groups according to the relative contents of the basic amino acids lysine and arginine in which these proteins are rich. Two different nomenclatures have been in use to describe these five classes; since both serve as a reminder of the erratic progress made in separating histones and now seem somewhat less than satisfactory in their relationships, I shall use a third nomenclature which was proposed recently[6] (see table).

The lysine-rich histone class H1 displays microheterogeneity and consists of several closely related proteins. This class is the most easily removed from chromatin and its removal allows the preparation to be solubilised; several studies of the physical state of chromatin depleted of lysine-rich histones have suggested the tentative conclusion that H1, as the least tightly bound, may be concerned with surface properties, perhaps with holding together a chromosome fibre consisting of the other components[7].

The two classes of slightly lysine-rich histones, H2A and H2B, show some conservation between species according to the criterion of gel mobility. The two classes of arginine-rich histones, H3 and H4, both show extensive conservation, with virtually identical amino acid sequences between organisms as unrelated as cow and carp (H3) and cow and pea seedling (H4); patterns of modification are similar but differ in detail between species. (The strict con-

servation of sequence makes these the most conserved proteins known.) Such striking suppression of variation suggests that the entire sequence of each of these histones is involved in its function and that this function may be virtually identical in all eukaryotes. A function common to such different species presumably must be structural, so that this implies that there may be common features in the molecular organisation of all eukaryotic chromosomes[7].

The tendency of histones to aggregate during extraction has been a complicating factor in analysing their function for some time. Kornberg and Thomas[8] suggested that this aggregation might be due to the denaturing conditions that were employed and therefore extracted histones by a milder method (in 2 M NaCl–50 mM Na acetate). When this histone preparation was fractionated on Sephadex, three groups of proteins could be identified: one peak contained a complex of H4 and H3; another contained a complex of H2A and H2B; H1 did not complex with any other histone. A tetramer containing two molecules of each arginine-rich histone ($H3_2$–$H4_2$) was obtained by applying ammonium sulphate precipitation and using a cross-linking agent; little of this tetramer was found when histones were extracted by the more usual acid and solvent procedure. The slightly lysine-rich histones also form an oligomeric complex (H2A–H2B), although its nature could not be so well defined. When the $H3_2$–$H4_2$ tetramer was mixed with the H2A–H2B oligomer, no reaction occurred as judged by the use of a cross-linking agent.

When the tetramer and the oligomer were mixed with DNA, however, Kornberg and Thomas found that they formed the same X-ray diffraction pattern as that displayed by chromatin. Based upon these observations, Kornberg[9] suggested a model for chromatin in which the basic structure is formed by the interaction of DNA with the $H3_2$–$H4_2$ tetramer and H2A–H2B oligomer; the lysine-rich histones H1 and the nonhistone proteins do not participate. The equal weights of histone and DNA present in chromatin

Histone nomenclature

	Original schemes		New scheme[6]
Lysine-rich	f1	Ib	H1
	(f2c	V	H5)
Slightly lysine-rich	f2a2	IIb1	H2A
	f2b	IIb2	H2B
Arginine-rich	f3	III	H3
	f2a1	IV	H4

correspond to about one histone each of the slightly lysine-rich and arginine-rich classes per 100 base pairs, with the lysine-rich H1 being present in only about half the molar amount. Following this equality, Kornberg proposed that the H3₂–H4₂ arginine-rich histone tetramer is associated with two copies each of the slightly lysine-rich histones H2A and H2B and with 200 base pairs of DNA; this forms the basic repeating unit. The lesser amount of H1 would correspond to one protein molecule for each repeating unit. By postulating that the arginine-rich tetramer forms the core of the repeating unit, it is possible to explain why these two histones are the last to be dissociated from DNA by mild extraction procedures and why they are the most conserved; the role of the slightly lysine-rich histones H2A and H2B might be to determine the spacing of the tetramer along the length of the fibre. This would generate a flexible structure, able to fold in the manner that must be necessary for compression within the chromosome.

Nuclease digestion

Support for this model is provided by several experiments which show that nucleases may cleave chromatin at regularly spaced sites, presumably the sites between adjacent repeating units. An early observation was that of Hewish and Burgoyne[10], who found that an endogenous nuclease in rat liver digests the DNA of chromatin when the nuclei are incubated *in vitro* in the presence of calcium and magnesium ions. When the DNA was purified, it formed a series of bands on acrylamide gels, suggesting that sites at regular intervals are available for cleavage. Clark and Felsenfeld[11] similarly found that staphylococcal nuclease is able to digest about half the DNA of chromatin to form fragments with an average length of 100–110 base pairs; in a more detailed report, Axel *et al.*[12] digested duck reticulocyte or calf thymus chromatin with this enzyme and found DNA fragments to be produced predominantly in the size classes 45–60 base pairs, 100–130 base pairs, >200 base pairs. Duck reticulocyte chromatin reconstituted *in vitro* from its components gave a somewhat similar result, except that the >200 base pair peak was more pronounced; the source of the DNA proved to be irrelevant, for the duck chromatin proteins were able to confer the same support against degradation upon any DNA.

Particles also have been obtained by digestion of DNA. Sahasrabuddhe and Van Holde[13] found that brief digestion with micrococcal nuclease converted chromatin into very compact particles sedimenting at 12S. Oosterhof, Hozier and Rill[14] more recently have prepared 11S particles by fragmenting calf thymus chromatin with DNase II; these particles contained DNA of a length of about 400 Å (125 base pairs). Less extended periods of digestion generated DNA in multiples of this length, of 250, 375, or 500 base pairs. Noll[15] found that more than 85% of the DNA of rat liver chromatin can be converted to subunits sedimenting at 11S upon digestion either with micrococcal nuclease or with the endogenous enzyme; milder digestion allows dimers of 16S to be seen. The 11S particle contained DNA of a length of about 205 base pairs; fragments of 405 and 605 base pairs, obtained upon the milder digestion, presumably correspond to dimers and trimers. The buoyant density of the particles of 1.45 g cm⁻³ in CsCl corresponds to a protein : DNA ratio of 0.77; all five histones and some non-histone proteins were present. Some DNA of 170 based pairs in length also was produced, probably as a product of degradation of the 205 base pair fragment, suggesting that shorter pieces of DNA can result from breakage of the basic unit.

In spite of some discrepancies between the size of the particle and the length of DNA contained in it, these experiments all support the general conclusion that there may be a sub-unit of chromatin which forms a distinct particle and contains a fixed length of DNA.

Electron microscopy

Results supporting the general model for histone–DNA association proposed by Kornberg and confirming that the length of DNA in the repeating unit is about 200 base pairs have been reported by Oudet, Gross-Bellard and Chambon[16]. In a direct visualisation of chromatin structure, chromatin of chicken liver was treated with 700 mM NaCl to dissociate the lysine-rich histone class and so give a preparation that is more readily dispersed; centrifugation through a discontinuous glycerol gradient in 600 mM NaCl then gave two fractions of chromatin, one more dense than the other. Both fractions gave the appearance of beads on a string when examined by electron microscopy, with particles of average diameter 128 Å connected by a fibre of 15–25 Å. Oudet *et al.* termed these particles 'nucleosomes', in analogy with the ν bodies; the connecting thread appears to be DNA since it is of an appropriate diameter and disappears after digestion with micrococcal nuclease. The less dense peak contained tightly packed nucleosomes separated by long stretches of free DNA; the denser peak contained only tightly packed nucleosomes. To exclude the possibility that nucleosomes might have been formed by rearrangement of histones in salt solution, selective degradation with trypsin also was used to prepare chromatin depleted of lysine-rich histones; this gave tightly packed nucleosomes of 124 Å connected by a thread of 18–30 Å diameter. To confirm that this structure represents that of chromatin *in vivo*, another technique was used; chicken liver nuclei were lysed directly on to the surface of a water drop on top of a grid. This revealed a very compact structure consisting of tightly packed 130 Å diameter nucleosomes.

By degrading the free DNA of the chromatin preparations that had been depleted of lysine-rich histone, it was possible to obtain strings containing a few nucleosomes, at later times converted to single nucleosomes. The nucleosome seems to sediment at 10.5–12S and represents a spherical particle with an average protein : DNA ratio of 0.97. Gel electrophoresis showed the presence of equal amounts of H2A, H2B, H3 and H4 histones. When the protein of the nucleosomes was digested with proteinase K, the isolated DNA could be visualised by electron microscopy and had an average length of 667 Å (197 base pairs). These results are consistent with the X-ray diffraction studies that suggested a diameter of 100 Å and repeating length of 110–120 Å; differences in hydration may explain the discrepancy in the spacing. The larger diameter of nucleosomes compared with ν bodies probably derives from differences in fixation procedures, for Oudet *et al.* found that 1% formaldehyde reduced the diameter of the particles to 96 Å.

The nucleosomes disappeared, of course, when the four remaining histones were dissociated in 2 M NaCl from chick erythrocyte chromatin that previously had been depleted of lysine-rich histones. When the chromatin was reconstituted by progressive decrease of the salt to 400 mM NaCl, particles of diameter 131 Å formed, connected by a thread of 15–25 Å. The only difference apparent in this preparation compared with those of chromatin was that somewhat greater lengths of free DNA connected the nucleosomes. Adenovirus DNA or phage lambda DNA gave the same structure when reconstituted with the four histones of calf thymus, a strong indication that the sequence of DNA is irrelevant to the formation of this structure. All four histones are essential if nucleosomes are to be reconstituted.

An indication that a regular repeating unit may also be constructed in another way is provided by the recent observation of Lohr and Van Holde[17] that treatment of nuclei of *Saccharomyces cerevisciae* with micrococcal nuclease generates bands of DNA of definite multiple sizes, 135, 275, 400, 520, 650 base pairs. The

•

653

behaviour of yeast chromosomes at mitosis differs cytologically from that of chromosomes of higher eukaryotes and their content of histones is smaller : only three histone bands are found on acrylamide gels, H1 seems to be absent and it seems likely that H3 may also be missing. In this case the regularly repeating unit must have components different from those of mammalian chromatin.

The basic unit of mammalian chromatin thus seems to be a complex of diameter about 125 Å; this contains about 200 base pairs of DNA that are compressed about five-fold in length, and possesses two molecules each of histones H2A, H2B, H3 and H4. The DNA presumably is recognised as a polynucleotide duplex chain. The role of each histone within the nucleosome remains to be established; however, it seems likely that application of techniques analogous to those used to investigate the self-assembling ribonucleoprotein structure of the ribosome may prove profitable. That nucleosomes of all higher eukaryotic chromatins may be constructed very similarly is implied by the lack of nucleotide sequence specificity in the DNA component and by Kornberg's proposal that it is the highly conserved arginine-rich histones, H3 and H4, which interact the most intimately with DNA. Presumably the nucleosomes cannot be identical, however, since there may be differences in the slightly lysine-rich histones, H2A and H2B, and it would be interesting to determine the relationship between the mammalian nucleosome and the structure of the repeating unit of yeast, which may lack H3. The relationship between nucleosomes in

mammalian chromatin presumably is established at the molecular level by protein interactions involving the lysine-rich histones and nonhistone proteins; a system in which to investigate the role of lysine-rich histones may be the avian erythrocyte, in which H1 is replaced by a new lysine-rich histone, H5.

One question that is highlighted by these results is the role of modifications (methylation, acetylation, phosphorylation) that histones seem to suffer in the cell, sometimes on a cyclic basis. Modification is species specific; the extent of modification of H3 and H4, for example, varies in those species in which these proteins have been sequenced. There have been speculations that histone modifications might be imposed to allow histones to bind to DNA sequences with sufficient specificity, but the *in vitro* reconstitution and simple repetitive nature of the nucleosome argue against this conclusion. Perhaps modification becomes attractive as an evolutionary mechanism for permitting changes in the histones or parts of histones whose amino acid sequences are strictly conserved; its role remains to be established.

The lack of nucleotide sequence specificity in the architecture of the nucleosome implies that it is with any higher orders of organisation that an explanation must be sought for chromosome ultrastructure. The compression of DNA within the chromosome or interphase chromatin is many times greater, of course, than within the nucleosome subunit. It is therefore important to establish in what manner nucleosomes may be packed together. If lysine-rich (H1) histones are engaged

in some such general role, than it is the nonhistone proteins which must be responsible for variations in ultrastructure, including the differences between euchromatin and heterochromatin that may affect comparatively large chromosome regions, the existence of specific bands in mitotic chromosomes, and the activation of specific genes (presumably transcription could not be accomplished within the nucleosome which would therefore have to be disrupted). Recognition of specific DNA sequences clearly must be accomplished by regulator proteins and the structure of the nucleosome poses an old question in new guise: how are DNA sequences recognised within the nucleoprotein structure?

What are tumour-specific antigens?

from D. Allen L. Davies

IN the spring of 1900 Paul Ehrlich, Director of the Prussian Institute in Frankfurt am Main, addressed the Royal Society with these words: "The idea has already been mooted by v. Dungern, of attacking epithelial new formations, particularly carcinoma, by means of specific 'anti-epithelial sera' ". Incidentally he also mentioned Metchnikoff's hope of attacking the symptoms of old age with anti-phagocyte serum; the latter has not been followed up with any success as far as I know (or was the paper turned down by *Nature*?). The former has been followed up but without the degree of success needed for clinical usefulness. In spite of this there are still generally great hopes for the future success of cancer immunotherapy and for reasons which are easy to grasp.

Today's cancer treatment is almost

wholly by one or more of three approaches: surgery, irradiation and chemotherapy. Though progress and improvements are continually being made in these areas, especially in relation to particular kinds of tumours, nobody believes that in any of them are substantial improvements likely, of such a scale that cancer would no longer constitute a personal threat of disastrous consequences. If tumour-specific antigens are a characteristic feature of all kinds of neoplastic cells, then they provide a marker to serve as the specific target for an immune attack which could be increased, sustained or artificially engendered for therapeutic use. In this case progress of more general applicability can be imagined.

Paul Ehrlich continued thus: "But even if in the immediate future no

great practical success is attained, we must remember that we are only at the beginning of a rational investigation of properties of cells which hitherto have been far too lightly regarded". If over the last 75 years that rational investigation can be said to have been undertaken, what do we have to show for it? We have vast accumulations of data, the conviction that cancer immunotherapy is still a favoured hope for the future, and the impression that the subject is much more complicated than originally envisaged. We could sympathise with Ehrlich if he were now to think that progress has been slow, but some rules have emerged.

There are, perhaps, three taxa: (1) tumour-associated antigens (carcinoembryonic antigen, α-foetoprotein, and so on), (2) those coded in viral genes (which are not necessarily exposed on

the tumour cell surface) and (3) new surface antigens resulting from intervention of abnormal DNA. This last group, but also some of group (2) are attractive targets for immunological attack, but it is not yet decided if all neoplastic cell surfaces have such new antigens. Authors adhering to one school of thought freely refer to 'non-antigenic' tumours; the other school attribute these to instances where the test methods were of inadequate sensitivity. There are certainly stronger and weaker tumour antigens as there are strong and weak histocompatibility (H) antigens. Tumours obey the transplantation rules (except under bizarre experimental conditions) implying that their H antigens are not grossly changed. From the practical point of view the allogenic situation is most revealing when enhancing alloantiserum blocks the recognition event, abrogating the prompt rejection of a histoincompatible tumour and allowing free growth.

Much early literature bears on H antigen changes on tumour cells (especially in mice) but these studies have not led to any clear guidelines. On page 713 of this issue of *Nature*, Invernizzi and Parmiani compare a non-antigenic spontaneous mouse tumour and an immunogenic carcinogen-induced tumour of the same (H–2^d) genotype to show that the latter expresses an H antigen belonging to other (H–2^b and H–2^k) mouse strains, and they believe this to be the true nature of the tumour-specific antigen. The suggestion is made that the tumour antigen possibly resulted from "random mutations at the level of histocompatibility genes". It is especially important to know if such a relationship exists between H and tumour antigens because there is something special about H antigens as targets for immune attack. Not only are they of prime importance in allogeneic situations, they are also the principal target for cellular immune attack even between different species. This surprising information is provided by Lindahl and Bach (*Nature*, **254**, 607; 1975). The two contributions make good reading for those working on immunotherapeutic approaches, especially as there is a resurgence of interest in tumour-directed antibodies as carriers of drugs (Davies and O'Neill, Eleventh International Cancer Congress, 1974). This is on the basis that the cellular response of the host has failed, that it cannot be replenished from an allogeneic (histoincompatible) source and antibody is not powerful enough, alone, to wreak sufficient damage on the target.

We should beware of generalising to simple rules such as that tumour antigens are derepressed or mutated H anti-gens. Such a suggestion was made, for example by Martin, Esber, Cotton and Rice (*Br. J. Cancer*, **28**, Suppl. 1, 48–61; 1973), but for at least one particular tumour, tumour-specific and H antigens are physically separable molecules (Davies, Baugh, Buckham and Manstone, *Eur. J. Cancer*, **10**, 781–786; 1974) and Yeferof and Klein (*Expl Cell. Res.*, **88**, 217–244; 1974) show that H antigens and tumour-specific antigens do not co-cap. Aberrant H antigens derived by mutation or derepression should co-cap using suitable H-directed antibody. On the other hand there are cases where, as tumour antigen increases, H antigen decreases (Haywood and McKhann, *J. exp. Med.*, **133**, 1171–1187; 1971); and there are other variations on this general theme.

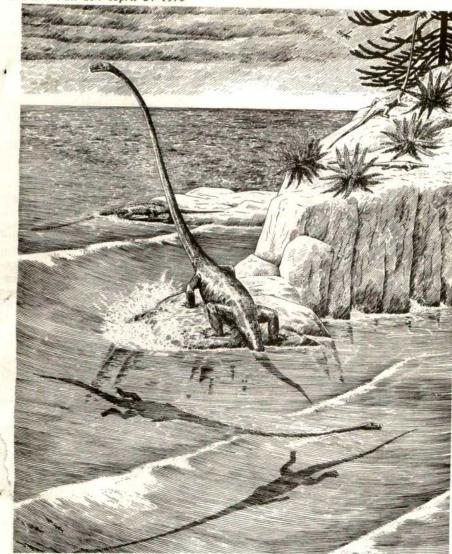
It is a sobering thought that whereas it would be convenient, and even promising from a practical point of view, if H antigens and tumour antigens had the relationships claimed, we do not actually know the natural physiological role of H antigens and their polymorphism. Among about ten possibilities listed at a recent meeting the favoured role was part of a cell surface recognition structure. One might conclude that a career in cancer research is still a safe one, not likely to be interrupted by an actual cure for the disease.

Hedges as relics of ancient woodland

from Peter D. Moore

MANY conservationists, particularly those with a botanical bent, are agreed that hedgerows in Britain act as an important reservoir for wildlife, though some feel that their importance may have been overrated especially as far as birds are concerned (see *Nature*, **249**, 514; 1974). Hooper, a leading botanical champion of the hedges, has stated that as many as 50 species of plant could be threatened with local extinction as a consequence of the current agricultural practice of hedgerow removal (in *Flora of a Changing Britain*, edit. by F. Perring, 58; Clarsey, 1970).

Hooper has also pioneered research into the relationship between plant species richness and the age of hedges, finding that the two are generally positively correlated. This fact can, however, be interpreted in two ways; long-established hedges may have had time for invasion by more species, or, alternatively, old hedges may often be relic strips of rich, ancient woodlands. If the former explanation is correct then it would imply that hedges could act as chan-nels along which plants migrate, and, if this is so, hedges can be regarded as doubly important, since they provide the means by which reinvasion of isolated fragments of woodland can occur.

Pollard (*J. Ecol.*, **61**, 343; 1973) coupled a study of hedge floristics in Huntingdonshire and the Soke of Peterborough with an historical analysis of their origins. His results agreed with the findings of Hooper as far as age and richness were concerned, but he also showed that the richest hedges were those which could be traced back through documentary evidence to old woodland edges, often associated with parish boundaries. Some shrubs were entirely confined to woodland relic hedges, such as field maple, *Acer campestre*, dogwood, *Thelycrania sanguinea* and hazel, *Corylus avellana*. This latter finding is rather surprising when one considers the rapidity with which hazel colonised the early post-glacial land surface of north-west Europe (see Deacon, *New Phytol.*, **73**, 1055; 1974). The concept of hedgerows as corridors for plant colonisation began to look unlikely.


Helliwell (*Biol. Cons.*, **7**, 61; 1975) has dealt this theory a further blow in his work on hedgerows in Shropshire. Association analysis of his site data split first into base-rich and acidic subsets, and subsequently separated off hedges rich in woodland plant species. These are considered to be relic woodland fragments. Of course the use of a classificatory system of analysis renders it inevitable that a strict division of sites should result. But it is surprising that some invasion of modern hedges has not occurred if they do provide migration routes for woodland plants. This would have produced a continuum of richness.

These conclusions in no way deny the value of hedgerows as objects for conservation; it is the emphasis in determining site priority which should be modified in their light. Hedges of considerable antiquity, due to their richness, remain worthy of conservation effort. The case for maintaining recently planted hedges as aids to botanical recolonisation, however, becomes rather tenuous.

The longest-necked lizard?

from Barry Cox

THE Middle Triassic reptile *Tanystropheus* is one of the most peculiar fossils ever found. The adults are up to 6 metres long but with the head and the enormously elongated neck together contributing nearly one half of the

Adult (foreground) and young (top right) *Tanystropheus*, according to Wild. From *Schweiz. paläont. Abh.*, **95**, 1–162; 1974.

length of the animal. Even more surprisingly, there are only 12 neck vertebrae, and most of the elongation is confined to numbers 3–11, some of which are nearly twice the length of the skull.

Tanystropheus has been found in Switzerland, Italy and Germany. A long and fully illustrated account of it, based on 25 more or less complete skeletons, has now been published by Wild (*Schweiz. paläont. Abh.*, **95**, 1–162; 1974). The characters of the skull, and the apparent presence of autotomy joints in the tail, suggest that despite its extreme specialisation, *Tanystropheus* was a very early branch of the lepidosaur (lizard and snake) stock.

Interpreting the anatomy of this reptile in terms of its mode of life obviously presents many intriguing problems. *Tanystropheus* is found in deposits of the Tethys Sea, and a number of adaptations suggest that it was a marine predator. The hind foot is enlarged and fan-shaped; it was probably webbed, and provided the main propulsive force. The forelimbs and neck could have been used to steer the

spindle-shaped body. Wild suggests that the long neck was flexible, like those of plesiosaurs. This seems a reasonable assumption, despite the small number of neck vertebrae, and some of the articulated specimens certainly show a considerable amount of curvature of the neck. The cervical ribs are thin and extremely long, some extending alongside more than four vertebrae, and Wild suggests that they acted as an elastic brace to strengthen the neck. He states that preserved stomach contents show that adult *Tanystropheus* fed on cephalopods and fish, biting and grasping with their simple, conical teeth. Wild points out that the shallow seas around tropical Triassic Europe, with many reefs and lagoons, probably contained a rich fauna.

The young *Tanystropheus* lived a very different life, according to Wild. He states that small specimens of two of the three species are unknown, and that small specimens of the third species (*T. longobardicus*) have never been found in purely marine sediments. Wild points out that specimens of this last species that are less than about two

metres long have three-cusped teeth. Such teeth are found today in some insectivorous lizards and in the marine iguana *Amblyrhynchus*. He then suggests that the young *Tanystropheus* were terrestrial, and that they stretched their long necks upwards to catch insects on the wing! But, though even the smallest specimens have an elongated neck, this would seem to confer little advantage on an insectivore. In any case, the vertebrae of the trunk show no sign of the large neural spines that would be needed for attachment of the large muscles necessary to hoist the heavy neck into the air—and that are, for example, found in sauropod dinosaurs. Perhaps *Amblyrhynchus*, which is a marine herbivore, provides a better clue to the use of the tri-cusped teeth of *Tanystropheus*, whose young may have fed on seaweed in near-shore waters. If so, this peculiar animal, like the crocodiles today, changed its diet during its life, but not its habitat.

Mad hatter's tea party among X-ray sources

from G. T. Bath

THE world of galactic X-ray sources produces a continuing supply of Lewis Carroll characters. Transient, short-lived X-ray sources, which flare up and then disappear (leaving behind not even a grin) are now a well established class. These flaring sources seem to resemble the optical flaring outbursts of novae, but in the X-ray region of the electromagnetic spectrum. The recent discovery of a further flaring source by the Ariel V satellite groups at Mullard Space Science Laboratory and at the University of Birmingham (Ives, Sanford, and Bell Burnell, *Nature*, **254**, 578; 1975; and Eyles, Skinner, Willmore, and Rosenberg, *Nature*, **254**, 577; 1975) has however added a new problem to exercise the theorists' ingenuity.

Until now the periods associated with X-ray sources seemed to be of three types. First, very short-period regular pulses of a few seconds. These are thought to be due to axial rotation of a magnetic neutron star, which is itself a member of a binary system. The radiation in the pulses is then produced by accretion heating of infalling matter at the magnetic poles. The accreted matter is lost by the stellar companion, which is being slowly cannibalised by the gravitational attraction of the binary neutron star component.

This binary structure itself then provides a second period—the period of the binary orbit—which is generally of the order of a few days in the

sources with which we are at present familiar. A third period, which only occurs in the extraordinarily complex system Her X-1, is the 35-day period on which the X-ray radiation in this source seems to be switched on and then switched off, like a regular recurring X-ray flare.

But the new transient source, which was only visible for about ten days, seems according to the Mullard group to have a 6.75-minute period present in the signal. The problem for the theorists will now be to fit such a period into a binary, mass transfer model. If it is the rotation period of the accreting star it would be extremely, and indeed uniquely, long. If it is the binary orbital period then it would be extremely, and excitingly, short—demanding a very small size for the companion as the source of accreted material. But perhaps, like the 35 day on–off period of Her X-1, it will require a completely different and

individual explanation. If other X-ray sources can be taken as an example it will not be long before a plethora of theories are produced trying to account for this totally unexpected new observation by the Mullard group.

Two recently published optical observations of the X-ray source Cen X-3 by Petro and by Osmer, Hiltner and Whelan (*Astrophys. J.*, **195**, 705 and 709; 1975) add a note of caution and sobriety to the world of X-ray sources. The first of these is a series of photoelectric observations of the variations in brightness of the Cen X-3 binary system about its orbit. The second is a study of the spectral type of the optical, mass-losing star. Both conclude that those values for the masses of X-ray binary stars which in the past have been determined on the basis of fitting the spectral type (that is, the appearance of the star's spectrum) and the luminosity (the star's intrinsic

brightness) to theoretical stellar models can be seriously in error. This is extremely important in the present search for black holes in X-ray sources. For it has been claimed that the masses of the compact X-ray sources in several systems must be greater than the theoretical maximum possible mass for a neutron star. But these two papers demonstrate conclusively that one must be extremely careful in determining the orbital parameters of such X-ray binary systems. Simple-minded arguments based on our general understanding of single-star structure may be seriously in error when applied to the pathological X-ray binaries.

Nonetheless, this work on the Cen X-3 system does not dispose of the problem presented by the system Cyg X-1, in which the X-ray source is almost certainly more massive than the critical neutron star mass. Like the grin of the Cheshire cat this conclusion does not seem to want to fade away. The evidence for the existence of a black hole in the Cyg X-1 system is still, as yet, neither substantial enough to confound the sceptics, nor weak enough for them to dismiss it. Demonstration using the techniques of these two papers that Cyg X-1 was not a unique system would have helped in resolving this critically important issue. Now we must wait either for the sceptics themselves to fade away, or for further dramatic news from present, and future, X-ray satellites.

More from Ariel V

by John Gribbin

FURTHER early results from Ariel V were reported at a press conference on April 17, organised by the Science Research Council to coincide with the publication of the papers describing the source dubbed 'Cen Xmas' (*Nature*, **254**, 577 and 578; 1975). The UK satellite has in fact already produced two important results apart from the Cen Xmas source. The first is a general comparison with the Uhuru surveys: so far, with 30% of the first Ariel V survey completed at a sensitivity 3 to 5 times better than the Uhuru 1971-2 surveys, it seems that 16 of the Uhuru sources have disappeared in the past few years. Nineteen new sources have already been found, one (the brightest for a time) being a transient with a lifetime of only a few weeks. This evidence for a changing X-ray sky highlights the need for Ariel V (and its successors) to continue sky survey programmes.

The second major news item came from Peter Willmore (now at University of Birmingham) who announced that an investigation of the galactic centre region showed a bright X-ray source in February, and that this source had definitely not been detectable as recently as November 1974. This might not seem too remarkable in view of the frequency with which other sources seem to be popping in and out of view, but of course the galactic centre is a particularly interesting region where events that we can only observe through a dust veil,

darkly, seem to be happening at many wavelengths.

The most up to the minute news came from Ken Pounds of the University of Leicester, reporting a second Leicester experiment which "within the past few days" has "shown positive evidence for spectral lines near 6.6 keV and 2.1 keV" in the supernova remnants Cas A and Tycho's Nova. Claims in a release distributed at the conference that "if confirmed, these will be the first positively identified X-ray lines from a cosmic source" may seem a little exaggerated to those who remember the days when Sco X-1 was the only known non-solar cosmic X-ray source; it depends, perhaps, on the definition of "positively identified", but there has long been quite convincing evidence that iron lines have been detected on occasion in the flux from Sco X-1.

But that does not detract from the importance of these observations, which suggest an abundance of heavy elements in the remnants several times greater than the cosmic norm, nicely in agreement with the generally accepted view that all elements except hydrogen and helium are synthesised in stars and distributed through the galaxies by nova and supernova events.

Where next for Ariel V? Peter Sanford (Mullard Space Science Laboratory) says that the satellite should have a useful life of a couple of years, so the story is far from over.

Meteors by television

from David W. Hughes

NEW techniques are always welcome and meteor scientists have acquired one: television. The time-honoured method of observing meteors—standing outside on a clear moonless night and gazing intently at the sky—still provides many useful results. About ten meteors per hour can be seen; the eye can detect meteors down to about the fifth magnitude (produced by particles with masses in excess of 0.1 g) in the direct line of vision. The field of view is a cone with an apex angle of around 120° but sensitivity to the meteor is strongly dependent on its position in the field of view: the possibility of a meteor far from the direct line of vision being seen decreases drastically with decreasing magnitude.

This field of view restriction can be alleviated by using a camera such as the Baker Super-Schmidt meteor camera. This has a low *f* number (0.8), a circular field of view 55° in diameter, uses high speed film and can photograph

down to fourth magnitude meteors. If used in conjunction with rotating shutters the meteor velocity can be calculated. Persistent glowing trains left by bright meteors have been studied using an objective shutter and taking successive exposures at two-second intervals, slewing the camera by 0.3° after each exposure to separate the images.

What advantages does television have over these older techniques? First, it is considerably more sensitive; Clifton reported in the *Journal of Geophysical Research* (**78**, 6511; 1973) that magnitude nine meteors can be detected using his SEC (secondary electron conduction) vidicon system coupled to a single stage image intensifier. Up to 180 meteors per hour were seen in a field of view 13° by 16°. An image orthicon system which could detect stars of the same limiting magnitude (11th) only recorded half this rate because it was less able to detect fast moving objects.

The second advantage is the high degree of time resolution. The television cameras effectually take a photograph of the meteor every 1/25th of a second. The video recording thus contains a nearly complete record of the train's movement, its growth and subsequent decay and the light intensity as a function of distance along the train. A comparison of the 1/25th-second time interval with the two-second interval of the slewed Super-Schmidt underlines the importance of the new technique. If two spaced cameras can be used a light intensity against height profile can easily be obtained for all meteors detected by both. A large number of these profiles, for meteors of differing velocities and from different meteor showers, should help sort out meteor ablation, fragmentation and structure problems.

More results of television observations have been reported by Hawkes and Jones (*Mon. Not. R. Astr. Soc.*, **170**, 363; 1975). They compared the inferred mass distribution and incident flux of the observed meteors with values obtained previously using radar techniques. Radar can detect trains produced by meteoroids of similar mass (that is $>10^{-4}$g) but measures the electrons produced by meteoroid ablation and not the de-exciting atoms and molecules. Radar suffers from an awkward selection bias inasmuch as the initial radius of the train and its speedy radial diffusion can lead to destructive interference in the reflected beam. As both initial radius and diffusion are height dependent the meteors which ablate high up could go undetected. There is also the underdense–overdense radio reflection transition around third magnitude. Here the equations governing reflected power change. Changes in flux and mass distribution index around

third magnitude could be caused by transition problems and not be inherent in the incident flux. Fortunately the television system does not suffer from any of these drawbacks. Increases in height and range simply decrease the observed light according to the inverse power law. The luminous meteor train being optically thin does not undergo the third magnitude transition, from surface reflection to reflection by all the train electrons, suffered by radar.

Hawkes and Jones conclude that television meteors with magnitude between three and six have a mass distribution index of 2.02, very close to the values obtained by radar in this range. Also the incident flux is, within experimental uncertainty, the same as that observed by radar. It therefore seems that the initial radius bias is of only minor importance in radar back-scatter work, the height of maximum ablation not depending as strongly on mass as previously supposed. The diurnal variation of influx is in qualitative agreement with theory with however a subsidiary maximum around 01 h local time. This supports the original observations of Clifton. Statistical analysis of meteor train lengths indicates that the very faint meteors observed by the television systems (fifth to seventh magnitude) have vertical train lengths of about 6.7 ± 0.7 km, in good agreement with Verniani's work (*J. geophys. Res.*, **78**, 8429; 1973) on faint radio meteors—once more indicating that these small meteoroids (mass $\sim 10^{-4}$g) are fluffy dustballs and not solid and compact pieces of rock.

The television system does have problems. Clifton, assuming all meteors had a spectral class of A0, found that his system detected all meteors brighter than magnitude 6.4, but only 50% of the meteors brighter than 8.1. This problem is also encountered by Hawkes and Jones who find the sensitivity of the television system decreasing as they move out from the centre of the field of view. Even more serious is the velocity dependence of the observations. The fainter the visual meteor the slower it has to go to be detected. The sytem is therefore biased towards bright fast meteors (the peak train intensity is proportional to the product of the mass and the fourth power of the velocity). But television detection of meteors is here to stay and will be put to many exciting uses. Only about 40 hours of observation are needed to observe enough meteors to sort out the long outstanding problem of the third magnitude transition. And it is possible to observe the whole magnitude range from about 7 up to -1 using television alone, instead of the hotch-potch of underdense and overdense radar, telescopic, photographic and visual techniques used previously.

Status report on the inner planets

by John Gribbin

ON April 11 the Royal Astronomical Society, the Royal Meteorological Society and the Geological Society held a joint meeting for the first time. Though the meeting was entitled 'Mariner 10 Results on Venus and Mercury', it included results on other planets and data obtained from other sources.

DISCUSSING the structure and composition of the clouds of Venus, G. Hunt (Meteorological Office) described the evidence for the presence of sulphuric acid in the cloud tops. In spite of Mariner 10, however, it is still far from clear what lies closer to the surface of the planet; Hunt plumped for a two-layer structure with an upper aerosol layer separated from a deeper cloud layer by a cloud-free region, but confessed that the field is "still wide open" for alternative models.

Some of the greatest interest in the Mariner 10 Venus pictures has centred on the dramatic evidence supporting the view that the Venus atmosphere rotates with a four-day period, producing V-shaped cloud formations. John Hinch (University of Cambridge) was persuaded to bring out of semi-obscurity a two-year-old model of the movement of the Venus atmosphere which, from rather simple assumptions, produces 'predictions' which seem, in the light of Mariner 10, almost too good to be true.

This is basically a 'moving flame' model, in which the heat of the Sun passing over the atmosphere (the moving flame) leads to a thermal tide with resulting circulation. Hinch's lucid discussion was memorable for the smooth way in which some rather unpleasant mathematical modelling was interpreted in physical terms which sounded quite plausible. By assuming a uniform temperature within the atmosphere, large magnitude fluctuations, a thin viscous boundary layer, long wavelength disturbances and a mean field approximation he came out with figures corresponding to a 2 K temperature flux travelling at 7 m s^{-1} leading to a disturbance propagating at 70 m s^{-1}, which corresponds to a five day rotation of the atmosphere (moving, correctly, in the retrograde sense). By comparison with this, the related model of Alan Plumb (Meteorological Office) was intimidatingly mathematical, though his numerical results looked as good as those of Hinch's model.

Jack Meadows (University of Leices-

ter) attempted to explain the evolution of the Venus atmosphere, comparing the process with the evolution of the Earth's atmosphere. The two seem greatly different today, chiefly because of the lack of water on Venus. Meadows pointed out that the difference could be explained in terms of a photo-dissociation process operating strongly on Venus to break water down (through interactions involving carbon dioxide) to oxygen and hydrogen, the latter escaping into space. But he said further that there is no need to invoke this process, and that he would be prepared to accept that Venus has had a predominately carbon dioxide atmosphere "from the start".

In this model, CO_2 is produced by the effect of heat on carbonates and silicates in the Venus rocks. Several reversible reactions involving these compounds include carbon dioxide as a product, and the amount of CO_2 present would then depend just on the temperature. Once a little atmosphere existed, the greenhouse effect would allow conditions very like those on Venus today to be established, given the boundary condition of the present output of the Sun. Since the Sun is slowly warming up, this suggests an increase in the density of the Venus atmosphere in future. The initial wisp of atmosphere needed to start the process could either come from a burst of volcanism, or slower outgassing.

Venus without its atmosphere must have been much the same as Mercury is today, and J. E. Guest (University College, London) described with the aid of Mariner 10 pictures the surface of Mercury and impact theories of the cratering. Much of this material formed something of a travelogue; for the mixed audience, the most interesting feature of the Mariner 10 pictures is that signs of compressional faulting indicate that the planet has shrunk by one or two kilometres since its formation.

The new studies of the inner planets support Runcorn's attempts to describe Mercury, Venus, Earth, Moon and Mars in one relatively simple model. If Mars and Mercury are both cratered like our Moon, then surely Earth and Venus have been through the same bombardment, providing a clue to events early in the development of the Solar System. If tectonic processes have occurred on Mars (and shrinkage on Mercury) geophysicists may gain a better insight into continental drift on Earth. And if satisfactory models of the Venus and Mars atmospheres are developed, this must help in understanding the workings of our own atmosphere.

As long ago as 1958, the RAS and RMetSoc held a joint meeting on planetary atmospheres. The way things are going, it certainly will not be a further 17 years before another tripartite meeting about the inner planets is held.

The sea as a chemical system

from Peter S. Liss

The Dahlem Workshop on the Nature of Seawater was held in Berlin on March 10-15, under the chairmanship of Professor E. D. Goldberg (Scripps Institution of Oceanography).

IN comparison with the solutions normally studied by pure chemists, seawater is a very complicated medium. Not only is its ionic strength high (~ 0.7 M), but the ions in solution represent virtually all the naturally occurring elements, with concentrations of different elements ranging over at least twelve orders of magnitude. Furthermore, many of the dissolved species are involved in biological processes and reactions at the air–sea and water–sediment interfaces. Pure and marine chemists met at the workshop to discuss techniques and concepts in chemistry which could deepen our understanding of seawater and of chemical reactions occurring in the marine environment.

The ionic strength and composition of seawater are very different from those of the aqueous media normally used for the determination of stability constants. Calculation of the effect of seawater yields only approximate values and for more accurate work, the discussion group which dealt with this topic concluded that it is much better to employ the ionic medium scale, that is, to use seawater (real or artificial) as the reference solution. A self-consistent set of conventions was proposed and its use will allow the development of uniform and thermodynamically rigorous data for seawater equilibria. The new approach has many important implications for marine chemistry, including the redefinition of pH and redox potential, and the use of reference solutions which closely match seawater in ionic composition for pH and ion-selective electrode measurements. It will obviate the need to use single ion activity coefficients and lead to phasing out of the scheme involving 'apparent' stability constants, which has served chemical oceanographers well for many years.

Sample collection is a perennial problem in seawater chemistry and is especially acute for the sea surface microlayer. Most techniques available at present involve dipping a screen or plate into the water to collect a layer approximately 200 μm thick. For the rapid collection of milligram quantities of material, consideration should be given to the technique of foam fractionation in which air or nitrogen is bubbled through the water to create a foam which, because of its large surface-to-volume ratio, will very efficiently scavenge surface-active molecules.

Less than 10% of the dissolved organic matter in seawater has been characterised and an important objective should be the identification of the remainder in representative samples from the deep ocean, above the thermocline and surface microlayer. Techniques are probably available for detailed identification, but these tend to be complex and expensive. Characterisation into broad classes of compounds and major functional groups is simpler and will yield much important information.

Our present knowledge of the particulate fraction in marine waters is rudimentary. For instance, in order to measure size distribution of particles the change in solution conductance due to the presence of the particles is often employed. However, using this method only part of the size spectrum can be examined at any one time and what is really measured is not the particles themselves but a complicated function of the relative conductivities of the particle and the solution. A much more promising technique is to use single-particle scattering counters. These devices, which use laser sources, have already been employed in studies of hydrosols and aerosols.

Though much is known about 'pure' solids (for example the role of electrical double layers, ion exchange reactions, particle–particle interactions), in the marine environment such properties are certainly very substantially altered because the particles have an organic coating. At present very little is known about the properties and composition of such layers, although it should be possible to use techniques such as microelectrophoresis and potentiometric titration to identify some of the major organic functional groups in the coatings, as well as in organic particles more generally.

The goal of the workshop was certainly achieved in a number of areas of seawater chemistry; reported here are only a few of the topics discussed. Where less progress was made it was generally due to the inability of the marine chemists to state the problems in a meaningful way, rather than any reluctance on the part of the chemists to get to grips with the complexity of the sea as a chemical system.

'review article

Form and function of cat retinal ganglion cells

W. R. Levick*

Recent explorations of the morphology of retinal neurones, combined with neurophysiological recordings have made it possible to link specific anatomical types with particular physiological classes. At the same time, the relatively complete anatomical mapping of the retina has revealed some bias in the sampling of neurones by electrophysiological techniques.

THE retina has always offered special opportunities to students of the nervous system. It is an extension of the brain conveniently located outside the skull and lining the inside of the back of the eyeball where it is accessible to exploration with a microelectrode under direct visual control. The ganglion cells, which are the retina's output neurones, are spread out as an essentially two-dimensional sheet and constitute the innermost cellular layer of the retina.

The ganglion cell dendritic tree provides the morphologist with a unique opportunity because it is confined to two major dimensions of spread. The pattern of a well stained dendritic tree can thus be directly determined in its entirety when the retina is mounted flat on a slide. The difficulties of assessing three-dimensional structures (thick sections, confusion from overlapping and obliquely running processes) are largely avoided.

The constraints which determine the form of the dendritic tree are not easily comprehended in a representative piece of nervous system but in the retina the sideways spread of the tree strongly conditions how much of the subjacent retinal image is accessible to a particular ganglion cell. There are considerable variations in the spread and mode of branching of different dendritic trees in the inner plexiform layer of the retina and so one is encouraged to expect important relations between structure and function in the spatial domain.

Morphology of retinal ganglion cells

A great deal was known about the appearance of ganglion cells long before their function became accessible to direct investigation. Cajal[1] made superlative analytical use of the Golgi method, which stains only a very small number of the cells actually present, but reveals their form in minute detail (Fig. 1). Cajal was keen to put forward a general morphological plan for all vertebrate retinae, based on certain characteristic forms of the cells. In the case of the ganglion cells, his classifications were based on: (1) the relative sizes of the cell-bodies (giant; middle-sized; small); (2) the number of layers in which the dendritic tree was arranged (single-layered; bilayered; multilayered; diffuse—that is, no obvious layering); (3) the particular strata of the inner plexiform layer to which the dendritic branches were distributed (first, second, . . . fifth); and (4) the density or sparseness of the dendritic branching pattern. Independent application of these four dimensions could lead to a very large number of morphologically distinct types of ganglion cell. According to Cajal, however, not all of

the possible types were observed in a 'typical' mammalian retina. Taking his descriptions literally, one may count up to 14 classes in the general case. In the cat, there could be still fewer classes because Brown and Major[2] cast doubt on the generality of Cajal's multistratified inner plexiform layer. They could distinguish only two sublayers.

The interesting recent development in the cat has been the substantial simplification of the morphological classification which has at the same time opened up the possibility of relating the form of ganglion cells to their function as revealed by neurophysiological studies on the responses of single cells. Boycott and Wässle[3] achieved their simplified classification by studying the cells in plan view, rather than on as Cajal had done, and arrived at a qualitative separation into three classes—alpha, beta and gamma cells. The discrimination was based on the recognition of differences in the form of the branching pattern of the dendrites.

Examples of alpha cells are shown in Fig. 2a, and b. They have rather sparsely branched dendrites going relatively straight out radially from a large perikaryon. Figure 2c–e shows beta cells. At equivalent retinal locations they are smaller in all respects than the alpha cells and have more branches per unit area of dendritic field. Most of the gamma cells (Fig. 2f, g) are characterised by small, often oval, cell bodies and a few very thin dendrites branching much less frequently than alpha and beta cells. Gamma cells may be a less homogeneous population than the other two classes. The example of Fig. 2g illustrates a form which may be sufficiently distinctive to constitute a separate morphological type, the delta cells.

Information on the size of axons is important for comparisons with physiological data. Unfortunately, quantitative measurements of diameters are unsatisfactory because of irregular distortions along their length. Qualitatively, Boycott and Wässle[3] noted that at equivalent retinal locations the axons of alpha cells were larger than those of beta cells and these in turn were larger than those of gamma cells.

A key result from the analysis of Boycott and Wässle[3] was the demonstration of a systematic quantitative gradation in size of alpha cells and beta cells with distance from the centre of the area centralis. The area centralis in the cat is the analogue of the human fovea which corresponds with the centre of gaze. The gradation involved principally the diameter of the field covered by the dendritic tree and to a more limited extent the diameter of the cell body. The recognition that a characteristic morphology may have a systematic quantitative variation with eccentricity has been essential in side-stepping the impasse which would result from rigid adherence to fixed size ranges of cell bodies[4].

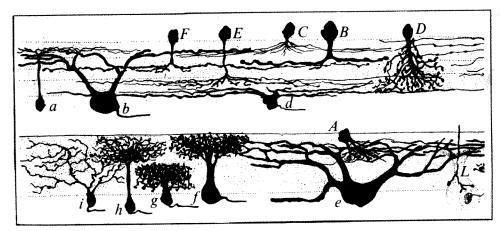
*Address: Department of Physiology, Australian National University, Canberra, Australia.


Fig. 1 Ganglion and amacrine cells from the dog stained by the Golgi method as seen in thick sections made perpendicular to the retinal layers. This is a selected part of Plate V in Cajal[1], who did not illustrate his work from the cat, but stated that cat, dog, pig and other mammals were virtually identical. Giant (*b*, *e*), middle-sized (*f*), and small (*a*, *d*, *i*, *h*, *g*) ganglion cells (all the rest are amacrine cells) have their dendritic trees running upwards and spreading out laterally in various fashions in this side-on view. It is interesting to compare *b* and *e* with alpha cells (Fig. 2 *a*,·*b*); *f*, *g*, *h* with beta cells (Fig. 2 *c*, *d*, *e*); *a*, *d* with gamma cell (Fig. 2 *f*) and *i* with a delta cell (Fig. 2 *g*), but Cajal unfortunately did not provide scales or relate the cells to eccentricity from the area centralis.

Physiological types of retinal ganglion cells

Cat ganglion cells became acecssible to functional testing by the technique introduced by Granit and Svaetichin[5]. The principle was to record the train of impulses which is the output message of a ganglion cell by bringing a delicate, insulated probe very close to the cell body. Rushton[6] showed neatly that such early recordings represented the activity of individual 'giant' ganglion cells. It was impractical to study the spatial sensitivity of ganglion cells until Talbot and Kuffler[7] devised a cannulation method for introducing the microelectrode into the intact eyeball, thus preserving the natural imagery. With the application of fine, sharp, electrolyte-filled micropipettes[8] or tungsten-in-glass electrodes[9] which penetrate rather than rest on the surface of the retina it has become possible to record from a wide range of ganglion cells.

A key property of ganglion cells is the concentric organisation of their receptive fields. Kuffler[10,11] showed that an individual ganglion cell was sensitive over a substantial patch of retina (0.8–2 mm), rather as Hartline[12] had found much earlier in the frog. The cat, however, differed from the frog in that the type of responsiveness was not the same throughout the patch. If a ganglion cell responded to a small flashing test spot by a discharge at turn-on for locations near the centre, then the discharge would come at turn-off when the spot was located in an annular surround zone at some distance from the centre. Such a cell would be of the on-centre off-surround type. Off-centre on-surround fields were also found and the two types occurred in about equal numbers.

Classification of cat receptive fields

For many years it was accepted that there were only the two classes of ganglion cell (on-centre off-surround and off-centre on-surround) with a continuum of variation of centre sizes and a preponderance of small-centred cells in the area centralis[13]. Enroth-Cugell and Robson[14], however, showed that the population of concentric receptive fields could be dichotomised according to the nature of the spatial summation of excitation over the receptive field. In one class of cell the processes of spatial summation were linear (X cells) whereas in the other the processes were very nonlinear (Y cells).

Two other dichotomising subsidivisions of concentric receptive fields have recently been developed. The sustained–transient[9] or tonic–phasic[15] dichotomy was based on applying a battery of visual tests, one of which depended on the extent to which the response of a ganglion cell was sustained when the eliciting stimulus was kept steadily on the centre. The brisk–sluggish dichotomy[16] was based on the responsiveness of cells.

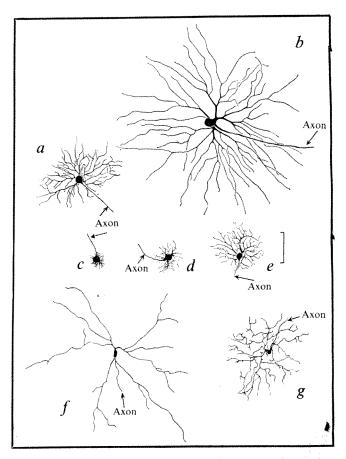
Brisk cells, which were encountered about six times as frequently as sluggish, could be induced to generate powerful responses by strong stimulation. The responses of sluggish cells increased far less steeply with stimulus strength and remained relatively feeble regardless of the form or conditions of stimulation.


Fig. 2 Golgi-stained ganglion cells from flat-mounts of the cat's retina as seen in plan view (from Boycott and Wässle[3], with permission of the authors and the Physiological Society). *a*, *b*: Alpha cells. *c*, *d*, *e*: Beta cells. *f*: Gamma cell. *g*: Delta cell. The cells *a*, *c*, *f* were located at 1.2 mm from the centre of the area centralis, *d*, *g* at 2.9 and 2.8 mm and *b*, *e* at 10.0 mm. All are shown at the same magnification (calibration bar near *e* = 100 μm).

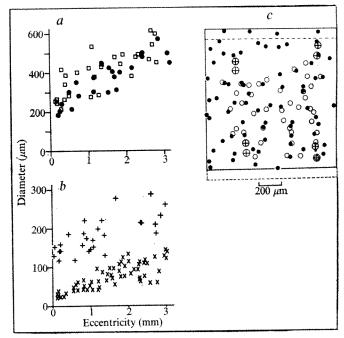
Table 1 Characteristics of five non-concentric classes

Receptive field types	Morphological identity
1. Concentric centre-surround types (comprising on-centre and off-centre varieties)	
a Brisk	
(i) Transient	Alpha
(ii) Sustained	Beta
b Sluggish	
(i) Transient	
(ii) Sustained	
2. Non-concentric	Gamma
a Local edge-detector	(delta, ...)
b Direction-selective	
c Colour-coded	
d Uniformity-detector	
e Edge-inhibitory off-centre	

Chiefly on the basis of the nature of responses when fine striped patterns moved over the receptive fields, it was argued that brisk-sustained cells were X cells (linear) and brisk-transient cells were Y cells (nonlinear)[16]. However, these affinities have not yet been checked with the specific stimuli used by Enroth-Cugell and Robson[14] in the case of sluggish-sustained and sluggish-transient cells. There is a recent tendency to classify cells as X or Y according to the conduction velocity of their axons. This is regrettable because the original principle of classification is interesting in its own right, and we do not know that it coincides with the conduction velocity principle for all types of cell.

Finally, it has gradually emerged[17-19] that there are rarely encountered ganglion cells having receptive fields organised quite differently from the concentric centre-surround type described by Kuffler. The situation has now been studied systematically on a large sample[20] and the characteristics of five distinct non-concentric classes described (Table 1). It was suggested[19,21] that such cells be referred to collectively as 'W cells'. The terminology has, however, become confused since Stone and Fukuda[22] now include sluggish concentric centre-surround receptive fields among the W cells, mainly on the ground that they have slowly conducting axons like the non-concentric classes.

Physiology and morphology

The diversity of types of ganglion cells immediately opens the possibility of relating morphological and physiological classes. One approach is to compare the spreads of dendritic trees and the sizes of receptive fields, just as Lettvin *et al.*[23] attempted many years ago in the frog.


The first complication is that the cat receptive fields are composite. Should the comparison be with the total receptive field or only with the central subdivision? Gallego[24] pointed out that dendritic fields of giant ganglion cells were much smaller than total receptive fields measured by Kuffler[11]. Gallego[25], Brown and Major[2] and Dowling and Boycott[26] (monkey) argued that the correspondence should be between the dendritic fields and the centre components of receptive fields. It was not until systematic measurements of the extents of receptive field surrounds were made[27] that these arguments became more acceptable. It turned out that all but the largest dendritic trees are smaller than the smallest (≈ 400 μm in diameter) total receptive fields. The comparison should therefore focus on dendritic trees and receptive field centres.

The next complication is to decide what is involved in a measurement of centre size since there are systematic discrepancies in the data presented by different investigators[13-16,22,27-29]. Scattered light[11] and optical degradation of retinal imagery eliminate the possibility of stimulating individual receptors in isolation in order to determine those which contribute to the centre response. The external test stimulus can be made sharp and tiny but the retinal image cannot. So the experimenter must fall back on stimulus spots of significant size and more or

less indirect methods. Cleland and Levick[16] pointed out that any particular measurement convention implies some assumption about the physiological processes underlying the organisation of receptive fields. There are important qualitative differences in properties between the classes and therefore differences in the nature of the underlying processes. Since these are only partly understood[28], one must proceed empirically and not be put off by minor discrepancies. Moreover, one should not necessarily expect to find exact dimensional matching between receptive field centres and dendritic fields. Ganglion cells do not receive input directly from receptors but only through intermediate neurones (bipolar cells, amacrine cells) which themselves have significant lateral spread of their processes.

Two of the physiological classes are compact and dimensionally distinct from each other: the brisk-transient and brisk-sustained classes[16]. So are two of the morphological classes: the alpha cells and beta cells[3]. It is natural to attempt to pair these off. The centre sizes of brisk-transient units are large and match very well the dendritic fields of alpha cells (Fig. 3*a*), both in the trend with eccentricity as well as in the range of variation at particular eccentricities. The possible identification of these entities is supported by the fact that the axons of brisk-transient units had the shortest antidromic conduction times[16]. This implies that they had the largest axons as was observed for alpha cells[3].

The identification of brisk-transient units and alpha cells was confirmed more directly by mapping out the centres of

Fig. 3 Comparison of diameters of receptive field centres and dendritic fields of: *a*, brisk-transient units (□) and α cells (●); *b*, brisk-sustained units (+) and β cells (×) (dendritic field data from Boycott and Wässle[3], receptive field data from Cleland and Levick[16] with permission of authors and the Physiological Society). The centre sizes were obtained from maps of the receptive fields made with small flashed test spots and show close agreement in *a*. *b*, Brisk-sustained centres have the same gradient of size (and similar variation)with eccentricity as beta dendritic fields, but are systematically about 100 μm larger at each eccentricity (note the increased vertical scale). *c*, Comparison of the plotted positions of the geometric centres of the receptive fields of all the brisk-transient units (○) in a small patch of retina with the position of the cell bodies of all the alpha cells (●) in the same piece of retina after mounting and staining with cresyl violet. The four pairs of cross within circle symbols indicate the position of electrolytic lesions made at predetermined sites during recording and later identified histologically. The separation of the members of each pair indicates that a small downward shift of the receptive field map relative to the alpha cell map was required for optimal registration of centres with cells.

the receptive fields of all the brisk-transient cells throughout a small patch of retina. This was identified by lesions and stained with cresyl violet to show the cell bodies of all the ganglion cells present. The distinctive large ones are the alpha cells[30] and they agreed in number and position (Fig. 3c) with the brisk-transient receptive fields[31] to within experimental tolerance. In retrospect, this demonstration supports the identification of dendritic fields with the central component of the receptive fields in the case of the alpha cells.

The comparison[16] of brisk-sustained centres and beta dendritic trees[3] (Fig. 3b) is not quite so encouraging. Even though the diameters of both increase gradually with increasing eccentricity, the centres are systematically larger by about 100 μm. The comparable data of Stone and Fukuda[22] on centre sizes would provide a better fit, but it should be noted that they used an unusual convention for determining centre size. Support for the identification comes from consideration of the axons: brisk-sustained cells had intermediate antidromic conduction times[16] and beta cells had axons of intermediate size[3].

By exclusion the remaining physiological classes (concentric receptive fields of the sluggish kind and the rarely encountered non-concentric receptive fields) may be associated with the morphological gamma (and delta cells.) On both sides there is substantial heterogeneity and little to be gained from dimensional comparisons at the present stage. About the only common feature is the possession of a thin axon and slowly conducted impulses.

Relationship of physiological and histological results

The linking of functional and morphological entities opens up a realm of interrelated data in which the physiological and histological methods play complementary roles. For example, it is comparatively simple to trace the central path of the axon of a ganglion cell physiologically by strategic placement of stimulating electrodes in the brain. Tracing particular axons is a rather difficult feat histologically. On the other hand, it would be an Herculean task to enumerate the brisk–transient cells in the retina by exhaustive physiological exploration, yet it is comparatively simple to count them as alpha cells in a cresyl violet stained flat-mount. There were 6,212 in one whole cat retina[30].

Again, microelectrode recordings have long been suspected of giving rather selective access to a heterogeneous neuronal population. For example, brisk-transient receptive fields were encountered on about 10% of recordings in the area centralis and on more than 50% in the periphery[16], yet the histology showed alpha cells to be an approximately constant 3% of the total ganglion cell density throughout the retina[30]. They are greatly over-represented in physiological recordings. This selectivity, which may be related in some way with the cross sectional area of the cell body, is much harder to assess in the three-dimensional structure of the brain[32]. The result in the retina is a warning against uncritical acceptance of recording percentages of different classes of neurones as direct indicators of actual numerical preponderance.

As a further example of the interplay of the two approaches, the histology gives us the average density of alpha cells over small regions throughout the retina together with the corresponding dendritic field size. The physiology links the latter to the receptive field centre size which is the significant component for representing the visual field. It is then a simple matter to calculate the extent to which a given point in the visual field is redundantly represented by the set of brisk-transient cells. The answer was a relatively constant, 4.0 to 7.3 in spite of variation of cell density from about 200 mm^{-2} at the centre of the area centralis to less than 10 mm^{-2} at the far periphery. The increase in centre size with eccentricity is

thus sufficient to offset substantially the reduction in density[31] and suggests the existence of a regulatory process during development.

The interpretation of dendritic architecture remains a challenging problem. The issue is this. Do the branching pattern and shape of the dendritic tree have a special significance for combining the input signals to form the output train of impulses[23]? Or does the form of the tree merely reflect the growth pressures and competition confronting the ganglion cell in maintaining contact with the elements delivering the input signals? Undoubtedly, the type of synaptic connections made by the ganglion cell strongly determines the message that it transmits[33]. The discussions of Dowling and Boycott[26], Dowling[34] and Boycott[35] show how far interpretations may be taken without explicitly considering the branching patterns of the various neurones. Ganglion cells may receive input from bipolar cells both directly (dyad synapses) and indirectly (conventional synapses) through amacrine cells. In addition amacrine cells feed back on to bipolar cells (reciprocal synapses) and also make connections with other amacrine cells. The idea is that all of the rich variety of ganglion cell classes is assignable to varying proportions and types of direct and indirect inputs. The pattern of the ganglion cell dendritic tree may therefore be inconsequential for function apart from merely reflecting the spatial extent of connections.

Nevertheless, it is still possible to consider that a particular branching pattern coupled with a strategic geometric distribution of synaptic connections might be responsible for a more complex operation on the incoming excitatory and inhibitory signals than simple, weighted, linear combination. It has been argued with substantial experimental support[36] that inhibitory inputs on the lateral dendrite of the Mauthner cell of the goldfish have a greater attenuating effect on excitatory inputs entering far out on the dendrite than those impinging close in to the cell body.

If there is processing significance in dendritic form then the pattern of the alpha cell should be an early candidate for finer examination since its physiological counterpart, the brisk-transient class has strongly nonlinear summation properties[14].

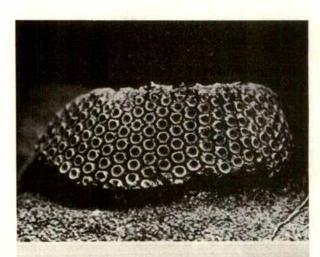
Trilobite eyes and the optics of Des Cartes and Huygens

Euan N. K. Clarkson
Grant Institute of Geology, University of Edinburgh, Scotland

Riccardo Levi-Setti
The Department of Physics, and The Enrico Fermi Institute, The University of Chicago, Chicago, Illinois

The thick lenses in the aggregate eyes of a group of trilobites were doublet structures designed to eliminate spherical aberration. The shape of the optically correcting interface is in accord with constructions by Des Cartes and Huygens and is dictated by a fundamental law of physics. Trilobites may have evolved such sophisticated eye-lenses to maximise optic neurone response in a dimly lit environment.


TRILOBITES, which occur in rocks ranging from Lower Cambrian (600 Myr old) to Upper Permian (250 Myr old), have the most ancient visual system known. From the beginning of their fossil record, compound eyes are present, symmetrically paired on the sides of the head. These compound eyes are primary structures and blindness in trilobites, which is not infrequent, is invariably secondary.

The primordial or holochroal eye, first found in the earliest genera, and thereafter taking many forms has numerous closely-packed lenses or prisms, each represented by a single crystal of calcite with its *c*-axis usually directed normal to the visual surface[1]. Most trilobites had such eyes, the main exception being the schizochroal eye, which is confined to the Ordovician–Devonian suborder Phacopina.

Schizochroal eyes, which are the subject of this study, have large thick biconvex lenses, each separated from its neighbours by a sclera; material similar in composition and structure to the rest of the cuticle. Eyes of this kind are present in the earliest Phacopina and there is some evidence that they were derived from the eyes of holochroal ancestors by paedomorphosis.

The structure of schizochroal eyes has been described in several publications[2,3] and it is now clear that in all known cases the lenses are doublets each of which has an upper unit of oriented calcite[4] (with its *c*-axis normal to the visual surface) interlocking with a proximally located intralensar bowl, the composition of which has not been determined. The distinction between these two units is apparent both in specimens which are preserved in limestone and thus retain their original structure, and in those preserved in silt or mudstone and subsequently decalcified. In the former case a compositional difference between the bowl and the upper lens unit is clearly visible in thin sections or polished surfaces unless diagenetic processes have destroyed or altered the primary structure; this is usually marked by a pronounced colour change. Invariably the lenses within any one eye are identical in structure. Where specimens are decalcified, the upper lens unit disappears, but the shape of its base may be preserved on the internal mould of the fossil. This is because the bowl has become detached or has decayed shortly after the death of the trilobite, and its former space is filled with silty or sandy matrix, preserving exactly the shape of the upper unit–bowl interface. The shape of this interface is clear

•

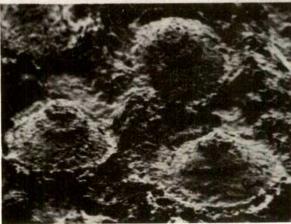
in both kinds of preservation; there seem to be two basic kinds of structure with a range of intermediates between. The two fundamental kinds of lens structures were first described by Clarkson[3] from Ordovician Phacopina preserved as decalcified siltstone moulds. In *Dalmanitina socialis* (Barrande) from the Caradocian (Middle Ordovician) of Bohemia, the intralensar bowl is thin and indented centrally by a small dimple (Fig. 1a). Really well preserved specimens (RSM Geol. 1967-32; FMNH


Fig. 1 *Dalmanitina socialis* (Barrande), RSM-Geol—1967–32 Letná Formation, Veselá. Bohemia. Caradocian (Ordovician). *a*, Left eye of a decalcified internal mould (steinkern) showing the intralensar bowls with central dimples. UC–1707) are rare, but from these, latex replicas can be made showing, as an average over many lens units, the surface shape as in Fig. 1*b*. The original reconstruction of Clarkson[3] has been slightly modified after a re-examination of the same material and some new material: the bowl is deeper and the upper surface is slightly more hyperbolic. Such lenses occur in other Dalmanitidae also.

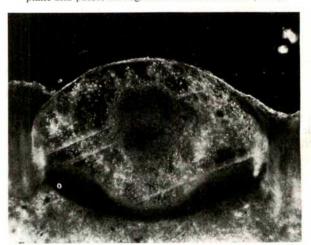
The other kind of structure originally described from the species *Crozonaspis struvei* Henry[3], from the Llandeilian (Middle Ordovician) of Brittany, is perhaps better seen in the eye of *Dalmanites pratteni* Roy[5] from the Devonian of Illinois (Fig. 2*a*) and in *Zeliszkella lapeyrei* (Bureau) also from the Llandeilian of Brittany (Fig. 2*b*). Here the lens is highly convex with a large and thick intralensar bowl, indented not by a small dimple, but by a wide and hemispherical depression. Lenses of this kind are not only found in these species of Dalmanitidae, but are the norm in the Siluro-Devonian family Phacopidae, especially in the genera *Phacops* and *Reedops* in which the lenses of the eye are very large, highly biconvex and relatively few in number[6].

The example shown in Fig. 3 is a lens in horizontal section of a large-eyed Silurian *Dalmanites*. Dark field illumination shows the difference between the intralensar bowl and the upper unit. The latter has typical calcite cleavages showing it to be a single crystal (with the *c*-axis aligned along the lens axis); these stop short at the edge of the bowl. The shape of the bowl's upper surface is intermediate between the two end types mentioned above.

Corrected optics in phacopid lenses

We first discussed the possible function of schizochroal lens structure at the NATO sponsored Trilobite and Merostome Conference in Oslo in July of 1973. Subsequently, Levi-Setti recognised that the two basic patterns of the intermediate refracting surfaces in *Dalmanitina* and *Crozonaspis* approximated in shape to that of the aplanatic surfaces described respectively by Des Cartes[7] and Huygens[8].

Such generally aspheric refracting surfaces belong to the class of so-called Cartesian Ovals. They were originally designed to obtain lenses free of spherical aberration. The original constructions by Des Cartes and Huygens are reproduced in Fig. 4*a* and 4*c* respectively, where for comparison, the structure[3] of the lenses of *Dalmanitina socialis* (Fig. 4*b*) and *Crozonaspis struvei* (Fig. 4*d*) are also shown. The similarity between the shape of the upper unit in *Dalmanitina* and the Des Cartes construction, as well as in that of the upper unit in *Crozonaspis* and the Huygens construction is strikingly apparent.

Cartesian Ovals


The physical principles underlying the function of the ovals of Des Cartes as optical refracting interfaces are derived from regarding these surfaces as the geometric representation of the stigmatic condition for an optical system (the requirement that a point in object space be mapped on to a point in image space). Their analytic expression, which is in general that of a fourth degree surface in Cartesian coordinates, takes a particularly significant form when cast in bipolar coordinates[9]. If the distances of a point *P* from two fixed points *O* and *O'* are called *r* and *r'* respectively, then *r* and *r'* are called bipolar coordinates of *P*. An equation connecting *r* and *r'* defining a locus for *P*, is called a bipolar equation. The ovals of Des Cartes are defined by the bipolar equation:

$$mr \pm nr' = k \tag{1}$$

where *m*, *n* and *k* are constants. If we now consider a system of two conjugate points *O* and *O'* in object (refractive index n_1) and image (refractive index n_2) space respectively, and *r* and *r'* the distances traversed by a light ray going from *O* to *O'* through a point *P* on the surface separating the two media, we can write the stigmatic condition as:

$$n_1 r + n_2 r' = c \tag{2}$$

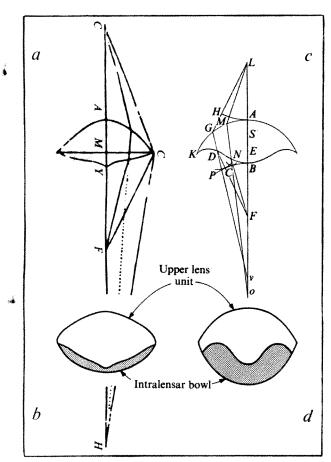
Fig. 3 *Dalmanites* sp. Silurian. Locality unknown. Single lens in thin section in dark field illumination, showing the dark intralensar bowl, and calcite cleavages truncated by a diagenetically altered central mass. Diagenetic effects within other lenses of the same eye are very variable; in some lenses it is only incipient, whereas in others irregular masses of amorphous calcite have filled up much of the interior. This section is cut in the horizontal plane and passes through the centre of the lens (×70).


Fig. 4 *a*, Original construction by Des Cartes of an aplanatic lens in air, making use of two Cartesian Ovals. *b*, Reconstructed lens of *Dalmanitina socialis*. *c*, Original construction by Huygens of aplanatic lens in air making use of spherical first surface, and a Cartesian second surface. *d*, Reconstructed lens of *Crozonaspis struvei*[3].

with *c* as a constant. This equation implies that whatever the position of the point *P* on the interface of the two media, the optical paths (represented by the left hand side of equation (2)) between the conjugate points *O* and *O'* must be the same. Alternatively, the shape of the interface must be such that light will traverse the path from *O* to *O'* in equal times, either travelling along the straight line connecting the two points (the shortest path hence the shortest time) or any other off-axis path. In his construction of a lens free of spherical aberration, Huygens[8] adhered explicitly to this condition. Ultimately, equation (2) is a specialisation of Fermat's principle of least times, which states that no matter to what kind of reflection or refraction a ray is subjected, it travels from one point to another in such a way as to minimise the time taken. We recognise that equation (1), restricting to the + sign, and equation (2) have identical forms. The bipolar representation of the ovals of Des Cartes thus acquires an immediate physical meaning through fulfilling the stigmatic condition when describing the shape of an optical interface. In this sense the ovals of Des Cartes represent the most natural economical solution to the problem of constructing optical elements free of spherical aberration. In our derivation, the only physics involved consists of Fermat's principle: Snell's (or Des Cartes') law of refraction is in fact already an implicit consequence of the former, as first demonstrated by Huygens on the basis of the wave theory of light. The ovals of Des Cartes could of course be described more laboriously with recourse only to the (weaker) refraction laws[7].

Optical function of phacopid lens doublets

Were it not for the presence of the intralensar bowl in the trilobite lenses, there would be virtually a one-to-one correspondence in

shape and function between trilobite lenses and the optimal construction of Des Cartes and Huygens (allowing for differences arising from the fact the trilobite lenses operate in water rather than in air).

The function of the intralensar bowl has been investigated empirically by two approaches: first, graphical ray-tracing through the lens structure for example, that of *Crozonaspis*, and second, constructing a large-scale model of a *Crozonaspis* lens.

In the problem at hand we assume that the refractive indices of the media in contact with the entrance surface (seawater, *n* = 1.33) and the exit surface (body fluid, *n* = 1.34) are known. We also assume that the refractive index along the axis of the upper lens unit is equal to that along the *c*-axis of calcite (*n* = 1.66).

Given the interface profile actually observed, the unknowns are the refractive index of the intralensar bowl and the focal distance of the lens doublet as a whole. In principle the problem is completely determined by making use of the two constraining conditions: the stigmatic condition as an extension of equation (2); and the requirement of continuity of the light rays at each refracting surface. (It should be noted that since equation (2) satisfies Fermat's principle, the law of refraction does not represent an independent constraint.)

Using both approaches, by trial and error, we have determined that the intralensar bowl of *Crozonaspis* should have a refractive index of about 1.63, and the resulting focal length equals approximately one lens thickness measured from the exit surface. The *f*/number (inverse of the relative aperture) of this lens, operating in water is ~ *f*/1.1.

Given the shape of the upper unit as observed in *Crozonaspis* the intralensar bowl is thus seen as a necessary element to ensure convergence of an incident parallel beam of light to a sharp focus, when the lens is immersed in water. The intermediate Cartesian interface acts as a correcting surface, to make the doublet aplanatic.

The graphical ray tracing construction for the corrected lens versus a similar uncorrected one is shown in Fig. 5*a*, where the effect of spherical aberration for the latter case can be appreciated. The experimental verification of the function of the *Crozonaspis* lens is illustrated in Fig. 5*b*, which shows the focusing of a parallel beam of white light by a large scale model of the lens. Considering the uncertainties inherent in this reconstruction of the profile of the lens and the imperfections in the manufacture of the model, the focal plane of the corrected lens is remarkably well defined. The value of refractive index derived for the intralensar bowl may give a clue to its unknown chemical composition. Calcite was probably present, possibly together with organic material such as chitin.

Advantages and disadvantages

The fact that this remarkable lens doublet system functions in the manner empirically determined, provides independent evidence for the presence of oriented calcite[4] in the upper unit *in vivo*. It can, moreover, easily be appreciated that such a system is adapted for light collection and for the formation of a sharp and undistorted image in its focal plane.

Calcite is the basic structural component of the trilobite exoskeleton[10], but its orientation in the lenses is optimised to the function being performed. In the first place, this orientation is the direction along which the ordinary and extraordinary rays of calcite propagate with equal velocity, thus eliminating birefringence for paraxial rays. In the second place, along the *c*-axis the refractive index is maximal (*n* = 1.66), thus yielding the largest possible relative aperture (and thus optimising light-gathering) for a lens of the shape given.

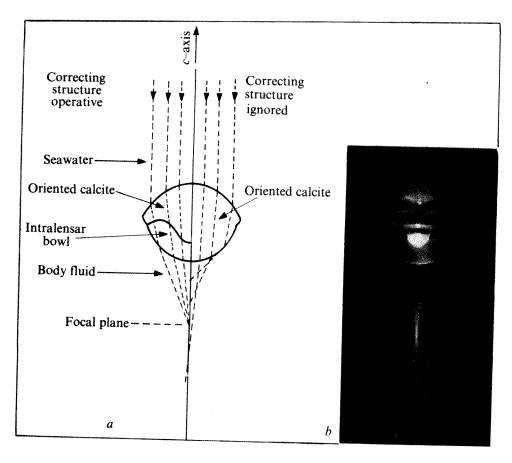
The production of a good quality image, however, may not have been the main advantage to the trilobite of evolving such lenses. Because it is (to a first approximation) free of spherical aberration, the distribution of light intensity along the axis peaks more sharply in the region of the focal plane than it would in


Fig. 5 *a*, Ray tracing through lens of *Crozonaspis struvei*. On left of the axis, the correspond structure is assumed operative indices of refraction: seawater 1. oriented calcite of upper unit 1. intralensar bowl 1.63, body fl 1.34. On the right of the axis, lens is assumed to have no inter structure, and made of orien calcite *n* = 1.66. *b*, Parallel be of white light incident upon a la scale model of a *Crozonaspis* le immersed in water, where the up unit is made of oriented calc (*n* = 1.66), and the intralens bowl is made of polysulpho (*n* = 1.63). The light beam is ma visible by a small amount of mi mixed with the water tank. T combination of refractive indic represent an optimum conditio arrived at after testing with intr lensar bowls made of vario plastics.

an uncorrected lens. A measure of this improvement is the full width at half maximum of such distribution. Scaled down to the actual size of the *Crozonaspis* lens (250 μm), we estimate the above width at about 20 μm, and possibly less. If the lenses were uncorrected, the corresponding width would approximate to about 100 μm. The increased concentration of light in the focal plane could conceivably raise the level of illumination in a dimly lit environment above the neural response threshold at the retina.

The use of a doubly refracting mineral such as calcite to construct a lens may seem disadvantageous. This drawback has been shown to be minimised by the orientation of the *c*-axis to coincide with the optic axis of the lens. Only for an object placed considerably off-axis would a secondary (extraordinary) image be formed, at varying depths, depending on the angle of incidence, but always deeper than the ordinary (o ray) image. As a consequence, the e ray image will not coincide with that formed by the o ray, nor will it focus in the same plane. One could envisage several means by which this ghost image could have been eliminated, although in any case it may have been of little consequence. A retina of limited thickness located in the image plane of the o ray would automatically filter out the e ray image: although accommodation of the eye would require a movable retina, a remarkable depth of field would still be available even with a fixed one. From the optical parameters of phacopid lenses, and requiring a circle of confusion in the retinal plane of diameter as small as 1 μm (the resolution limit due to diffraction), the depth of field would extend from several mm (~1 trilobite length) to infinity. Alternatively, one could invoke the use of photoreceptors sensitive only to the direction of polarisation of the o ray, thus eliminating the effect of the e ray image (the polarisation analysing capability of the rhabdomes is well known).

Finally, one could object that chromatic aberration may have offset the correction of spherical aberration. This is unlikely, however, since the environment under the sea is essentially monochromatic even at moderate depths.

Visual function of schizochroal eye

The function of schizochroal eyes can be better appreciated whei contrasted with that of holochroal eyes. Holochroal eyes ii trilobites normally have pronounced curvature in both the azimuthal and vertical planes (often assuming a toroidal shape and have numerous optical elements which could, as in insec and crustacean eyes, have formed a true visual mosaic. Schizo chroal eyes, however, have too few optical units to form a detailed mosaic image. Furthermore, the arrangement of the lenses in files often widely separated and pointing in diverging directions, leads to a discontinuous coverage of the object space[2] Such eyes as these were formerly thought[2] to be capable only of gross movement perception, though the discovery of corrected lenses now calls this view into question.

What use did phacopid trilobites actually make of their corrected lenses? They may have been used primarily as light concentrators, as has recently been proposed[11] for *Limulus polyphemus*. Alternatively, they may have served a more complex function. If the photoreceptor had the form of a thin retina, as suggested by the aplanatic properties of the lens, and if it was composed of numerous subunits, then the corrected image formed by the lens at the level of the focal plane or immediately beneath it, could be perceived as a micromosaic. The schizochroal eye could then be regarded more as an aggregate of individual eyes, each surveying a different part of the object space, rather than as a true compound eye. Evolution would have in this case proceeded from the external mosaic scheme of the ordinary compound eye towards the utilisation of an internal mosaic, much as in the lens–retina eye system of more advanced life forms. It is unfortunate that the genetic information of such a perfected visual apparatus became lost to further evolution in the animal kingdom, when the phacopid trilobites became extinct.

The presence of crystallised *in vivo* calcite in the lenses of fossilised trilobite specimens may prove valuable in a different context. It is conceivable in fact, that this primary mineral retained its original isotopic composition, in equilibrium with

the depositional environment. If so, trilobite lenses may afford an unprecedented opportunity for determining the temperatures of Palaeozoic seas using the $^{18}O/^{16}O$ relative abundance method[12].

We thank Professor S. Chandrasekhar for pointing out to us the elegant use of bioplar coordinates in dealing with Cartesian Ovals and for stimulating discussions, Professor V. L. Telegdi for criticism and suggestions, and Dr John Miller for his critical reading of the manuscript. Dr J. L. Henry of Rennes kindly donated specimens for this study, others were loaned by Dr E. Richardson (Field Museum of Natural History (FMNH)), Mr. P. Aspen (Grant Institute of Geology (Gr. I)) and Dr C. D. Waterston (Royal Scottish Museum (RSM)). Scanning electron micrographs were obtained in the University of Chicago Microscope Laboratory established with a grant from the Sloan

Evolutionary implications of different types of microbial enzymology for L-tyrosine biosynthesis

Roy A. Jensen & Duane L. Pierson

Department of Biology, University of Texas Systems Cancer Center, Houston, Texas 77025 and Department of Microbiology, Baylor College of Medicine, Houston, Texas 77025

Several patterns of enzymology for L-tyrosine biosynthesis exist in modern microorganisms, each differing in the apparent degree of regulatory efficiency. The extent of pathway evolution in a particular organism may reflect the relative selective pressure for regulation encountered in different ecological niches.

THE biochemical similarities of major metabolic pathways utilised in nature have reinforced a long standing concept of the biochemical unity of all forms of life[1,2]. Against this background, instances of diversity offer intriguing prospects for insight into evolutionary relationships. Biosynthetic pathways for amino acids are undoubtedly ancient and generally exemplify the concept of biochemical unity. The occasional existence of different amino acid-forming pathways seems to reflect significant phylogenetic divergencies, for example, biosynthetic pathways for L-lysine[3], L-methionine[4,5] and L-tyrosine[6,7].

Several enzyme arrangements that serve L-tyrosine biosynthesis in various microorganisms differ in pattern of regulatory control. At one extreme, species of blue-green bacteria (algae) possess a seemingly primitive pathway (pretyrosine) which has a less refined regulation, in contrast with that of the 4-hydroxyphenylpyruvate pathway of *Escherichia coli*. We report here results obtained with several other microorganisms in which features of pathway enzymology and regulation seem intermediate between those of blue-green bacteria and enteric bacteria. These data, considered together with previous published results, suggest an overall picture of pathway evolution in which modern organisms possess pathways representing different stages of an apparent evolutionary sequence. We propose that the selective pressure for regulation of L-tyrosine biosynthesis varies substantially within the ecological niche occupied by a given microbial group, and that the evolutionary stage of pathway development seen in modern organisms reflects the degree of selective pressure for regulation.

Pathways of L-tyrosine biosynthesis

The biosynthetic pathway for aromatic amino acids begins with the condensation of erythrose-4-phosphate and phosphoenolpyruvate, the first of seven enzyme reactions that culminate

with the formation of chorismate[8]. Chorismate is either used for tryptophan synthesis or converted to prephenate. So far as is known, all organisms able to synthesise L-tyrosine and L-phenylalanine utilise prephenate as the last common intermediate of a branching pathway. Although the enzyme sequence of the biosynthetic branchlet leading to L-phenylalanine may be universal, different L-tyrosine pathways exist. The pretyrosine and 4-hydroxyphenylpyruvate pathways, named for the intermediate between prephenate and L-tyrosine, are illustrated in Fig. 1. In each case both transamination and decarboxylation–dehydrogenation reactions occur—but in reverse order. The enzymes of each pathway are quite specific in organisms such as *Bacillus subtilis* and *Agmenellum quadruplicatum*[6,7], the most studied species exemplifying the 4-hydroxyphenylpyruvate and pretyrosine pathways, respectively. Hence, in *B. subtilis* a partially purified dehydrogenase utilises prephenate (prephenate dehydrogenase) but is not reactive with pretyrosine. No other dehydrogenase able to utilise pretyrosine was found in crude extracts or in fractions obtained during purification procedures. An aromatic transaminase of *B. subtilis* that was reactive with phenylpyruvate did not utilise prephenate[7]. Attempts to resolve other transaminases that might be reactive with prephenate were unsuccessful.

In *A. quadruplicatum* a single dehydrogenase is specific for pretyrosine, and no prephenate dehydrogenase activity was detected[6,7]. A single transaminase would seem to catalyse the transamination step within each pathway branchlet (that is, prephenate transaminase and phenylpyruvate transaminase). Transamination occurs far better with prephenate or phenylpyruvate than with 4-hydroxyphenylpyruvate[7]; likewise, in the non-biosynthetic direction L-phenylalanine is a far better amino donor than is L-tyrosine[6]. So far, the exclusive presence of enzymes of the pretyrosine pathway are known only in blue-green bacteria. The 4-hydroxyphenylpyruvate pathway for L-tyrosine synthesis seems to be the most widely distributed (Table 1), based on the comparative survey of dehydrogenase specificities in a limited range of microorganisms[7].

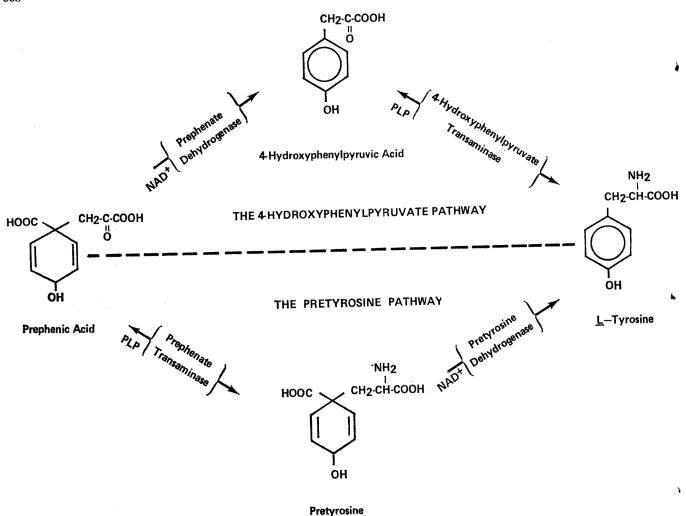
In addition to the pretyrosine and 4-hydroxyphenylpyruvate pathways, a third type of enzymology exists (denoted ambiguous in Table 1). Here transaminase and/or dehydrogenase activities are markedly ambiguous in substrate recognition. For example, *Pseudomonas aeruginosa* has the enzymological potential to synthesise L-tyrosine by either pathway. Table 2 shows the


Fig. 1 Enzyme sequences of L-tyrosine biosynthesis. The upper sequence is the 4-hydroxyphenylpyruvate pathway, and the lower sequence is the pretyrosine pathway. A third ambiguous type refers to the presence of ambiguous transaminase (prephenate/4-hydroxyphenylpyruvate) and dehydrogenase (prephenate/pretyrosine) activities that allow either sequence to operate. NAD^+, nicotinamide adenine dinucleotide; PLP, pyridoxal-5'-phosphate.

substrate ambiguities observed for enzymes of *Neurospora crassa* and *P. aeruginosa*. In *N. crassa* only prephenate-specific dehydrogenase activity was found. A nonspecific transaminase, however, utilises either prephenate or 4-hydroxyphenylpyruvate. We have found (unpublished observations with S. L. Stenmark-Cox) that transaminase reactivity with prephenate in *N. crassa* can be expressed *in vivo*, resulting in dead-end accumulation of pretyrosine. Prephenate dehydratase mutants of *N. crassa* accumulate prephenate which is readily transaminated to pretyrosine, and substantial amounts of pretyrosine are accumulated in the growth medium. In *P. aeruginosa* an apparent single species of dehydrogenase is recovered[9] that reacts with either prephenate or pretyrosine. Although several transaminase activities were resolved from crude extracts of *P. aeruginosa* (I, II and III of Table 2), each transaminase species exhibited similar substrate ambiguity with respect to prephenate and 4-hydroxyphenylpyruvate utilisation.

Regulation of three pathway types

Three general patterns of L-tyrosine biosynthesis are discernable, exemplified by *A. quadruplicatum* (pretyrosine), *P. aeruginosa* (ambiguous) and *B. subtilis* (4-hydroxyphenylpyruvate). Each organism possesses a distinctive pattern of regulation for L-tyrosine synthesis, as compared schematically in Fig. 2. Unlike the L-tyrosine branchlet, the enzyme sequence within the L-phenylalanine branchlet is invarient in all species studied (that is, prephenate dehydratase followed by phenylpyruvate transaminase). Inevitably, prephenate dehydratase has been

found to be feedback inhibited efficiently by L-phenylalanine (Fig. 2, bottom row).

In *B. subtilis* (Fig. 2, right panel), the tyrosine and phenylalanine sequences are symmetrically analogous, each containing an initial irreversible reaction followed by a transamination step

Table 1 Pathways of L-tyrosine biosynthesis

Taxonomic occurrence	Type of enzymology	Apparent efficiency of regulation
Blue-green bacteria	Pretyrosine	+
Pseudomonas	Ambiguous [D], [T]	+ +
Neurospora	Ambiguous [T]	
Aerobacter		
Bacillus		
Brevibacterium		
Clostridium	4-Hydroxyphenylpyruvate	+ + +
Escherichia		
Serratia		
*Phaseolus**		
Saccharomyces		

Data supporting this summary are given or cited in refs 6 and 7. The most detailed published data to document *Pseudomonas* and *Neurospora* enzymology patterns are given in Table 2. Details of pretyrosine enzymology in *A. quadruplicatum* and references documenting the distribution of pretyrosine, 4-hydroxyphenylpyruvate or ambiguous pathways in nature are given in refs 6 and 7. [D], [T] Means that both dehydrogenase and transaminase activities exhibit substrate ambiguities, whereas [T] indicates that only transaminase (prephenate/4-hydroxyphenylpyruvate) is ambiguous in substrate recognition. These pathway types are illustrated in Fig. 4.
* Our recent results with cotyledon tissues from species of *Phaseoli* reveal very substantial pretyrosine pathway enzyme activities.

Table 2 Multi-substrate reactivities of L-tyrosine biosynthetic enzymes

Microorganism	Dehydrogenase substrates				Transaminase substrates	
	Prephenate	Pretyrosine			Prephenate	4-Hydroxyphenylpyruvate
			$(\text{nmol min}^{-1}\text{ mg}^{-1})$			
N crassa	8 2	0			6 4	10 3
P aeruginosa	24 6	32 4		I	32 9	131 8
				II	56 9	89 8
				III	124 8	274 8

Mycelia of a wild-type strain of *N crassa* (74-OR 23-1A) were collected after 72 h growth at 25 °C in Vogel's minimal medium[23] supplemented with 2% (w/v) sucrose Cultures were started from heavy conidial inoculations Mycelial yields from 10 l of medium were lyophilised Extracts were prepared by addition of mycelial powder to 50 mM potassium phosphate buffer, *p*H 7 5, containing 50 mM KCl, 2mM MgCl₂ and 20% (w/v) sucrose The suspension was stirred at 4 °C for 20 min and centrifuged at 25,000*g* for 30 min The clarified supernatant was dialysed at 4 °C against 500 volumes of buffer overnight This cell-free extract was used for dehydrogenase and transaminase assays In *P aeruginosa* partially purified enzyme preparations were used The dehydrogenase and transaminase I were recovered from DEAE cellulose as before[9] Transaminase II and III are the leading and trailing bands of activity eluted from hydroxylapatite[9] Details of the dehydrogenase assays were previously given[9,10] The validity of NADH formation as a measure of pretyrosine dehydrogenase activity was verified by the fluorometric measurement of tyrosine[24] The following reaction mixture was used to measure transaminase activities 50 µl of 40 mM glutamate, 100 µl of 5 mM prephenate or 4-hydroxyphenylpyruvate, and 50 µl of enzyme preparation After 20 min of reaction at 37 °C, the volume of the reaction mixture was brought to 5 ml with 2 5 N NaOH When prephenate was used as substrate, 100 µl of 1 N HCl was added and the incubation was continued for 10 min prior to the addition of NaOH to convert prephenate to phenylpyruvate Phenylpyruvate absorbance was measured at 320 nm and 4-hydroxyphenylpyruvate absorbance was measured at 331 nm, using a Gilford spectrophotometer

Regulation of each pathway is classically straightforward Excess L-tyrosine feedback inhibits prephenate dehydrogenase (Fig 2, top right), while excess L-phenylalanine feedback inhibits prephenate dehydratase (bottom right) In *E coli* the pathway and its regulation is essentially identical to that of *B subtilis* with the exception that prephenate dehydratase and prephenate dehydrogenase are both multifunctional proteins, each also catalysing the chorismate mutase reaction[11]

Unlike *B subtilis*, the pretyrosine pathway of *A quadruplicatum* contains an initial reversible step, activity of which is not affected by L-tyrosine A degree of control is indirectly accomplished through the activating effect of L-tyrosine on prephenate dehydratase[6] Thus, high intracellular levels of L-tyrosine would tend to favour flow of metabolites towards L-phenylalanine and away from L-tyrosine (Fig 2, top left) The apparent K_m for prephenate of the competing prephenate dehydratase (0 23 mM) and prephenate transaminase (1 05 mM) activities suggest that flow towards phenylalanine is intrinsically favoured The transaminations of phenylpyruvate and prephenate are probably catalysed by a single protein[6], this has the same affinity (K_m, 1 05 mM) for prephenate or phenylpyruvate but has a five-times greater V_{max} with phenylpyruvate The conditions assumed at the top left of Fig 2 (excess tyrosine, limiting phenylalanine) would promote a relative increase in the intracellular supply of phenylpyruvate together with a decreased supply of prephenate (owing to enhanced prephenate dehydratase activity) This would favour transaminase function as phenylpyruvate transaminase (rather than prephenate transaminase) On the other hand, high intracellular levels of L-phenylalanine would tend to shift prephenate flow towards L-tyrosine formation (Fig 2, bottom left) Inhibition of prephenate dehydratase would increase levels of prephenate substrate for transamination while decreasing levels of phenylpyruvate substrate for transamination

The regulatory pattern for L-tyrosine biosynthesis in *P aeruginosa* can be viewed as intermediate between those of *A quadruplicatum* and *B subtilis* To whatever extent the pretyrosine reaction sequence may be realised *in vivo* owing to substrate ambiguity in *P aeruginosa*, the overall picture of regulation (or lack of it) would resemble that of *A quadruplicatum* The middle panel of Fig 2, however, depicts the probable domination *in vivo* of the 4-hydroxyphenylpyruvate sequence in *P aeruginosa*[7] Prephenate is preferentially channelled towards L-phenylalanine by virtue of a single, multi-functional protein[12] which catalyses both the chorismate mutase and prephenate dehydratase reactions Prephenate dehydrogenase, which is subject to relatively weak competitive inhibition by L-tyrosine, has been characterised recently[9] When L-phenylalanine is present in excess (Fig 2, bottom middle) inhibition of the second half-reaction of the enzyme complex leaves the prephenate formed in the first reaction free for utilisation by

prephenate dehydrogenase[12] The pseudomonad pattern of regulation resembles *B subtilis* in its feedback regulation of the initial reaction of the tyrosine branchlet On the other hand, the pseudomonad enzymological pattern resembles that of blue-green bacteria in the preferential flow of chorismate toward L-phenylalanine and in the dominating regulatory role of L-phenylalanine, directly in the phenylalanine branchlet and indirectly in the tyrosine branchlet[12] Preferential entry of prephenate into the L-phenylalanine branchlet has been observed in several other microorganisms[13,14]

Possible ancestral pathway

It is reasonable to assume that the most ancient biochemical pathways were unregulated, for regulatory properties seem to be secondary refinements that must have followed the primary acquisition of catalytic capabilities Branching amino acid pathways such as those forming aromatic amino acids and branched-chain amino acids probably originated as simple, uncomplicated pathways forming a single amino acid Subsequent additions of pathway branchlets resulted in families of related amino acids Certain abiotically-formed amino acids in the primitive *milieu* inevitably became growth-limiting before others Biosynthesis of a limiting aromatic amino acid would have conferred a selective advantage on organisms with this capability If one assumes that the tryptophan sequence (or any other chorismate-containing pathway, for example, to folate or ubiquinone) originated before the phenylalanine and tyrosine pathways, tyrosine and phenylalanine-forming enzymes may have evolved as shown in Fig 3, a sequence which is based on non-enzymatic chemical reactivities of chorismate and prephenate Tiny amounts of L-phenylalanine and pretyrosine could have been synthesised from chorismate in ancient cells without the benefit of new enzymes Chorismate is readily rearranged thermally to form prephenate[15], and this conversion can be substantial at physiological temperatures Prephenate, in turn, is quite labile at acid *p*H, and even mildly acidic conditions consistent with cell growth can promote acid-catalysed conversion to phenylpyruvate[16] Assuming that some ancient transaminase possessed the broad specificity that commonly characterises modern transaminase enzymes, the dual possibility existed for transamination of phenylpyruvate to L-phenylalanine and/or of prephenate to pretyrosine Like prephenate, pretyrosine is acid-labile[6] and would readily be converted to L-phenylalanine

Subsequent selective advantages arising from the biosynthesis of L-phenylalanine would favour the evolutionary development of enzymes to catalyse the previously non-enzymatic steps more efficiently Pretyrosine may also have been a component of ancient proteins, and indeed the possibility that it may be an amino acid residue in modern proteins of blue-green bacteria has not yet been explored In any event, the availability of the

pretyrosine molecule would permit the development of L-tyrosine-synthesising capability following acquisition of a single new enzyme Presumably, this occurred by duplication of a gene encoding an ancient dehydrogenase, followed by mutational modification of that duplicated gene[17,18] to produce a pretyrosine-reactive dehydrogenase The hypothesis that L-phenylalanine biosynthesis preceded L-tyrosine biosynthesis is consistent with the uniformity of L-phenylalanine enzymology and regulation in nature (Fig 2)

Evolutionary alteration of specificities

The ultimate ancestral pathway for L-tyrosine biosynthesis that is hypothesised in Fig 3 is identical to that of modern blue-green bacteria In Fig 4, blue-green bacteria are depicted as having the most primitive pathway while *E coli* possesses one of the most evolved pathways of L-tyrosine biosynthesis Assuming that the 4-hydroxyphenylpyruvate pathway of modern *E coli* originated as a pretyrosine sequence, one can view the L-tyrosine pathways of other modern organisms as reflecting stages of pathway evolution that may once have been intermediate evolutionary stages in *E coli*

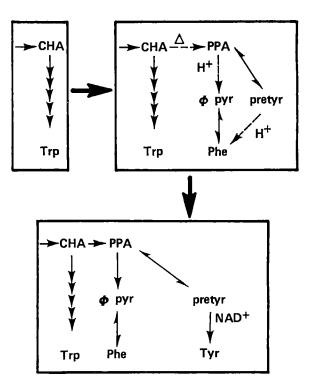
Beginning with the transaminase and dehydrogenase specificities found in modern blue-green bacteria, transaminase and dehydrogenase enzymes may have evolved through stages similar to those still retained in modern pseudomonads and *Neurospora*, finally developing the reversed specificity of enzymes found in the 4-hydroxyphenylpyruvate pathway of *E coli* Thus, in the stage exemplified by *Pseudomonas*, a single NAD-dependent dehydrogenase has evolved reactivity with prephenate and diminished reactivity with pretyrosine Likewise, a single transaminase possesses an increased reactivity with 4-hydroxyphenylpyruvate but less reactivity with prephenate Continued selection for this flip-flop change of specificity, resulting in loss of pretyrosine pathway capability and increased 4-hydroxyphenylpyruvate pathway capability, is shown in Fig 4 (lower right) The pathway of *N crassa* is shown as intermediate between pseudomonads and *E coli*, owing to the lack of ambiguity of dehydrogenase (as in *E coli*) but the


Fig 3   Hypothetical evolution of capability for L-tyrosine and L-phenylalanine biosynthesis in ancestral cells Enzymatic capability for synthesis of the aromatic amino acid family is postulated to have evolved in the order L-tryptophan, L-phenylalanine and L-tyrosine CHA, chorismate, PPA, prephenate, φ pyr, phenylpyruvate, pretyr, pretyrosine, Trp, L-tryptophan, Phe, L-phenylalanine, Tyr, L-tyrosine Solid arrows and dotted arrows represent enzymatic and non-enzymatic reactions, respectively Prephenate and pretyrosine are acid-labile, undergoing quantitative conversion to phenylpyruvate and L-phenylalanine respectively Chorismate is converted to prephenate at elevated temperature (͵)
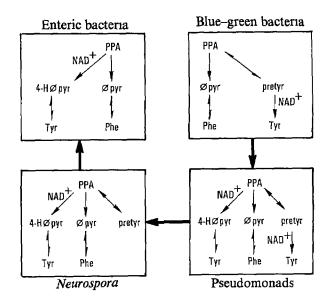

presence of prephenate/4-hydroxyphenylpyruvate transaminase (as in pseudomonads) Finally, *E coli* exhibits dehydrogenase and transaminase specificities that are distinct from those seen in blue-green bacteria

Pathway regulation and ecological niche

The 4-hydroxyphenylpyruvate pathway of *B subtilis* and many other eubacteria such as *E coli* seems to be more sophisticated (in terms of regulatory versatility) than the other L-tyrosine-forming pathways of various microorganisms This is not to suggest that *E coli*, for example, is biologically superior to other microorganisms in any general sense The presence of a more highly evolved pathway implies an evolutionary response to strong selective pressures It is clear that biological success in one ecological niche involves different selective pressures than in another We suggest that the regulatory efficiency of each microbial type of enzyme sequence for L-tyrosine synthesis is generally appropriate to the ecological niche in which a given microbe is successful At one extreme, *E coli* resides in the gut of man where the nutritional regimen is one of periodic feast and famine A selective advantage results from a simple, direct and efficient regulation of both enzyme activity and synthesis *E coli* is geared for substantial amino acid biosynthesis during famine as well as for efficient utilisation of exogenous amino acids during feast

The ecological relationships of blue-green bacteria are quite different The competitive advantage of blue-green bacteria in nature is their photoautotrophic mode of metabolism They utilise small organic molecules poorly, and heterotrophic capabilities are generally undeveloped In fact, amino acid molecules and other organic compounds are often inhibitory to the growth of autotrophic bacteria[19-21] In the ecological niche of blue-green bacteria, characterised by the constantly diluting effect of the fresh or marine water *milieu*, most L-tyrosine molecules probably originate from endogenous metabolism When exogenous tyrosine is present under laboratory conditions, the regulation seems poor since no direct mechanism exists to decrease L-tyrosine biosynthesis The regulatory scheme shown in Fig 2 may, however, satisfactorily partition the flow of endogenous prephenate into the tyrosine and phenylalanine branchlets If so, one must assume that the kinetic properties of the competing enzymes at the branchpoint are appropriate for some endogenous and relatively constant level of prephenate Thus, the primitive stage of development of the L-tyrosine pathway may be adequate for the ecological niche of blue-green bacteria The persistence of the pretyrosine pathway in modern blue-green organisms may reflect the lack of selective pressure for more elaborate regulation

Enteric and pseudomonad microorganisms provide an especially apt comparison of the relationship of metabolic specialisation and regulation The most striking metabolic capability of pseudomonad organisms is their versatile utilisation of organic compounds as sole sources of carbon, nitrogen and energy Enteric bacteria provide the most dramatic examples of repression control of biosynthetic enzyme levels, although scarcely any repression control of biosynthetic enzymes is known in pseudomonads On the other hand, pseudomonads provide the most impressive examples of induction control for numerous degradative enzymes Thus, metabolism seems to be geared to biosynthesis in enteric bacteria and to catabolism in pseudomonads Since survival value is undoubtedly equated with these metabolic capabilities, selection for the most finely tuned regulatory mechanisms may be maximised within the pathways providing metabolic specialisation The presence of enteric-like repression control mechanisms for biosynthetic enzymes in pseudomonads would not necessarily be an advantage, since that might impose restrictions on overall capability for regulatory variation of degradative enzymes In natural soil and water environments, substantial accumulation of free amino acids does not occur[22] Pseudomonads in nature do not experience the regular exposure to high levels of amino acids and so on which place a premium on responsiveness to end-product

Fig 4 The evolutionary development of the 4-hydroxyphenylpyruvate (4-H⌀pyr) pathway viewing the existing pathway in *E coli* as the most highly evolved and that in blue-green bacteria (algae) as the least evolved Abbreviations are as given in Fig 3

levels in enteric bacteria Even plant or animal pathogens (such as *P aeruginosa*) do not encounter the regularity of concentration flux, as is the case with enteric organisms It seems reasonable that selection for efficiency of regulation would be maximised for biosynthetic pathways in enteric microorganisms Presumably other organisms have different metabolic priorities that are dictated by differing selective pressures For example, rigorous selection for regulatory efficiency would be expected for catabolic enzymes of pseudomonads and for enzymes of autotrophic metabolism in blue-green bacteria

It is interesting that the apparent differences in regulatory refinement for enzymes of L-tyrosine synthesis are paralleled by the same qualitative differences in apparent regulatory efficiency for 3-deoxy-D-arabino-heptulosonate 7-phosphate synthetase in *A quadruplicatum*[21], *P aeruginosa*[25] and *B subtilis* (or *E coli*)[26]

Vertical crustal movements of the Andes in Peru

John S. Myers

Geological Survey of Greenland, Østervoldgade 10, DK 1350 Copenhagen, Denmark

Although the Peruvian Andes provide no evidence of the widespread, strong deformation which might be expected in a tectonic belt widely held to overlie a zone of oceanic subduction, consideration of the tectonic and magmatic history shows that the occurrence of large scale, vertical block faulting in that region is not incompatible with a plate tectonic model

THE important association between vertical crustal movements and magmatism during the evolution of the Andean mountain range was recognised[1,2] in the nineteenth century Most mountain belts later became interpreted in the light of alpine tectonics[3] and comparisons with the Alps continued throughout the period during which mountain belts were viewed as expressions of the final phase of geosynclinal cycles The concept of plate tectonics eventually emphasised the fundamental differences between many mountain belts[4], but the Andes was equated[4] with the cordilleras of western North America where it was postulated that major doming of the continental margin above underthrust oceanic lithosphere has caused overthrusts on the continent and the spread of sediments over the adjacent oceanic crust There is little supporting evidence for this hypothesis in the Peruvian Andes[5,6], where consideration of the past 100 Myr of tectonic and magmatic history suggests a tectonic model which is different from that postulated[4] for western North America The description is based on detailed mapping of the western Andes between latitudes 10° and 10° 30' S (ref 7) and published descriptions of adjacent regions[8-10], supplemented by radiometric age determinations (P A Wilson, unpublished)

Regional tectonics

During Cretaceous time, northern Peru consisted of two ribbon-like belts of subsidence known as the West and East Peruvian troughs[8,11] (Fig 1) They were separated by a belt of relative uplift, the Marañon Geanticline[8], and a second belt of relative uplift, the Paracas Geanticline[12], formed the western edge of the continent Each belt was founded on a block of Precambrian basement with thin Phanerozoic cover[13], and was bounded by

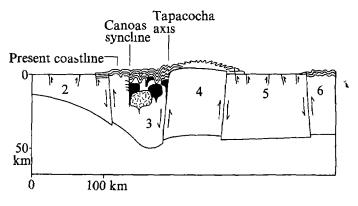

Fig. 3 Schematic section (part of *A–B,* Fig 1) showing the different kinds of deformation of Mesozoic sedimentary and volcanic rocks which resulted from uplift of different crustal blocks (numbered as on Fig 2) about 95 Myr ago Ornamentation as on Fig 2

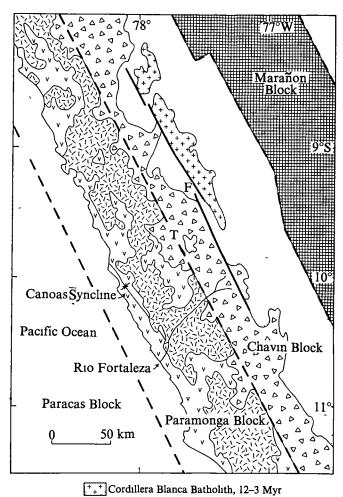
steep fractures and shear zones Oscillatory vertical movements of these ribbon-like blocks controlled both the deposition of sediments and their near-surface deformation from at least Cretaceous to early Tertiary time

The West Peruvian Trough was itself divided into western and eastern belts by another steep shear zone, the Tapacocha Axis[14], which between 115 and 95 Myr ago allowed the western belt to subside about 4,000 m more than the eastern belt (Figs 1 and 2) The crustal blocks which underlie the western and

eastern belts of the West Peruvian Trough are here called the Paramonga and Chavin blocks, respectively, and those which underlie the Paracas and Marañón Geanticlines are called the Paracas and Marañón blocks, respectively (Fig 2)

Casma Volcanics and the Coastal Batholith

The Casma Group of volcanic rocks was erupted through the descending Paramonga Block from the rising Coastal Batholith below, forming a pile of andesite lavas, sills and pyroclastic rocks 3,000–6,000 m thick (Fig 2) Meanwhile, about 3,000 m of sandstone and limestone[10] accumulated on the more slowly subsiding Chavin Block Relative variations between the amount of volcanic material erupted and the rate of subsidence of the Paramonga Block resulted in oscillatory cycles of deeper and shallower marine and terrestrial volcanism within the Casma Group The age ranges of ammonites interbedded with the volcanic sequence indicate that most eruptions occurred in the late Middle Albian and early Upper Albian (about 100 Myr ago)[7,14] The occurrence of granodiorite, diorite and gabbro fragments in some pyroclastic flows suggests that the Casma Group of volcanic rocks was erupted through, and was probably associated with, plutonic rocks similar to the Coastal Batholith which was later emplaced into the Casma Group

The oldest intrusions of the Coastal Batholith are numerous bodies of hornblende gabbro and diorite, collectively called the Patap Complex[7], which were emplaced into the eastern side of the Paramonga Block (Fig 2) They contain more hornblende than pyroxene and seem to have crystallised from hydrous magmas Many bodies of hornblende gabbro show rhythmic layering which may have formed in association with volcanoes within the upper part of the Casma Group


Regional deformation

Intermittent pulses of deformation during intrusion of the Patap Complex folded the Casma Group into folds with vertical axial surfaces and sub-horizontal fold axes parallel with the Andes The anticlines are mostly broad and open whereas the synclines are narrow and tight (Fig 3) The gentle northwesterly plunge of the Canoas Syncline reveals that at structurally deeper levels to the south-east, the fold becomes even tighter and passes into a 2–4 km wide belt of isoclinal folds The grade of metamorphism also increases progressively towards structurally deeper levels, from being hardly noticeable in the north-west where the structure is an open fold, to greenschist and amphibolite facies where the folds are isoclinal The Canoas Syncline lies near, but is slightly oblique to, the western edge of the Coastal Batholith (Fig 4), and a similar belt of strong deformation and syntectonic metamorphism occurs at the eastern edge of the batholith along the Tapacocha Axis (Fig 3) These belts of deformation may be the upward expression of major shear zones in the crust below, which partly controlled the edges of the rising batholith, and were channels of high heat flow from the rising plutons

The style of deformation of the contemporary rocks on the Chavin Block was completely different (Fig 3) There, the sequence of limestone and sandstone was folded as a single unit by décollement on the underlying Lower Cretaceous Oyon Shale in the south, and the Jurassic Chicama Shale in the north[9,10] Upright ribbon-like folds with axes traceable for 100 km or more occur on the centre of the Chavin Block, whereas towards the margins of the block, the folds are overturned outwards, and lower fold limbs are increasingly attenuated and pass into outwardly directed thrusts

To the east, the thin, Cretaceous sedimentary rocks and pre-Mesozoic basement of the Marañón Block were broken up by normal and reverse faults[9,10] (Fig 3)

The distinctions between the Paramonga, Chavin and Marañón blocks which had previously been marked by different kinds and thicknesses of sediments during differential rates of block subsidence, were thus emphasised by three distinct deformation styles during uplift of the blocks The Paramonga Block was underlain by rising magmas of the Coastal Batholith

Fig 4 Map of northern Peru showing the spatial association of the Coastal Batholith and Casma Volcanics, both restricted to the Paramonga Block, and the Calipuy Volcanics which spread on to the edge of the Chavin Block Map simplified after ref 15 T, Tapacocha Axis, F, fault

and the folds represent the high penetration of ductile deformation above steep, basement shear zones associated with the rise of the batholith through the block The Chavin Block to the east was not infiltrated by rising magma, and it rose intact and was tilted or arched, causing folding of the Cretaceous sediments which lay on it by gravity sliding on a lubricant of shale Further to the east on the Marañón Block, the shale lubricant

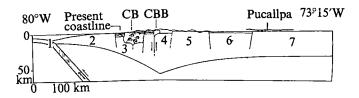


Fig 5 Schematic section (A–B, Fig 1) across Peru, showing the sum of Tertiary and Quaternary block movements, the location of the whole Coastal Batholith (CB) and Cordillera Blanca Batholith (CBB), and the present topography Continental crust—white, mantle—stippled Crustal blocks numbered as on Fig 2, thickness of continental crust after ref 16

was absent and faults of the rigid basement penetrated the thin cover of sedimentary rocks The overturned folds and out-wardly directed thrusts at the eastern edge of the Chavin Block locally transgressed onto the Marañón Block and were dissected by the block faulting (Fig 3) This suggests that the centre of the Chavin Block was raised higher than the Marañon Block, and that the folds flowed eastwards under the influence of gravity

Calipuy Volcanics and the main intrusions of the Coastal Batholith

A 2,000–4,000 m thick terrestrial sequence of andesite, dacite and rhyolite, lava and pyroclastic flows, called the Calipuy Volcanics, lies unconformably on folded Casma Volcanics on the Para-monga Block, and spreads eastwards over the non-volcanic Cretaceous sediments on the western part of the Chavin Block (Fig 4) It is intruded by many plutons of the Coastal Batholith and is probably the product of fissure and caldera eruptions from tonalite, granodiorite and granite magmas which formed much of the batholith

The batholith is a tabular complex of plutonic rocks, 50 km wide and about 15 km thick which extends for over 1,100 km along the eastern part of the Paramonga Block (Fig 4) It is made up of a large number of plutons of mainly tonalite, granodiorite and granite which were emplaced by repeated cauldron subsidence into the centre of the pile of Casma and Calipuy volcanic rocks to within 3 km or less of the surface[12] Individual plutons form ring dykes and rectangular bodies parallel with the continental margin, with steep walls and flat roofs and floors

Chronology of volcanic and plutonic history

The Casma Volcanics were erupted 100–95 Myr ago They immediately preceded, and locally overlapped in time with, the intrusion of the earliest, Patap Complex of the Coastal Batho-lith, and were probably derived entirely from magmas of the rising batholith[12] The Calipuy Volcanics which postdate uplift and erosion of the deformed Casma Volcanics and Patap Complex, were probably erupted from magmas which formed the younger complexes of the batholith 95–30 Myr ago (P A Wilson, unpublished) There was thus a close association between volcanic eruptions and plutonic intrusions in the eastern part of the Paramonga Block for at least 70 Myr during oscillatory vertical movements of the block

Uplift and erosion of the modern Andes

The succession of erosion surfaces which are preserved on the western flank of the Andes indicate sporadic uplift of a gently undulating landscape formed by erosion of the Coastal Batholith and its volcanic envelope[7] The erosion surfaces increase in altitude with increasing antiquity and distance from the western edge of the Paramonga Block The steady increase in the slope of the erosion surfaces with age indicates that uplift occurred mainly by arching of the Chavin Block and westward

tilting of the Paramonga Block Major uplift and erosion of the modern Andes occurred between the time of emplacement of the last major plutons of the Coastal Batholith 30 Myr ago (P A Wilson, unpublished) and the eruption of an ignimbrite down the aggraded ancestoral Rio Fortaleza Valley 6 Myr ago (P A Wilson, unpublished) Later incision of the valley through this ignimbrite indicates further uplift of at least 500 m within the past 6 Myr

In addition, the Chavin Block was split by a complex of steep major faults along the western foot of the Cordillera Blanca (Figs 4 and 5) The faults have been intermittently active from at least 6 Myr ago to the present time, and have raised the eastern part of the Chavin Block, which forms the crest of the Andes, a further 500–1,000 m The fault complex may be the upward expression of a deep fracture–shear zone system which was active during late Tertiary time and which localised the ascending magmas that formed the Cordillera Blanca Batholith 12–3 Myr ago[17]

Andean structure and plate tectonics

The Peruvian Andes do not show any evidence of the strong deformation of the continental margin which occurred[4] in western North America during eastward movement of oceanic crust beneath the continent In Peru the relative rigidity of the continent enabled it to float intact on the weaker oceanic crust which was deflected beneath it, and only weak tensile and compressive stresses were intermittently transmitted through the continental margin, causing oscillations of the crustal blocks The steep fault and shear zones which bound the main crustal blocks are parallel with similar structures which were active during late Palaeozoic and early Mesozoic time, and they may all have been initiated in the same major tensile stress regime which during Precambrian time split the South American con-tinent from continental crust to the west

Fieldwork was done during tenure of a National Environment Research Council postdoctoral research fellowship held at the University of Liverpool I thank P A Wilson for permission to quote unpublished K–Ar radiometric age determinations, and E J Cobbing, A E Escher, and A K Higgins for criticism of the manuscript

Is Cir X-1 a runaway binary?

RUNAWAY stars are produced when there is a supernova explosion in a close binary system Usually such an explosion disrupts the binary system, but Gott[1] has suggested that in a significant fraction of such supernovae the collapsed residue of the explosion may be retained in orbit around the runaway

second star, the resultant system being a binary with high eccentricity and large space velocity We suggest here that Cir X-1 is such a system

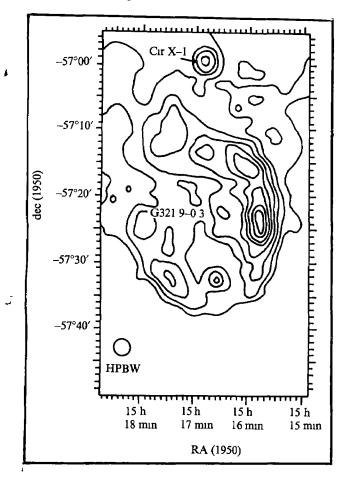
Figure 1 shows a 408-MHz radio map of the Cir X-1 region The map was produced from observations made with the Molonglo Cross radio telescope, and is centred on the recently


Fig. 1 Map of the supernova remnant G321 9—0 3 made at 408 MHz with the Molonglo radio telescope (half power beam-width, HPBW, as shown) The contour unit of brightness temperature averaged over the beam solid angle is 23 8 K (corresponding to 0 1 Jy for a point source)

discovered supernova remnant (SNR) G321 9—0 3 (refs 2, 3) Figure 1 also shows a point radio source approximately 7' north of the SNR boundary The position and flux density estimates for the point radio source are given in Table 1

The position of Cir X-1 has recently been revised by Jones *et al*[4] and the point radio source lies well within their 2' × 1' error box, approximately 16" from their best position We therefore suggest an association of the X-ray source Cir X-1 and the point radio source Location of the radio source within the error box is not sufficient grounds for a definite association The probability of finding a radio source of 0 5 Jy inside the X-ray error box is, however, approximately 1 in 3,000 (see ref 5) The detection of correlated short term variability in the X-ray and radio sources, as found in several other similar systems, would secure the identification, and we plan to make such observations in the near future

The radio flux density estimates give a spectral index (flux proportional to v^α) $\alpha^{5,000}_{480} = -0\ 25$ This is an unusual spectrum for a point radio source (singling out the source from most extragalactic sources or galactic H II regions[6]) The radio source associated with Cyg X-1 also has an unusual spectral index, with a non-thermal spectrum below about 2,700 MHz and a spectral upturn at higher frequencies[7] Between our measuring frequencies of 408 MHz and 5,000 MHz, a similar change of spectral index for the Cir X-1 radio source could explain the apparently shallow spectrum obtained Cir X-1 and Cyg X-1 do differ, however, in one important respect the ratio of radio to X-ray emission for Cir X-1 is at least an order of magnitude greater than that for Cyg X-1 An alternative explanation for the unusual radio spectral index obtained for Cir X-1 could be long

term variability of the radio source, since the 5,000 MHz observations were made 18 months later than those at 408 MHz, but such variability would in itself make the source of considerable interest A possible pulsar-like behaviour of the radio source has been investigated at Molonglo, without success (J Sutton, personal communication) A pulsar with period less than 160 ms, or a dispersion measure greater than 500, would not have been detected in this search

Are Cir X-1 and the SNR G321 9—0 3 related and, in particular, is Cir X-1 a runaway system ejected from the supernova? A distance estimate for the SNR may be inferred from comparison of its surface brightness and angular diameter with those SNRs with well determined distances Using such a technique, Clark and Caswell[8] derive the following parameters for G321 9—0 3 linear diameter 39 pc, distance from Sun 5 5 kpc, distance from galactic plane — 29 pc In spite of limitations in the technique, the uncertainty in these parameter estimates is believed to be less than ±30% The estimate of age for SNRs, however, remains particularly uncertain, a comparison of the surface brightness of G321 9—0 3 with the values for those few remnants of known age suggests a possible age range of 2 × 10⁴ to 10⁵ yr These parameters then give a required average transverse velocity for Cir X-1, if it were indeed created in the supernova, of 10²–10³ km s⁻¹, assuming the centroid of the radio remnant gives the position of the initial supernova explosion

The properties of Cir X-1 are in fact compatible with it being a runaway binary at a distance of ~5 kpc and with an age of ~ 10⁴–10⁵ yr, as shown below

Until an optical counterpart is discovered, the distance to Cir X-1 must remain uncertain, and difficult to estimate X-ray spectra of Cir X-1 are strongly attenuated[9,10] at energies ≤2 keV Below approximately 6 keV the spectra can be fitted with an exponential (thermal Bremsstrahlung) spectrum with a temperature in the range 3 5 × 10⁷–4 3 × 10⁷ K and a hydrogen column density 2 5 × 10²²–2 9 × 10²² cm⁻² It is likely that a considerable fraction of the attenuation is circumstellar, however, if we assume it is all interstellar we obtain an upper limit to the distance of 9 kpc taking an average interstellar density of 1 H atom cm⁻³

Jones *et al*[4] have reported that there is no star brighter than 15 mag in their error box By considering stars of various spectral types we can set a lower limit on the distance to the source by taking the average visual absorption to be 1 5 mag kpc⁻¹ for this direction in the galactic plane Five of the eight variable X-ray sources with known optical counterparts have been identified with binary systems having early type stars as primaries For a B0 supergiant, consistent with its not being brighter than 15 mag, a lower limit to the distance is 5 0 kpc, for an A0 supergiant the distance drops to 4 5 kpc and for a B0 main sequence to 4 0 kpc For later stars the minimum distance decreases accordingly

The distribution of 2–10 keV luminosities for galactic X-ray sources has been investigated by Margon and Ostriker[11] who found a range of values between 10³⁶ and 10³⁸ ergs⁻¹ with a peak near 5 × 10³⁷ ergs⁻¹ Taking the 2–10 keV Uhuru maximum count rate of 720 s⁻¹ (1 count s⁻¹ = 1 7 × 10¹¹ erg cm⁻² s⁻¹) gives a distance range of 1 to 9 kpc with the most likely distance, corresponding to the peak of the distribution, at 6 kpc We conclude that the data now available for Cir X-1 are not inconsistent with it being at the distance of the SNR (5 5 kpc) Further improvements in defining this distance are clearly needed, but must await an optical identification

By analogy with all of the other galactic variable X-ray sources Cir X-1 is likely to be a binary system, the X-ray production being due to accretion onto a collapsed object Although observations of X-ray 'eclipses' have been reported[4,12], no unique binary period has yet been found, Jones *et al*[4] claiming that if a binary period exists it must be greater than 12 d

If Cir X-1 originated in the supernova with remnant G321 9—0 3, it is likely that the explosion increased the eccentricity and the period of the binary system For a system with a large eccentricity and long period, the accretion process may break

	RA (1950)	dec (1950)	Flux density (Jy)
408 MHz (Molonglo)	15 h 16 min 47 3s	− 56° 59′44″	0 46
5,000 MHz (Parkes)	15 h 16 min 46 4s	− 56° 59′54″	0 25

The 408 MHz and 5,000 MHz positional estimates have 12″ and 20″ standard errors respectively

down for a time around apastron giving what seems to be an eclipse in the light curve and so hampering the determination of a binary period Such a determination would also be hampered if the system is precessing so that it does not seem to eclipse on each orbit It is likely that after some considerable time tidal forces will tend to circularise the orbit[13], as observed in such a system as Cen X-3 which is believed to be 10^5–10^6 yr old Without an identified period, it seems possible that Cir X-1 is a relatively young system, 10^4–10^5 yr old (the estimated age of the SNR), whose orbit has not been circularised as in the older, better understood binary systems This is the first possible SNR–binary system association to be discovered and gives credibility to theories suggesting that supernovae have given rise to all the close binary systems, if not all the galactic X-ray sources

We thank Professor R L F Boyd for encouragement, Dr J Sutton for providing unpublished data and Dr A Fabian for comments

Note added in proof An optical plate taken by A J Longmore and R D Cannon with the UK 48-inch Schmidt telescope at Siding Spring, Australia, shows that there are two stars brighter than 20 mag within 20″ and five stars within 30″ of the best 408-MHz position

Acceleration of pulsars to high velocities by asymmetric radiation

Here we propose that pulsars are accelerated by the emission of asymmetric low frequency electromagnetic radiation and rapidly attain characteristic velocities exceeding 100 km s^{-1}

Pulsars are believed to be rotating neutron stars that have intense surface magnetic fields The structure of the field is often assumed to be dipolar, with the magnetic axis of symmetry

passing through the centre of the neutron star at an angle to the rotation axis Such a field is modelled nicely by a magnetic dipole of moment μ located at the centre and oblique to the axis of rotation An oblique dipole rotator generates electromagnetic radiation at the rotation frequency and the energy radiated is at the expense of the rotational kinetic energy[1] The rotation period consequently increases, in rough agreement with observation

Various sources of evidence suggest that the oblique dipole rotator is an oversimplified model Recent studies of magnetic variable stars[2,3] have shown that an inclined magnetic dipole moment, displaced from the rotation axis, provides an improved model for reproducing the surface field Displacements of 0 1 or more of a stellar radius are not unusual Of the six pulsars[4,5] known to have interpulses well separated from their main pulses, three (PSR0823+26, PSR0904+77, PSR1929+10) have weak interpulses located midway between their main pulses The magnetic dipole moment for these pulsars is perpendicular to the spin axis, and is possibly displaced from the centre in directions parallel and perpendicular to the spin axis If the pulsed luminosities are proportional to the square of the field intensity, then the displacements from the spin axis are approximately one-third of the radius of the neutron star The other three (PSR0531+21, PSR0950+08, PSR1055–51) have strong interpulses located asymmetrically at 140°–150° from their main pulses The field configurations of these pulsars are also easily reproduced by a dipole moment, in a plane perpendicular to the spin axis, and offset from the spin axis a distance that is again about one-third the radius of the neutron star It is of interest to note that Earth and Jupiter also have oblique off-centred dipole fields All known observations suggest that planetary and stellar objects are generally oblique off-centred dipole rotators

We consider, then, a pulsar with a magnetic dipole moment that is arbitrarily oriented and also displaced from the rotation axis In cylindrical coordinates the components of the dipole moment are μ_z, μ_ρ, μ_φ, where the z coordinate is along the rotation axis Unlike an oblique centred dipole rotator that radiates only at the rotation frequency Ω, the oblique off-centred dipole rotator radiates at all harmonics of Ω Moreover, the radiation field is not that of a pure dipole, but consists of a superposition of both magnetic and electric multipoles of all orders If s is the distance of the dipole from the rotation axis, then when $s\Omega/c \ll 1$, most of the energy is emitted at the fundamental frequency and the total low frequency luminosity is approximately

$$L = \frac{2\Omega^4}{3c^3}\left[\left(\mu_\rho{}^2+\mu_\varphi{}^2\right) + \frac{2}{5}\left(\frac{s\Omega}{c}\mu_z\right)^2\right] \qquad (1)$$

The first term on the right, enclosed in the parentheses is the power radiated by a simple dipole rotator, whereas the second term in parentheses represents the power radiated by the sum of the electric-dipole and magnetic-quadrupole fields

In addition to an increase in luminosity, we find that the luminosity averaged over a rotation period is asymmetric about the rotational equatorial plane This asymmetric emission is the result of interference of magnetic-dipole radiation fields with electric-dipole and magnetic-quadrupole radiation fields The asymmetric emission of low frequency electromagnetic radiation results in a net reaction force on the neutron star that is approximately

$$F = -2s\Omega^5\mu_z\mu_\varphi/15c^5 \qquad (2)$$

in the direction of Ω On writing $F = \varepsilon L/c$, we have

$$\varepsilon = -\frac{s\Omega\mu_z\mu_\varphi/c}{5(\mu_\rho{}^2 + \mu_\varphi{}^2) + 2(s\Omega\mu_z/c)^2} \qquad (3)$$

for the 'radiation asymmetry coefficient' We note that ε has a maximum value of 0 16 when $\mu_\rho = 0$, $\mu_\varphi = 0 63s\Omega\mu_z/c$ Also,

when a pulsar is young, $s\Omega/c$ may be a significant fraction of unity and therefore values of $\varepsilon\sim0\,1$ are quite possible

For a young and rapidly spinning pulsar the luminosity and radiation force are both large, and it is possible that the radiation force rapidly accelerates the whole pulsar to a high velocity The acceleration of the pulsar is

$$dV/dt = \varepsilon L/Mc \qquad (4)$$

and since εL is proportional to Ω^5, maximum acceleration occurs on the time scale $I\Omega_0^2/2L_0$, where I is the angular moment of inertia and the zero subscript denotes initial values Thus, the velocity of the pulsar, as a result of asymmetric emission of radiation, is

$$\Delta V \sim \varepsilon_0 I\Omega_0^2/2Mc \qquad (5)$$

For a neutron star of radius 10 km this gives $\Delta V\sim10^{-4}$ $\varepsilon_0\Omega_0^2$ km s^{-1}, and for initial values $\varepsilon_0\sim0\,1$, $\Omega_0\sim10^4$, the final velocity is $\sim10^3$ km s^{-1} It is evident that with reasonable values of ε_0 and Ω_0 this radiation acceleration mechanism is efficient and capable of explaining the remarkably high velocities of many pulsars For example[6], PSR113+16 has large proper motion that is equivalent to a velocity in excess of 380 km s^{-1}, if the pulsar is at a distance of 120 pc (In our analyses (to be published) we find evidence for pulsar velocities exceeding 700 km s^{-1})

Most pulsars are probably born in binary systems, and it can be shown that the mass ejected from close binary systems in a supernova event is generally inadequate to unbind the binary members[7] It can be shown, however, that the radiation reaction force is initially sufficiently strong to wrench apart all but the closest binaries, thus explaining why most pulsars are not members of binary systems In the case of those pulsars that survive as members of binary systems (for example, the Hulse–Taylor pulsar[8], PSR1913+16), the radiation force plays a dominant role in the evolution of the orbital parameters

The theory of radiative acceleration of pulsars with its various ramifications and implications will be presented elsewhere.

Comets and interstellar masers

RECENT advances in our understanding of the origin of the Solar System have led to renewed speculation on the origin of comets[1,2] Oort[3] proposed that long-period comets originate in a cometary cloud about 10^5 AU from the Sun and Cameron[4] has suggested that this cloud has its origin in association with the primordial solar nebula Other investigators have placed the origin in the interstellar medium[5]

Whipple and Lecar[6] have suggested that long-period comets arise from the interaction of the primordial solar nebular with the interstellar medium The opposing action of the solar wind from the new star and the interstellar radiation field squeezes the excess nebular material into a ring at the nebular edge

where saturated molecules such as H_2O and heavy metal compounds condense

High density rings around young stellar and protostellar objects at heliocentric distance $r = 10^4$–10^5 AU have also been suggested as the location of interstellar masers[7] Because these objects contain large fractional abundances of H_2O and perhaps other saturated molecules such as CH_3OH, and exist in an environment believed to be favourable to comet formation, there may exist an ontological relationship between masers and comets I suggest that the long-period comets are among the condensed remnants of cooled interstellar masers formed in a dense region at the nebular boundary I shall discuss the dynamics of the maser–comet transition and suggest ways in which this relationship may be exploited to expand our understanding of star and planet formation

Maser radiation from OH, H_2O, SiO, and perhaps CH_3OH has been observed from small knots of gas and dust in the direction of molecular radio sources associated with H II regions, and also towards certain infrared stars[7-9] The most common source of maser radiation, the OH radical, is often associated with H_2O maser radiation and the H_2O maser is always closely associated with OH-maser sources[7] The sizes of the emitting regions vary from 10 AU for H_2O regions to 10^3 AU or greater for OH regions Theoretical considerations of the pumping mechanism place limits on the density of H_2 in these regions of $10^6\leqslant n(H_2)\leqslant10^9$ cm^{-3} (refs 7 and 10) Fractional abundances for OH of 10^{-6} and for H_2O of 10^{-5}–10^{-4} are suggested The H_2O region may be contiguous with the OH region but higher in density and temperature, and perhaps closer to the central star

It has been demonstrated (J C Weisheit, A Dalgarno and M O , unpublished) that the chemical process

$$O+H_2 \rightleftharpoons OH+H \qquad (1)$$

is the only source capable of providing the large abundance of OH H_2O is formed by

$$H_2+OH \rightleftharpoons H_2O+H \qquad (2)$$

and by ion–molecule reactions initiated by penetrating cosmic rays H_2O is removed slowly by the reverse reaction (2) and more rapidly by[11,12]

$$C^+ + H_2O \rightarrow HCO^+ + H \qquad (3)$$

and

$$H_2O + h\nu \rightarrow H + OH \qquad (4)$$

Other saturated molecules are removed by analogous processes Photons which ionise carbon and dissociate H_2O do not penetrate much beyond $10^{21}/n$ cm into a region with the normal interstellar dust-to-gas ratio The residual ionisation of C^+ from cosmic rays is small and, except at the edges of the maser region, most of the oxygen is bound into H_2O and other molecules for $T>200$ K The lifetime of H_2O is greater than 10^{12} s, except at the edges of the region, even if it lies near an O-type star Unsaturated chemical species are removed much more rapidly by reactions among themselves such as

$$OH+N \rightarrow NO+H \qquad (5)$$

$$OH+O \rightarrow O_2 +H \qquad (6)$$

with time scales of $10^{14}/n$ s (ref 11)

The elevated temperatures needed to produce masers are obtained in or near protostellar objects and young stars Observational evidence and theoretical considerations suggest that some masers exist in rings of hot dense gas on the edge of protostellar objects and nebulae associated with young stars[7] A shock front related to the infall of material into a new star or the interaction of the solar wind of a new T-Tauri star with the remnant nebular gas may generate maser action at several

points circumferential to the object Many maser point sources exhibiting variations on time scales of the order of a year are found associated with single compact H II regions which may be cocoon stars

Consider the thermal evolution of maser sources that lie on the edge of the nebula of a new star The chemical scheme and the theoretical excitation mechanism suggest $T \geqslant 300$ K in an OH–H_2O maser region[7] There is probably an excess of dust by comparison with the interstellar value because of accumulation at the nebular edge Carbon monoxide, initially present in substantial amounts in the interstellar medium (M O and A Dalgarno, unpublished), may be converted to CH_4 and other saturated molecules at the elevated temperatures of the maser Eventually, the shock wave that heats the region dissipates or moves on, and the maser cools Maser fluctuation periods and shock speeds indicate a lifetime for the hot phase of 10^8–10^{10} s Cooling proceeds through emission from grains and in molecular transitions A lower limit on the cooling rate is found from the cooling through thermalised CO transitions For the velocity gradients, temperatures, and densities typical of these regions, the cooling time is $10^3 n$ s (T de Jong, S-I Chu and A Dalgarno, unpublished) H_2O will itself cool the gas very efficiently Conversion of CO to hydrogenated species increases the cooling rate[13] Conceivably it is this conversion which shuts off the maser

The time scale for cooling is much shorter than that for chemical removal of the saturated species H_2O, NH_3, CH_4 and other saturated molecules are frozen in with their maser-region densities for $n \lesssim 10^9$ cm^{-3} at depths where ultraviolet photons do not penetrate On the other hand, OH, O, N and other chemical radicals disappear during cooling

The presence of H_2O and any other molecular hydrides increases the cooling rate in the maser region significantly as compared with the surrounding medium, even after maser action ceases The resulting pressure gradient and decrease in volume of the H_2O region may lead to a greatly enhanced density Simultaneously, the saturated species will accrete on to grains as they cool with the gas The time scale for accretion is $10^{17}/n$ s in the interstellar medium[14], and probably shorter in the outer regions of the nebula Thus the accretion of ice mantles of saturated species proceeds before they are chemically removed The combination of large pressure gradients and competing solar-wind and interstellar-photon pressure[6] may bring about the enhanced density of grains needed for accumulation of the matter into a comet[4] The mass of condensable elements in a cylindrical maser[7] of radius r_m and depth l is

$$10^{-3} \alpha \delta n M (\pi r_m{}^2 l) \qquad (7)$$

where M is the average molecular weight, δ the depletion factor and α the degree of conversion to condensable molecules for minor constituent elements In an H_2O-maser region[7] with $r_m = 5 \times 10^{13}$ cm, $l = 3 \times 10^{15}$ cm, $n = 10^6$ cm^{-3}, $M = 20$ and $\delta \sim \alpha = 1/3$, the condensed mass is about 6×10^{22} g, this corresponds to a comet nucleus of radius 200 km with density of 1 g cm^{-3}, reasonably close to the estimated values for bright comets within the uncertainties of the model For lower values of α and δ, or larger density (representing a different chemical evolution), a smaller comet is generated I have chosen a maser of relatively low density Masers of higher density may fragment into several comets The total mass of condensables available in a ring of density 10^6 cm^{-3} and width 10^{16} cm at a distance of 3×10^{17} cm from the primordial Sun corresponds to 10^9 large comets, enough to explain the observed frequency of appearance of new comets[2] This density is in accord with values derived for the maser region in the Orion nebula[10] at about 10^{17} cm from the HCN emission peak

If the postulated maser–comet relationship is correct, information on the origin and composition of comets can be obtained from observations of interstellar masers, and of masers from observations of comets The chemical imprint in comets of the early stages of the formation of the Solar System[18]

may yield information on the temperatures and densities at that epoch for the outer region of the nebula As an example, I shall consider the equilibrium involving CO, CH_4, H_2 and H_2O in comet and maser regions Donn[15] has suggested that this equilibrium may serve as an indicator of the temperature in the gas when the comet formed The overall reaction is

$$CO + 3H_2 + 59 \text{ kcalorie} \rightleftharpoons CH_4 + H_2O \qquad (6)$$

The forward direction is favoured over the reverse for $T < 1,000$ K (refs 16 and 17), but the rate-determining steps are much slower than the probable thermal time scales in a maser region None of the gas-phase reaction schemes proposed for the interstellar medium produce CH_4 in abundances comparable to CO[11,18] Observational and theoretical evidence (M O and A Dalgarno, unpublished) suggests that 10–100% of the carbon atoms are found in CO in dense interstellar clouds Therefore, unless CH_4 is produced efficiently on grain surfaces[14], one does not expect

$$n(CO)/n(CH_4) \ll 1$$

in interstellar clouds Since CH_4 is not produced in the cometary coma[19] that ratio should not be much different in comets unless the parent maser region has experienced a high temperature phase of evolution

Similarly, H_2O is clearly in substantial abundance in the maser region Since H_2O is not removed during cooling, the H_2O should contain a substantial fraction of the oxygen in the cometary coma Contrary evidence would suggest heating of the parent region to $T > 2,000$ K (ref 17), or penetration of that region by dissociating photons Interpretation of chemical imprints is complicated by the fact that comets originating on the outer edge of the maser ring, where photons penetrate, will have a different thermal and ionisation history from those formed deep within the ring In addition, observed masers may occur near stars with mass greater than $1 M_{\odot}$, whereas our comet observations are restricted to the solar neighbourhood In spite of these complications, the maser–comet relationship may be a useful tool in understanding the early Solar System

Invalid 4.01-Gyr model U–Pb 'age' of the Nakhla meteorite

NAKHLA, an achondrite composed dominantly of the minerals 'diopside' and olivine[1], is possibly a unique meteorite It has a ^{39}Ar–^{40}Ar age of about 1 3 Gyr (refs 2 and 3) and recently its Rb–Sr age was shown by Papanastassiou and Wasserburg[4] to be similar In their discussion, these authors[4] use the concept

Table 1 U and Pb concentrations and Pb isotopic composition in samples of Nakhla

Sample	Weight (g)	U (p p m)	Pb (p p m)	$^{206}Pb/^{204}Pb$	$^{207}Pb/^{204}Pb$	$^{208}Pb/^{204}Pb$	Blank* (%)	μ†

of model Rb–Sr 'ages' as part of their argument that Nakhla originated in a differentiated planetary body not unlike the Earth, and in particular to argue that this parent body suffered gross differentiation between 3 6 and 1 37 Gyr ago We show that the U–Pb systematics of Nakhla are inconsistent with one or more of the assumptions required for the calculation of a model U–Pb 'age', thus indicating that model 'ages' for other radioactive decay schemes may be generally invalid

Table 1 shows U and Pb contents and the atomic ratios $^{207}Pb/^{204}Pb$ and $^{206}Pb/^{204}Pb$ determined for each of three bulk samples of Nakhla The techniques used are described elsewhere[5,6], U concentrations are determined to about ±1% and Pb concentrations to about ±1 5% Blank levels were about 0 05 ng U and 2 ng Pb It is clear that single stage model 'ages' are close to 4 01 Gyr (Table 2), indeed the mean model 'age' is 4 01 ± 0 09 Gyr, where the error quoted is twice the standard

Table 2 Radiogenic $^{207}Pb/^{206}Pb$ ratios and single-stage model ages for Nakhla

error of the mean In these calculations the initial Pb isotope ratios are Tatsumoto's revised values for Pb in the troilite (FeS) of the Cañon Diablo iron meteorite[7], and the latest values for the U decay constants are used[8]

Model 'age' calculations are used when the initial isotopic ratio of a daughter element cannot be obtained directly from measurements, for example, in the U–Pb and Rb–Sr systems 'primitive' Pb and Sr isotopic ratios of meteorites have been combined with lunar, terrestrial and meteoritic measured values to obtain the 'age' of the early lunar differentiation[9–11], the 'age' of the Earth[12,13] (U–Pb only) or the 'ages' of certain stony meteorites[7], respectively The various assumptions which must hold for a model 'age' calculation to be valid when the U–Pb system is used, are as follows

(1) The Pb isotope ratios of Cañon Diablo troilite represent the initial ratios of the material being studied

(2) The ratio $^{235}U/^{238}U$ has changed with time by radioactive decay only, and is at present 1 137 88

(3) Changes in Pb isotope ratios were brought about by U decay only

(4) The system has remained closed, that is, the U/Pb ratio has not changed by chemical fractionation

Many meteorites suffered a thermal event about 4 56 Gyr ago[14,15] and Pb isotopic dating is broadly consistent with the assumption that Cañon Diablo troilite has retained the Pb isotopic ratios which generally obtained at that time[16] If Nakhla is composed of matter which evolved in the Solar

System, as did the stuff of other meteorites, then 4 56 Gyr ago, it too, or its parent body, should have had the same Pb isotopic composition as other meteorites Lead of the isotopic composition found in Cañon Diablo troilite could, however, not have evolved in a single stage into modern Nakhla Pb in a time other than about 4 01 Gyr unless the isotopic composition of its U was different from the accepted one (see (2)) and/or it had preferentially lost or gained ^{207}Pb or ^{206}Pb, that is, either or both of assumptions (2) and (3) did not obtain If Nakhla experienced a two-stage history, it could have evolved from the Cañon Diablo composition at 4 56 Gyr, but only provided that the first stage had a U/Pb ratio of zero (usually expressed as zero μ, $^{238}U/^{204}Pb$) and the second stage lasted for about 4 01 Gyr This implies that the Nakhla parent body was free of U from 4 56 to 4 01 Gyr, when U was introduced without the introduction of radiogenic Pb This seems improbable It is possible to invent three-stage (or higher order) histories which allow Nakhla to evolve to its present U and Pb content and Pb isotopic composition from the Cañon Diablo composition over 4 56 Gyr, but we have no evidence of such histories In any case assumption (4) would have been violated Thus, if assumptions (2), (3) and (4) did hold, the initial isotope ratios of Nakhla or its parent body were different from Cañon Diablo troilite Pb (assuming that this composition is linked to the time 4 56 Gyr), that is, assumption (1) did not hold For Nakhla, at least one of assumptions (1)–(4) is false

Fig 1 Nakhla (chip A) Pb growth two interpretations *a*, Single stage, curve HCM, observed μ = 5 04 Growth begins 4 56 Gyr ago from H with hypothetical primitive values, $^{207}Pb/^{204}Pb$ = 9 1 and $^{206}Pb/^{204}Pb$ = 8 6, passes through C, the Cañon Diablo point, 4 1 Gyr ago and continues to M, with present-day measured ratios *b*, Three-stage curves (diagrammatic) C–3 6 Gyr–1 3 Gyr–M (1) From Cañon Diablo values, growth begins 4 56 Gyr ago with μ = 1 81 till 3 6 Gyr ago, when $^{207}Pb/^{204}Pb$ = 11 0 and $^{206}Pb/^{204}Pb$ = 9 8 (2) Growth continues with μ₂ = 5 46, till 1 3 Gyr ago, when $^{207}Pb/^{204}Pb$ = 12 3 and $^{206}Pb/^{204}Pb$ = 12 7 Here the single-stage curve is rejoined (3) From 1 3 Gyr ago, with measured μ₃ = 5 04 till the present We emphasise that we have no evidence for selecting any particular three-stage model, nor do we have evidence for the hypothetical primitive point

The simplest, single-stage explanation is that the Nakhla Pb isotopic ratios grew by U decay over the past 4 56 Gyr from Pb more primitive than that of Cañon Diablo troilite and with the following approximate ratios $^{207}Pb/^{204}Pb = 9\ 1$ and $^{206}Pb/^{204}Pb = 8\ 6$ (Fig 1) The existing U–Pb data are insufficient to prove whether or not this explanation is valid for Nakhla, or to reconcile it with the evidence from the Rb–Sr system[4], it is mentioned here merely as a possibility By chance, Papanastassiou and Wasserburg's interpretation of their Rb–Sr data[4] could be compatible with a three-stage model based on our U–Pb data and Cañon Diablo initial lead isotopic ratios at 4 56 Gyr, U–Pb fractionation could have occurred at about 1 37 and 3 6 Gyr (Fig 1) The second event, which these authors interpreted as representing internal redistribution of Rb and Sr, must, however, necessarily have changed the μ value in the bulk meteorite It seems likely that any major change in the U/Pb ratio would also be accompanied by change in the Rb/Sr ratio so obliterating the record in the Rb–Sr system The choice of 3 6 Gyr as the time for the earlier fractionation must therefore be arbitrary and is not specifically required by the U–Pb data Indeed, we have established a 16 point internal isochron for the Nakhla Rb–Sr system which confirms this interpretation (to be published)

Because the Rb–Sr system has a single parent and single daughter isotope, in theory any value of the ratio $^{87}Sr/^{86}Sr$ could have developed by Rb decay from any less radiogenic initial ratio Thus the applicability of a particular 'initial' $^{87}Sr/^{86}Sr$ ratio of meteorites, such as BABI[17], to determining model 'ages' (which, in the literature, are almost always single-stage 'ages') of other materials can be neither proved nor disproved It seems likely, however, that Rb–Sr model 'ages' might well suffer from uncertainties similar to those shown to exist in the U–Pb systematics of Nakhla, and so it is desirable that meteorite chronologies be based on internal isochrons using both the Rb–Sr and U–Pb systems

The systematics of Nakhla clearly demonstrate that the widely accepted 'primitive' Pb isotope ratios of Cañon Diablo troilite cannot represent initial values for single-stage evolution of the U–Pb systems of this other meteorite The use of Cañon Diablo Pb in determining the 'ages' of lunar rocks (see, for example, ref 11), the 'age' of the Earth[13,18,19] or the 'ages' of stony meteorites[19,20] by single-stage calculations might also be invalid We are merely reiterating a reservation already expressed by numerous earlier workers (see, for example, refs 11, 13, 19 and 20), but we do so with added proof

Ages of fossil bones from British interglacial sites

THE time gap between the upper limit of radiocarbon dating ($\approx 60{,}000$ yr BP) and the lower limit of dates generally obtainable using the K–Ar method ($\approx 250{,}000$ yr BP) accounts for the scarcity of dates for the last two interglaciations (the Ipswichian and Hoxnian of Britain, the Eemian and Holsteinian of northern Europe) Accordingly, the ages of such important fossils as the Swanscombe and Steinheim skulls can only be guessed at For that reason, the adaptation of a method that may date these interglacial periods is highly desirable We discuss here the application of a uranium-series dating technique pertaining to that span of time

Results were obtained for six samples of fossil bones from British interglacial sites (Table 1) Fossil bones can be dated using the uranium-series method by taking measurements of uranium isotopes and their long-lived daughters, ^{230}Th and ^{231}Pa (refs 1–4) The bone samples described here were cleaned by scraping and by ultrasonic scrubbing The samples were crushed to a fine powder and ignited at 800 °C for about 6 h The abundances of uranium and thorium were determined using mass spectrometry, the $^{234}U/^{238}U$ and $^{230}Th/^{234}U$ activity ratios were determined using α spectrometry[5] The $^{231}Pa/^{235}U$ activity ratios were determined using neutron activation and α spectrometry[6]

Sample localities, analytical data, and calculated ages are given in Tables 1 and 2 The uranium content of the bones varies from 23 to 67 p p m The concentration of common thorium, ^{232}Th, is low in all the samples, therefore, no correction for the initial ^{230}Th component is required The measured $^{230}Th/^{234}U$ ratio yields a ^{230}Th date of $245{,}000 + 35{,}000 - 25{,}000$ yr BP for sample 37 from the Clacton locality The $^{231}Pa/^{235}U$ ratio in this sample is $1\ 00 \pm 0\ 04$, indicating that this fossil apparently remained a closed system with respect to uranium and its daughter elements, ^{230}Th and ^{231}Pa, during at least the last 150,000 yr of its history The calculated ^{230}Th date therefore seems to be reliable

*Experimentally measured activity ratios.
†Calculated using ^{230}Th half life of 75,200 yr.
‡Calculated using ^{231}Pa half life of 32,500 yr.
§Open-system date after Szabo and Rosholt[5].

Two samples from Swanscombe could not be dated. In sample 38, both the ^{230}Th/^{234}U and ^{231}Pa/^{235}U ratios are anomalously high (1.31 ±0.05 and 1.44 ±0.66, respectively). That is, the amounts of the daughter elements ^{230}Th and ^{231}Pa are in excess with respect to their radioactive parents, ^{234}U and ^{235}U. Accordingly, no ^{230}Th or ^{231}Pa dates can be calculated; and the open system model, which allows for the migration of uranium, also yields no finite date[5]. The ^{230}Th/^{234}U ratio of 1.21 ±0.05 in sample 63 is also too high to yield a ^{230}Th date. Sample 39 from Swanscombe, on the other hand, has a measured ^{230}Th/^{234}U ratio of 1.01 ±0.04 which yields a finite ^{230}Th date of 326,000 +99,000 −54,000 yr BP. The ^{231}Pa/^{235}U ratio of 1.01 ±0.04 indicates that this sample remained a closed system during at least the last 164,000 yr of its history. The large error of the ^{230}Th date arises because the calculated date is near the limit of resolution of the method.

Sample 41 from Stutton and sample 42 from Brundon yield finite ^{230}Th dates but the amount of ^{231}Pa in both cases is excessive with respect to the parent isotope ^{235}U. Using the open system model the dates of sample 41 from Stutton and sample 42 from Brundon work out at 125,000±20,000 and 174,000±30,000 yr BP, respectively.

The Clacton deposits, including artefacts, mammalia and mollusca, have been placed by most workers in the Hoxnian Interglaciation[7-9] although Collins[10] and Kerney[11] have argued for an early–middle Hoxnian age (zone II). Singer et al.[12] have, however, suggested that the gravels belong in the Anglian Glaciation. The Swanscombe skull level is also placed by most workers in the Hoxnian[7,9,13], though possibly very close to the end (zone IV or late III)[10,11].

The Stutton deposits, only some 8 km from the type site of the Ipswichian[9], are usually placed in the Ipswichian[7]. If, however, a temperate interval existed during the glaciation between the Hoxnian and Ipswichian, the Stutton deposits could possibly be correlated with this interval. Similarly, the Brundon faunal level, only tenuously connected with the Ipswichian in the absence of palaeobotanical data, though clearly post-Hoxnian, may correlate with a possible temperate interval between the Hoxnian and Ipswichian.

Among these samples only sample 37 from Clacton gives a satisfactory closed system finite date, of 245,000 yr BP. This date agrees with a 'medium chronology' for the Pleistocene interglaciation. The date is too old for the short chronology of Emiliani[14], and too young for the long chronology of Ericson et al.[15]. The Swanscombe date may be regarded as a minimum, at least 272,000 yr BP. Most chronologies would require Swanscombe to be later than Clacton; the circumstance can be reconciled for the samples reported here by adopting the older limit for Clacton, that is about 280,000 yr BP.

The Brundon date, 174,000±30,000 yr BP (open system), is older than most recent estimates for the last interglaciation, even the 120,000 yr age favoured by Shackleton[16]; it would correlate well with a Wolstonian temperate period (inter-Hoxnian–Ipswichian), or with the Ipswichian, if a longer chronology is assumed. The Stutton date, 125,000±20,000 yr BP (open system), is very close to Shackleton's[16] estimate for the Ipswichian. Within the limits of statistical error, the Stutton date would also agree with a date of about 100,000 yr BP for the Ipswichian. Alternatively, this date, like that from Brundon, would correlate with a hypothetical inter-Wolstonian temperate period at about 145,000 yr BP; this leaves the Ipswichian to be mainly younger than 100,000 yr BP, as has been widely suggested.

The Clacton date may be compared with two K–Ar dates that bear somewhat indirectly on the age of the Holstein (Mindel–Riss) Interglaciation in Europe: the KA 409 date[17] from Monte Cavo, 20 km south-east of Rome, which dates leucite from a post-Flaminian (Mindel/Elster) eruption at 277,000 yr BP; and a Leilenkopf III date of 220,000±40,000 yr BP on lava from an eruption some 36 km SSE of Bonn in the 'mittlere Mittel' terrace of the Rhine[18], which is roughly contemporary[19] with the beginning of the Holstein Interglaciation. The Clacton, Monte Cavo, and Leilenkopf dates are all consistent with a date of about 250,000 yr BP for the early part of the Holstein Interglaciation, if allowance is made for the full range of statistical error.

The four dates reported here support a medium chronology (see refs 10, 20 and 21) for the Pleistocene interglaciations. The dates do not support the short[14,18] or long[15] chronologies. A date of about 250,000 yr BP would seem to be the best estimate at present for the time of the Holstein Interglaciation.

Subglacial silica deposits

SUPERFICIAL carbonate deposits are common on bedrock surfaces recently exposed by retreating temperate glaciers[1-5]. Their morphology indicates that they formed subglacially in intimate contact with sliding ice. Besides suggesting that chemical transport is an active subglacial process, these relatively widespread deposits reflect high solute concentrations in subglacial waters. This is a fact of considerable significance because solutes at the glacier–bed interface can impede significantly the sliding of temperate glaciers[5]. The dynamics of temperate glaciers and especially the more intriguing aspects of their behaviour, such as surging[6], are thought to depend critically on the basal sliding process[7]. Thus, chemical exchange at the base of a glacier may affect significantly its entire motion. Moreover, because glacial erosion and deposition are largely dependent on glacial sliding, they too are affected by the presence of solutes at the bed. To date, reported subglacial deposits have all been carbonates. On the basis of previously unrecognised subglacial deposits rich in silica, I suggest that subglacial deposits are not exclusively carbonates, but that

silicates are of wider significance, than is believed at present.

Figure 1 shows a sample of hypersthene–augite andesite, from the vicinity of Paradise Glacier in Mount Rainier National Park, Washington. This rock has a thoroughly striated and polished surface which merges in the down-glacier direction into a slightly irregular surface, coated with a thin light grey layer of mineral material. The surface of the coating is characterised by a pronounced lineation parallel to the local glacial striations, suggesting that it formed in intimate contact with actively sliding ice in much the same way as carbonate deposits[5].

This millimetre-thick deposit consists of two contiguous, distinct types of material that differ markedly from the underlying bedrock. The more abundant type consists principally of angular, micrometre-sized rock and mineral fragments, presumably glacial flour, embedded in an amorphous matrix. The other type of material is finely laminated and contains only a few small clastic fragments. It ranges in colour from light to

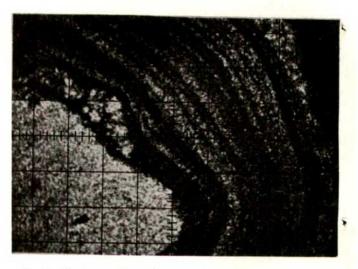

Fig. 2 Electron-probe, sodium-sensitive micrograph of feldspar phenocryst in andesite bedrock partially coated with finely laminated, subglacially precipitated, silica rich coating. The lighter areas are relatively rich in sodium. Grid spacing, 25 μm.

dark brown in transmitted light and is characteristically optically isotropic, although in places it may be slightly birefringent. Electron microprobe analyses (EMA) indicate that the deposit is highly siliceous, in places consisting of as much as 95 % SiO_2.

Figure 2 is an oscilloscope presentation of the characteristic X-ray radiation of sodium from an electron microprobe scan of the finely laminated, optically isotropic material partially coating a feldspar grain. The lamination is clearly compositional in nature with alternating layers relatively richer and poorer in sodium. A silicon micrograph of this same area revealed little structure in as much as the entire deposit is rich in SiO_2.

An X-ray powder diffraction pattern of the silica-rich coating showed sharp plagioclase peaks, presumably representing detrital feldspar grains in the deposit. There were no diffraction peaks of quartz or other silica polymorphs in the powder patterns. Transmission electron microscopic (TEM) examination of the deposit revealed a few submicrometre sized and larger, angular, mineral fragments embedded in a homogeneous matrix. No crystallographic subdomains could be detected in the matric at magnifications of up to ×83,000. Electron-diffraction patterns of the silica deposit invariably consisted of several families of spots, interpreted as a result of the presence of detrital grains of feldspar and ferromagnesian minerals. If the silica-rich matrix consists of crystalline subdomains, they are too small to cause significant diffraction of the electrons. Thus, the SiO_2 in the subglacially formed deposit is either

Fig. 1 Glacially polished andesite surface on the right grades to the left into an irregular surface covered with a thin furrowed coating that formed in intimate contact with sliding temperate ice. Former direction of ice flow is indicated by the arrow, which is 2 cm long.

amorphous, or else the size of the ordered domains does not exceed several hundred angstroms

Insight into the mode of formation of the subglacial silica-rich deposits can be obtained by analogy with previous studies of the subglacial precipitation of $CaCO_3$, which is intimately related to the basal sliding of temperate glaciers[1-5] These glaciers, at their melting points throughout, flow by a combination of two processes internal deformation and basal sliding Sliding ice accommodates itself to irregularities in the bedrock by plastic deformation and by regelation In the latter process, the basal ice melts in zones of higher pressure and reduced temperature, and the resulting water flows between the ice and bedrock toward zones of lower pressure and higher temperature, where it refreezes because of the pressure reduction The heat necessary for the fusion is provided by the latent heat of freezing, which is conducted through ice and rock from the lee to the stoss sides of bed obstacles[8,9] The meltwater continuously produced by regelation sliding contains impurities originally present in the basal ice in addition to these resulting from the dissolution of the bedrock As this water refreezes in areas of locally reduced pressure, generally along lee surfaces, solutes are continuously rejected into the liquid phase by the growing ice The continuous rejection of dissolved silica, which is probably similar to the rejection of solutes in freezing NaCl (ref 10), KOH (ref 11), HCl (ref 12), and $CaCO_3$ (ref 5) solutions, and which must occur in the sliding process, will therefore cause progressive enrichment and eventual precipitation of silica from regelation waters in the lee of bed obstacles at the bases of actively sliding temperate glaciers Solutes are concentrated subglacially in much the same way as in the zone melting process used for refining metals and semiconductors, in this process impurities are removed preferentially by the passage of a molten zone in which impurities tend to accumulate

Concentrations of dissolved silica as high as 8 p p m are present in the water emerging from under two Mount Rainier glaciers[13] Regelation melt water, flowing in intimate contact with the bedrock, should also contain high concentrations of dissolved silica The subglacial, silica-rich deposits indicate that a portion of this mobilised silica is deposited, as an essentially amorphous precipitate trapping much glacial flour, at a temperature very close to 0 °C, a pressure not exceeding a few bars, and a pH close to 7 (ref 13) The deposit I have mentioned (Fig 1) formed recently, perhaps during the last major glacial advance, around 1850 AD (ref 14)

Solutes in regelation waters tend to inhibit glacial sliding because they accumulate at the lee of bed obstacles where freezing is localised They reduce selectively the temperature there, thereby reducing the temperature gradient and thus the heat flow across bed obstacles that is essential for regelation sliding Concentrations of silica exceeding the saturation value of 80 p p m (ref 15) can be expected where amorphous silica is precipitating subglacially Together with other dissolved species generally present[13], a difference in the concentration of solute of this magnitude between stoss and lee surfaces can be expected to inhibit glacial sliding significantly, especially if the glacier bed is characterised by uneven elements which have mean wavelengths that do not exceed 0 5 m (B H , unpublished)

Subglacially formed carbonate deposits are relatively widespread, having been recognised on calcareous rocks in Scandinavia[3], the Alps[4], and the Rocky Mountains[1,5] This is the first report of subglacial silica-rich deposits They are probably not restricted to the Mount Rainier locality, but rather, are likely to be widespread perhaps as thinner coatings and inconspicuous crack fillings, in glaciated areas underlain by silica-rich rocks Considerable amounts of solutes are, therefore, likely to be present to the lee of bed obstacles at the base of practically all temperate glaciers, because most rocks are rich in carbonates or silica, Thus, the effect on glacial sliding is of general importance, because it will have a definite influence on the behaviour of practically all temperate glacial ice masses

I thank Drs R L Shreve, W E Reed, and J L Rosenfeld for discussions and criticism, and J McCormick for his assist-

ance with the electron microscopy This work was supported by the National Science Foundation

Observations of a nonlinear interaction involving three electromagnetic waves in a laboratory magnetoplasma

POLARISATION requirements and wave number matching dictate that a nonlinear interaction involving three electromagnetic waves that propagate in a magnetoactive plasma must necessarily be two-dimensional if one of the waves propagates parallel to the external magnetic field B_0 We report here what we believe to be the first observation of a three wave interaction of this kind Our experiment involved the production of a whistler mode wave (k_3, ω_3) (referred to as WMW) through the interaction of two beams of high frequency electromagnetic waves (k_1, ω_1) and (k_2, ω_2), propagating somewhat above the local plasma frequency ω_p The resonance conditions for the interaction are

$$k_1 = k_2 + k_3 \text{ and } \omega_1 = \omega_2 + \omega_3 \qquad (1)$$

If $\omega_{1,2} > \omega_p$ and ω_3 is sufficiently small compared with the electron gyrofrequency ω_e $(\omega_e < \omega_p)$, the high frequency beams must be directed[1] almost at right angles to B_0 (Fig 1 inset) The strength of the coupling of the beams is determined by two factors first, the magnitude of the matrix element for the interaction, and second, the time in which a stationary state is established as a result of the convection of the WMW packet across the finite interaction region of width, l An expression[2,3] for the steady-state amplitude, E_3 of the electric field of the WMW, can be obtained in terms of the amplitudes E_1 and E_2 of the beams

$$E_3 = \chi E_1 E_2 \qquad (2)$$

where

$$\chi = \frac{1}{2} \frac{el}{mc^2} \frac{\omega_3^2}{\omega_1 \omega_2} \frac{\omega_e \mu^2}{(\mu^2 \omega_e^2 + 4\omega_1^2)^{1/2}}$$

where e and m are the charge and mass of the electron, respectively, c the speed of light, μ, the refractive index for the WMW, and other symbols are as defined previously

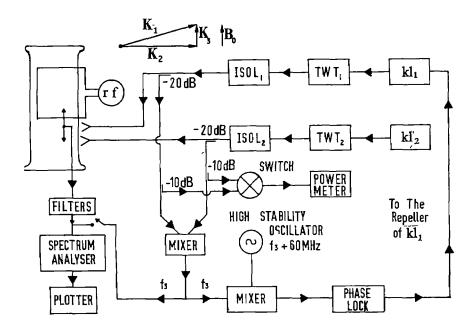
The laboratory plasma is produced by transverse r f excitation of Argon gas in a 1-m long, 15-cm diameter, glass tube immersed in an axial magnetic field variable from 20 to 200 gauss, and uniform to within 2% over 60 cm length This


Fig. 1 Schematic diagram of the apparatus used in our experiment For the true disposition and orientation of the horn antennae see text Vector diagram at the top shows wave vector configuration for the interaction $(\mu_{1,2}\sim1, \mu_3\gg1)$

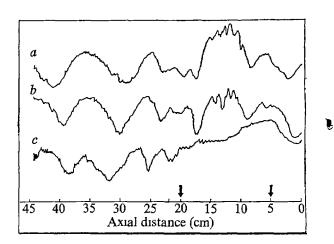
method of plasma production[4,5] creates a plasma with electron temperature $T_e\sim3$ eV and density $n_e\sim10^{12}$ cm^{-3} Langmuir and wave field probes can be inserted radially into the plasma and a motor driven probe is used for the detection of the wave field along the tube axis

Two microwave beams at frequencies f_1 and $f_2\sim11$ GHz are derived from two Klystron oscillator and TWT amplifier systems, and fed into the plasma through two horn antennae, which are situated side by side around the circumference of the tube The beam from one horn (f_1) is oriented perpendicularly to the axial magnetic field with the electric vector E_1 at right angles to B_0, and the other (f_2) is oriented at 5-10° off the perpendicular, with E_2 parallel to B_0 The power in each beam is controllable up to 15 W


The frequency difference $f_3 = f_1-f_2$ is stabilised using a double down converting system, locked to a 60 MHz standard which controls the repeller voltage of one of the Klystron oscillators, and can be varied at will in the range 0-400 MHz As the deviation rate of the residual f m in the Klystrons is relatively slow, the response rate of the phase locked system is more than adequate to achieve overall frequency stabilisation to within some tens of Hz Narrow band detection and frequency stabilisation are essential in the somewhat noisy plasma, and considerable care has been taken in eliminating pick-up

Signals at f_3 are detected using the axial loop probe and a spectrum analyser (see Fig 1) The combination of the frequency locking system and the stabilisation on the spectrum analyser results in an overall bandwidth at f_3 of ~20 Hz, with a sensitivity of -120 dBm, which corresponds to a minimum detectable oscillating magnetic field of 10^{-8} gauss for the frequencies we are interested in Figure 2 shows the results of interferometric measurements of wave amplitude as a function of axial position of the probe, for $f_3 = 43$, 51 and 67 MHz, while the plasma conditions were kept constant The two arrows on the figure define the length $(l\approx15$ cm) of the interaction region, that is, the length of the plasma volume illuminated by the two microwave beams At a short distance from this region the signal exhibits a clear phase variation with distance, from which the wavelength can be deduced After allowing for small changes in wavelength $(\sim10\%)$ related to a weak beach field in the last 10 cm of the detection region, we have fitted (Fig 3) the experimental points to the low frequency WMW dispersion relationship appropriate to the geometry of this experiment[6,7] The average

plasma density $n_e = 1\,2\times10^{12}$ cm^{-3}, deduced from this fit, is in good agreement (to better than 20%) with the density deduced from Langmuir probe measurements

The same figure also shows the dispersion relation for quasistatic waves[8] which can exist in this experiment under the same plasma conditions The identification of the waves at f_3 with a WMW is unambiguous The existence of long wavelength, quasistatic waves in our apparatus was indeed established during preliminary investigations, by observing (in separate measurements without a reference signal in the spectrum analyser) the beating between short wavelength WMWs $(\lambda_3\sim15$ cm) and quasistatic waves $(\lambda_{q\ s}\sim200$ cm) We have also verified that the WMW field is proportional to the product of the input fields, and that for a fixed orientation of the high frequency beams, the amplitude of the WMW field varied with varying plasma parameters as predicted by the theory,

Fig. 2 Interferometer traces of WMW fields, detected by the loop probe, at three different frequencies, as a function of axial distance a, $f_3 = 43$ MHz, b, $f_3 = 51$ MHz, c, $f_3 = 67$ MHz Arrows on the distance scale mark the approximate extent of the region over which the microwave beams interact The maximum amplitude corresponds to an electric field $E_e\sim$ 3×10^{-4} V m^{-1}

that is, it exhibits a broad resonance centred on the resonant condition of equation (1)

Care was taken to match the microwave beams at the glass-plasma interface, and microwave absorbers were packed around external sources of reflection Nevertheless, some internal reflection did occur, and the possibility that regions of enhanced microwave field could give rise to other non-linearities (for example, on the sheaths, probes, connections, and so on) and produce spurious signals at f_3 with the same spatial structure was investigated These fields were examined by scattering measurements, and detection on the loop probe, and shown to be at least 30 dB down on the fields in the interaction region and to have a spatial structure along the axis totally unrelated to those obtained by phase measurements

The magnitude of the coupling coefficient for the present experiment can be obtained by substituting the measured values of the amplitude of the high frequency beams ($E_1 \approx E_2 \approx 300 \text{ V m}^{-1}$) and the amplitude of the emerging WMW ($E_3 \sim 3 \times 10^{-4} \text{ V m}^{-1}$) into equation (2) This gives

$$\chi_{\text{exp}} = 3 \times 10^{-9} \text{ m V}^{-1}.$$

On the other hand, the value of χ predicted theoretically from equation (3), using the experimental values for ω_1, ω_2, ω_p and ω_e gives

$$\chi_{\text{th}} \sim 1 \ 3 \times 10^{-9} \text{ m V}^{-1}$$

The good agreement between these two figures confirms the validity of the weak coupling model for this interaction

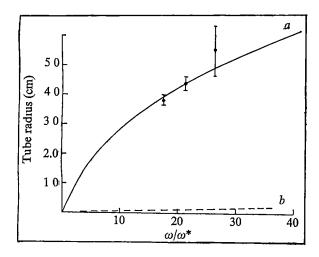


Fig. 3 Experimental data fitted to the theoretical dispersion curve (a) of low frequency whistlers (helicon waves[6]) $\omega^* = B_0/4\pi nea^2$ The inferred value of the plasma frequency, n ($\sim 1 \ 2 \times 10^{12} \text{ cm}^{-3}$) is in good agreement with independent Langmuir probe measurements[7] b, Dispersion curve for quasistatic waves

The original motivation for this experiment was to verify the theoretical predictions concerning the feasibility of an active field experiment[1] to excite WMWs in the Earth's ionosphere by means of two ground based high frequency transmitters of equal beam strengths ($E_{\text{ion}} = E_1 = E_2 = 1 \text{ V m}^{-1}$) and illuminating a region such that $l_{\text{ion}} = 2 \times 10^4 \text{ m}$

It is interesting to extrapolate the laboratory measurements of χ to the ionospheric situation described here This can be achieved by noting that the coupling coefficient for equal beam strengths scales as El (where $E = E_1 = E_2$), if the ratios

ω_3/ω_p, $\omega_{1,2}/\omega_p$ and ω_p/ω_e are kept constant We then find that

$$\chi_{\text{ion}} = \chi_{\text{lab}} \left[(El)_{\text{ion}}/(El)_{\text{lab}} \right]$$

$$= 1 \ 3 \times 10^{-6} \text{ m V}^{-1}$$

which is in good agreement with values calculated previously[1]

Finally, the positive results of this laboratory experiment seem to substantiate the suggestion that the very low frequency bands observed[9] from the satellite Ariel 3 (and subsequently[10], from Ariel 4) over the magnetically conjugate area of the eastern USA may be caused by the interaction in the - Earth's ionosphere of powerful, medium wavelength signals (the f_1 and f_2 phases of our experiment) from commercial transmitters concentrated in that region, which excites WMWs (the f_3 of our experiment) which subsequently undergo natural amplification by a mechanism similar to that observed by Helliwell[11]

Vacancy migration and void formation during annealing of electron irradiated molybdenum

WE have used a combination of three techniques—resistivity, positron annihilation and transmission electron microscopy (TEM)—to examine the recovery on annealing of point defect damage introduced into high purity molybdenum by 10 MeV electron irradiation The work produced two points of particular interest, both arising directly from the sensitivity of the positron annihilation technique to vacancy defects

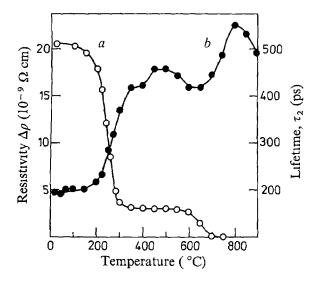
The first point concerns the well known stage III recovery occurring in molybdenum at between 150 and 300 °C following either cold work[1,2], neutron irradiation[3,4], or electron irradiation[5,6] That this recovery stage is caused by the annihilation of vacancies with interstitials is little disputed but in molybdenum, as in the face centred cubic (f c c) noble metals, there has been controversy as to the nature of the migrating species[4] We therefore irradiated molybdenum specimens at 50 °C to a dose of 2 4 × 10[18] electrons cm[-2] and then combined liquid helium resistivity measurements with room temperature positron annihilation measurements to follow the changes occurring


Fig. 1 The recovery of induced resistivity (*a*) and the behaviour of the long positron lifetime, τ_2 (*b*), during the isochronal annealing of electron irradiated molybdenum Heating rate 1 °C min^{-1}

during stepwise isochronal annealing (Fig 1) The resistivity measurements showed that $\sim 80\%$ of the induced resistivity annealed out in stage III centred at ~ 250 °C indicating, as expected, that the majority of radiation induced defects annihilate in this stage

Meanwhile, in exactly the same temperature range the long positron lifetime increased from 195 ps to 400 ps It is well established that positrons are sensitive to the presence of vacancies and vacancy clusters, the parameters of the clusters, such as shape and size, particularly influence the magnitude of $\tau_2^{7,8}$ On this basis, therefore, the significant rise in τ_2 can only be interpreted in terms of the formation of such clusters Since it is difficult to see how interstitial migration can lead to this formation of vacancy clusters we believe that the stage III recovery in molybdenum must arise from the thermal migration of radiation induced vacancies Models based on the migration of metastable interstitials or the detrapping of interstitials are, therefore, untenable, from the combination of resistivity and positron annihilation data it seems clear that during the vacancy migration a large number of the vacancies are annihilated at immobile interstitials (trapped at impurities during the irradiation^{6,9}) and that also, not unreasonably, a significant fraction of vacancies interact with each other to form clusters

The second point of interest concerns the nature of the clusters, particularly as the 400 ps value for τ_2 suggested strongly that they could be three-dimensional To obtain further experimental information we therefore continued annealing to higher temperatures Figure 1 shows that the two significant stages are the well defined annealing of the remaining radiation induced resistivity at 650 °C, and the 800 °C peak in τ_2 where the long positron lifetime reaches a value of 550 ps before the lifetime parameters return to their pre-irradiation values In the light of results from a previous analogous positron annihilation study on neutron irradiated molybdenum^8 the interpretation of these two stages is comparatively straightforward In the neutron work it was suggested^8, and subsequently confirmed by TEM^{10}, that a large rise in τ_2 in the range 750–900 °C was caused by the thermal coarsening of voids, whereas an earlier shoulder on this peak at 650–700 °C reflected the growth of voids at the expense of thermally shrinking vacancy loops

Thus, it seems that during the stage III vacancy migration the vacancies escaping annihilation at interstitials nucleate clusters in two forms, one planar and one three-dimensional, which then grow to vacancy loops and voids, respectively On annealing, the sensitivity of resistivity measurements to lattice

strain effects allows the thermal shrinkage of the small vacancy loops to be detected, leaving the void behaviour to be followed by the positron lifetime parameters These conclusions are fully supported by investigations using the angular correlation technique (M E *et al*, unpublished)

For further confirmation we cut disc-shaped specimens, suitable for electron microscopic study from the resistivity foils, these were annealed to 900 °C before transmission microscopy examination at 100 keV Small voids with diameters of 20–30 Å were found within the foils, the void concentration was about 10^{13} voids cm^{-3} Of the estimated number of vacancies (70 p p m) surviving the irradiation, certainly not more than 1 % survived the annealing to form voids

It is worth emphasising the importance of these positron annihilation results because they reinforce the usefulness of such measurements in point defect studies Furthermore, it seems possible that outstanding problems concerning other metals— for example, the vacancy–interstitial problem in stage III of the noble metals, or the intrinsic–extrinsic defect argument for stage III in the group V refractory metals—might be profitably examined by adding positron annihilation measurements to the normal range of techniques used in such studies

Fossil hominid body weight and brain size

Reliable estimates of body weights in early hominids are essential to the study of their brains and body proportions[1] Obviously the evolution of the size of the human brain must be studied in terms of the size of the body Although the endocranial volume is known for many individual fossil hominids, body weight is poorly known The present study is an attempt to estimate body weight of the South African Plio-Pleistocene hominids as accurately as possible from the available fossil evidence East African early hominid postcrania are excluded because of the difficulty in taxonomic assessment, especially within the genus *Australopithecus*

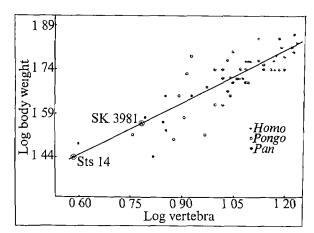
Most previous estimates of body weight for these fossils have been based on visual assessment or extrapolations from stature estimates[1-5] This study attempts to predict body weight directly from skeletal size Of the fossils preserved in South Africa, the vertebrae present one of the best opportunities to do this since adult vertebrae of the same kind are known from both *A africanus* (Sts 14 from Sterkfontein)[5] and *A robustus* (SK 3981 a and b from Swartkrans)[5,6] Also, vertebral size is highly correlated with body weight in humans In my human sample, a measure of cross-sectional area of the last lumbar vertebra has a correlation of 0 72 with body weight A measure of the volume of the last thoracic vertebral centrum has a correlation of 0 70


Fig. 1 Regression line and dispersion based on eight measurements of human vertebrae predicting body weight Two male and five female *Pan* and eight female *Pongo* specimens are plotted for comparison purposes only

The Terry collection at the Smithsonian Institution, Washington, provided the comparative human sample This is one of the most extensive skeletal collections, with body weights at death, somatotype photographs, cause of death, sex, age, and other statistics Forty-three specimens were used with about equal numbers from each sex Excessively emaciated or obese individuals are eliminated as well as those over the age of 50 yr For comparison several specimens of orangutan (*Pongo*) and chimpanzee (*Pan*) with known body weights are measured

The sagittal and transverse diameters of the last thoracic and last lumbar centra are taken on the cranial surface and at the middle (corresponding to Martin measurements numbers 4, 6, 7 and 9)[8] The average of the four sagittal diameters is multiplied by the average of the four transverse diameters forming an approximation of the cross-sectional area of the centrum The regression formula

$$\log (\text{weight}) = 0\ 603\log (\text{vertebra}) + 1\ 085$$

has a correlation of 0 69 (Fig 1)

Using this formula the body weight of Sts 14 is estimated to be 27 6±10 5 kg (60 8±23 0 lb) and that of SK 3981, 36 1±10 7 kg (79 3±23 5 lb)

These weights are probably close to the minimum for their taxa The Sts 14 specimen (*A africanus*) is one of the smallest known from Sterkfontein although its estimated body weight is similar to estimates made by other investigators using different methods[1-5] The estimate of body weight for the Swartkrans hominid (*A robustus*) is also probably close to the minimum for that taxon but close to the predictions made by other authors[1-3] It is much smaller than the 68 1–90 8 kg (150–200 lb) estimate derived by Robinson[5] The latter estimates seem excessively heavy since even using the great apes as models, the fossil remains are not consistent with such large weights Figure 1 shows that *Pan* and *Pongo* vertebrae are close to the human regression line Even some of the largest hominid postcranial remains from Swartkrans do not correspond to Robinson's minimum estimate For example, of 14 *Pan* femora measured, the size of the SK 82 femur corresponds to an individual weighing 41 6 kg (91 5 lb) SK 97 is only slightly larger If Robinson's estimates are correct, then the ratio of minimum posterior dentition surface area to body weight in *A robustus* would only be about half that found in *A africanus* which is just the reverse of what is expected[4,9] The other postcranial fossils of the South African *A robustus* indicate a body size smaller than 150 lb (ref 3)

If these body weight estimates are representative and reasonable minima, then the brain to body weight ratios can be calculated with more security than was possible before There are several methods of comparing brain size and body weight Using Holloway's[10] estimates of endocranial volumes (442 cm[3]

for *A africanus* and 530 cm[3] for *A robustus*), the encephalisation quotient[11] is 4 0 for *A africanus* and 4 0 for *A robustus* (compared with *Homo* = 7 1 and *Pan* = 2 5) The index of progression[12-14] is 16 4 and 16 6 in the two fossil forms (*Homo* = 28 8 and *Pan* = 10 4) The constant of cephalisation[12,15] yields values of 42 0 and 47 4 (*Homo* = 103 5 and *Pan* = 35 5) Finally the extra neurone index[16] gives 3 9 billion and 4 4 billion (*Homo* = 8 5 and *Pan* = 3 6)

Figure 2 presents these indices of encephalisation as percentage deviations from *H sapiens* Although there is considerable debate about which of these indices allows the most meaningful comparisons[11-18], a general pattern emerges the two forms of South African early hominids are similar to one another and intermediate between *H sapiens* and *Pan* although much closer to the latter These findings do not support the view expressed by Holloway[19] that the australopithecine brain bears the same relationship to body weight as it does in modern humans The relative size of the brain in these early hominids is very small These fossil forms can be characterised as relatively small-brained but bipedal hominids, a grade in human evolution predicted in general by Darwin, and specifically by Haeckel, in which upright posture precedes brain expansion[5,7,20,21]

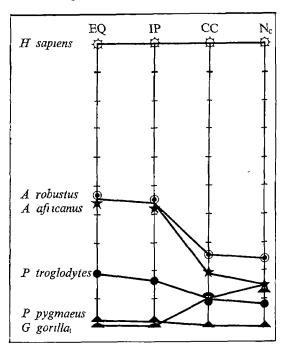

Fig 2 Encephalisation indices expressed as percentage difference from *H sapiens* Comparative data derived from various sources[11-16] EQ, encephalisation quotient[11], IP, index of progression[12-14], CC, constant of cephalisation[12,15], N_c, extra neurones[16]

How the cerebellum could memorise movements

THE neurones of the cerebellum are arranged in an extremely regular fashion and their synaptic connections are known in detail[1], this has led to considerable speculation about the functioning of these neuronal circuits In particular, following a proposal that the cerebellum is involved in the learning of movements[2], there have been a number of theories about how the cerebellar circuitry could be used in this way[3-5] These theories are all based on the postulate that the signals relating to motor output which are to be stored in the cerebellum have been computed in the cerebral cortex, and transmitted from there to the cerebellum for storage They assume that the initial learning process, during which the animal learns to produce motor outputs with favourable consequences for itself, takes place somewhere in the cerebral cortex and not in the cerebellum only after the cerebral cortex has learned how to generate these motor outputs is the information for their production stored in the cerebellum Recent results suggest, however, that this postulate is incorrect, and that the cerebellum is directly involved in the learning of motor actions which have satisfactory consequences for the animal To account for these results I describe a new way by which the cerebellum could be used for storing information relating to movements

A previous theory[5], which followed an earlier one about learning in single Purkyne cells[3], showed how groups of Purkyne cells arranged as in Fig 1 (called a unit) could be used for this information storage The learning process was postulated to occur by changes in the strengths of the parallel fibre synapses on the Purkyne cells in a unit when the climbing fibres fired It was demonstrated that a unit could learn to respond with a certain output (that is with a particular frequency of firing in the nuclear cell) to a certain parallel fibre input (that is a specific pattern of frequencies of firing in the parallel fibres) This output would then cause movement in a muscle and sensory feedback would create a new pattern of firing in the parallel fibres If the unit had learned to respond to this new input then a new output would be produced and the movement would progress in this manner

This method of memorising movements assumes, however, that the animal already knows how to perform the movements, and can send the appropriate signals required for a movement from the cerebral cortex, by way of the climbing fibres, to be stored in the cerebellum An alternative scheme is suggested by work on the nucleus locus coeruleus Thus it is known that axons from the noradrenaline-containing cells of the locus coeruleus contact Purkyne cells in the cerebellum[6] (as shown in Fig 1), and that stimulation of the locus coeruleus cells inhibits the firing of Purkyne cells[7] Furthermore, the locus

coeruleus is connected with the reward, or positive reinforcement, system of the brain in that it will support intracranial self-stimulation behaviour[8]

Therefore the locus coeruleus could be used in the consolidation of the motor signals stored in the cerebellum This would be done in the following manner When a movement was carried out the changes in synaptic strengths would be the same as those described above, but they would not be made permanent unless a signal was sent by means of the locus coeruleus axons to the Purkyne cells in a unit indicating that the outcome of the movement was satisfactory and that the movement was suitable for storage This signal is presumably caused by increased rates of firing of locus coeruleus cells which then release larger quantities of noradrenaline at their synapses on the Purkyne cells The release of noradrenaline has been shown to lead to the phosphorylation of membrane protein in guinea pig cerebral cortex[9], and the requisite changes in strengths of parallel fibre synapses could possibly be mediated in this fashion in Purkyne cells Although the immediate effect of noradrenaline is to inhibit the firing of Purkyne cells[7], a mechanism like this could lead to a long term increase or decrease in synaptic strengths Crow[10] has proposed that the noradrenaline system could be used for transforming short term synaptic changes into long term changes Because a motor action would be made up by a sequence of outputs from the units of Purkyne cells, there would probably be a signal requiring the synaptic changes corresponding to a number of these outputs to be made permanent simultaneously As the synaptic changes at a parallel fibre synapse required for the storage of successive outputs are additive[5], there is no difficulty in constructing biochemical models for this type of memory storage

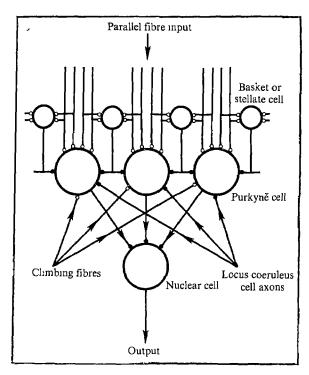
Figure 2 shows the different stages involved in the learning process For long term memory, signals are required at a synapse from three separate sources The initial short term


Fig 1 The diagram shows the arrangement of the cells in one of the units involved in memorising movements Each unit contains a large number of Purkyne cells which project to the same nuclear cell, or group of nuclear cells[5] Every Purkyne cell receives excitatory inputs from as many as 200,000 parallel fibres, and inhibitory inputs from basket and stellate cells[1] The Purkyne cells are also contacted by climbing fibres and fibres from locus coeruleus cells The unit can learn to respond to different parallel fibre inputs with specific frequencies of firing in the nuclear cell, through appropriate changes in the strengths of the parallel fibre synapses

**Fig 2** The proposed scheme for the storage in the cerebellum of information relating to movements is shown Initially a movement is carried out through signals from the cerebral cortex These signals cause climbing fibre signals in the memorising units of the cerebellum projecting to the muscles involved in the movement The simultaneous firing of the parallel and climbing fibres produce changes in the parallel fibre synapses on the Purkyne cells giving a short term memory of the movement Only if the movement is judged to be satisfactory will a signal be sent from the locus coeruleus to convert the memory into a long term form

changes in strength of synapses are produced in the cerebellum by the conjunction of signals from two of these sources transmitted by the parallel and climbing fibres The synaptic changes take place at the parallel fibre synapse and it is the parallel fibre input to the cell which is used for the memory recall process The climbing fibre input has a different role it specifies the times at which motor outputs are to be memorised by a unit and later recalled during the learned movement It was originally postulated[5] that the climbing fibre could transmit signals of differing magnitude so that the unit could learn to fire with different output frequencies (this accounted for the observed changes in the frequency of firing of cerebellar nuclear cells during the performance of learned movements[11]) Recent observations of climbing fibre signals during the learning of movements[12] do not, however, support this postulate With the present memorising scheme it is only necessary for a climbing fibre to send signals of one magnitude and cause only one output frequency of firing to be learned by the unit (the memory capacity of a unit is very similar in this situation) If this frequency were not sufficient for the muscular action at a certain point in the movement then a second signal could be sent the next time the movement was practised, and this could be repeated until the movement was judged completely satisfactory The changes in strength at the parallel fibre synapses are not made permanent and converted into a long term memory until a signal is received from the locus coeruleus If the motor output is unsatisfactory and no signal is received then the short term changes in the synaptic strength will decay to zero and there will be no memory of this motor output Presumably the spontaneous firing of climbing fibres about 1–2 times per second[1] causes short term changes of this type which are not consolidated into long term changes

Evidence for this proposed role of the locus coeruleus in the learning of movements comes from a study[13] on the effect of locus coeruleus lesions in rats These lesions abolished the ability to learn to run with increased speed for a food reward, while causing no apparent motor deficit Similarly it has been shown[14] that depletion of brain catecholamines produces a severe impairment in the learning of a complex motor sequence, though once the task is learned there is no retention defect

Various parts of the brain besides the cerebellum are involved in the production of movements, and therefore these studies show that the locus coeruleus may be involved in learning elsewhere in the nervous system This is also indicated by the

widespread distribution of terminals from locus coeruleus cells to regions other than the cerebellum[15]

In conclusion, the cerebellum seems to be a favourable system for studying the neuronal circuitry associated with short term and long term memory The failure to demonstrate learning in the cerebellum at the cellular level[16] could have resulted because no account was taken of the locus coeruleus in these experiments

Acceptance of novel flavours is increased after early experience of diverse tastes

WE believe that the more an animal experiences diversity of flavours at one time the more it will accept novel flavours later Thus, rats given several distinctive flavours early in life would be more likely to accept an unfamiliar flavour later than would rats whose early gustatory experiences have been less varied This hypothesis has had some empirical support in the literature Kuo[1], for example, mentions pilot research suggesting that cats, dogs and mynah birds raised on restricted diets for

extended periods avoided new food, while others of their kind reared on varied diets ate novel foods readily We have now found a similar effect with rats using flavoured solutions rather than solid foods

The basic experimental plan (Table 1) was to expose mature and immature albino and hooded male rats (equally divided between ages and conditions) to either one or several flavours in the 'training' phase of the study Thus, for mature and immature rats alike, each of three groups was restricted to a single flavoured water to drink with its food for the 12 d of training, while a fourth group received all three of these flavours, one at a time, during the same period A further group of immature rats was given tap water during training The appropriate solutions and Charles River chow were available throughout the study After a 2-d interim of water following training, the rats were given a choice between tap water and a novel chocolate solution for 10 d During these two-bottle tests, as during training, the rats were never without food and drink except for the time it took each morning to weigh the animals, record the liquid consumed (to nearest 0 5 g) and refill the bottles to a common level (each holding more than the rat could consume in 24 h) A series of identical tests, lasting 6 consecutive days, was conducted a month after the initial block of tests, the rats being given tap water during the interim Individually caged, the rats were naive at the start of the experiment with respect to the training and testing flavours, which all consisted of 30 parts tap water to 1 part flavour by volume (All flavours were of an imitation variety (Kroger brand), except for the test flavour which was a pure chocolate extract) The solutions, given at room temperature were refreshed periodically The right-left position of the test bottles was changed after each day's weighing and refilling

The main results for each age category are given in Figs 1 and 2, which present the mean percentage of chocolate solution

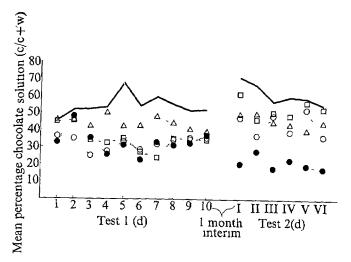

Fig 1 Mean percentage chocolate solution consumed by immature rats (10 per group) Mean percentages of chocolate drunk over all test days test 1, tap water (●) = 0 33, rum (□) = 0 35, black walnut (○) = 0 36, vanilla (△) = 0 44, varied (—) = 0 56 test 2, tap water = 0 21, black walnut = 0 44, vanilla = 0 45, rum = 0 53, varied = 0 62 (Symbols are the same for both tests) Mean amount (g) of solution consumed in training (given first) and test 1 black walnut (23 7, 46 7), rum (21 7, 49 9), vanilla (25 7, 44 2), varied (26 8, 49 6), tap water (24 8, 39 8) The experiment was repeated with immature rats using maple rather than chocolate A 30/1 solution of Kroger's imitation maple proved to be too palatable, with all of the groups, restricted and varied alike, drinking large proportions of the novel flavour When the concentration of maple was increased to 10/1 midway through the first test series, the curves separated, with the varied group holding at a high level of maple consumption and all of the restricted groups declining noticeably for the duration of the tests This illustrates the importance of using test flavours of only moderate to low 'natural' palatability so as not to obscure any training effects which might otherwise be there

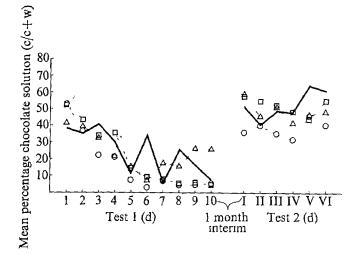

Fig 2 Mean percentage chocolate consumed by mature rats (nine per group) Mean percentages of chocolate drunk over all test days test 1, black walnut = 0 16, rum = 0 21, varied = 0 25, vanilla = 0 29 test 2, black walnut = 0 38, vanilla = 0 49, rum = 0 52, varied = 0 52 Mean amount (g) of solution consumed during training (given first) and test 1 black walnut (43 3, 51 8), rum (43 2, 49 5), vanilla (49 1, 46 7), and varied (49 8, 48 4) The symbols are as in Figure 1

consumed in each of the initial tests (1–12) and in the second series (I–VI) given 1 month later Individual scores were transformed (arc sin√preference ratio) before statistical analysis to normalise the distribution Basic to the design was our belief that relative consumption of the novel solution would be greatest by the 'varied group' trained on all three flavours The prediction was borne out for the immature rats (Fig 1) analysis of results for the first series of tests showing a significant training effect across training conditions $(F = 2 72, d f = 4,45, P < 0 05)$ but not over blocks of test days $(F = 1 33, d f = 4, 180)$ A significant training effect allowed us to compare individual training conditions over all days in test 1 by a Newman–Keuls procedure[2] All restricted groups, including the water controls, drank significantly lower percentages of chocolate solution than did the rats trained on three flavours $(P < 0 05)$ If a percentage of 0 50 or higher indicates a preference for chocolate, then only the varied group showed a slight to moderate preference for this novel flavour on several days of test 1 This is reflected in the overall averages reported at the bottom of Fig 1, with the highest mean percentage of 0 56 in test 1 for rats trained on a variety of flavours The intermediate mean of 0 44 for the vanilla group was significantly different $(P < 0 05)$ from the water control (0 33), but not from levels reached by the other restricted groups (rum = 0 35 and black walnut = 0 36) This suggests that vanilla and chocolate taste more similar to rats than do any of the other training flavours and chocolate

Results of the second series of tests for immature rats underscore the earlier finding, that is, relatively greater consumption of chocolate solution by the group that experience diversity of flavours early in life $(F = 3 39, d f = 4,45, P < 0 05)$ A significant main effect was found over blocks of test days $(F = 6 36, d f = 2,90, P < 0 01)$, with individual comparisons showing the varied group to have drunk significantly higher percentages of chocolate solution on days I–IV than its restricted counterparts $(P < 0 05)$ In addition, all curves for the flavour-trained groups were well above the level reached by the water control rats for the entire test period $(P < 0 01)$ This uniformly low consumption of chocolate in the control condition may reflect the impact of even a modest degree of diversity (be it a single training flavour) on later retention or augmentation of such preferences

The results for the mature rats (Fig 2) are unlike those for the immature subjects Most importantly, these groups of rats trained at an older age did not differ from one another in test 1

($F = 1 22$, d f $= 3,32$), though they all showed, more or less, a steady decline in percentage of chocolate consumed over the 10-d test period ($F = 28 21$, d f $= 4$, 128, $P < 0 01$) When retested a month later, the chocolate consumption of all groups increased from that at the conclusion of test 1, approaching levels attained by rats trained when immature (comparison of test 2 in Figs 1 and 2) As in the initial tests, however, the mature groups did not differ from one another in test 2 ($F = 1 87$, d f $= 3,32$) in a manner consistent with our hypothesis The mature rats, as a whole, more than doubled their mean percentage intake of chocolate solution from test 1 to test 2 (from 0 23 to 0 48), while the immature rats increased much less (from 0 41 in test 1 to 0 51 in test 2)

Finally, the average daily amounts of flavoured solution consumed by all groups during the training and first testing phases of the experiment are presented in the captions of Figs 1 and 2 For the immature rats, there seems to be a slight positive relationship between the amount of training flavour consumed and the percentage of chocolate drunk in testing, with the vanilla and varied groups ingesting the most chocolate and the most training solution But although these two groups drank similar amounts during training, the varied group consumed proportionately more of the chocolate during both test periods than did the vanilla group

Table 1 Summary of experimental design and procedure

Age (d)						
(Immature)	25–36	37–38	39–48	49–79	80–85	
(Mature)	65–76	77–78	79–88	89–119	120–125	

Group	n	Training	Interim	Test 1	Interim	Test 2
Restricted	10/9	Black walnut	T a p w a t e r	24-h choice of novel chocolate solution or tap water	T a p w a t e r	24-h choice of chocolate solution or tap water
Restricted	10/9	Rum				
Restricted	10/9	Vanilla				
Varied*	10/9	All three				
Control†	10	Tap water				

*The flavour solutions for this group were varied every 2 training days, such that some rats received black walnut for the first 2 d, then 2 d each with rum and vanilla, others were given rum, vanilla and black walnut, and still others, vanilla, black walnut and rum, each order repeated for the duration of training Each of the other groups was restricted to a single flavour (either black walnut, rum or vanilla) or tap water for the entire training period

†This condition was included after the main study was completed It serves as an additional comparison group (the most restricted of all) from which to gauge the effects of training A comparable group of mature rats was not used because of the general ineffectiveness of training for these animals

‡A 'novel' flavour is operationally defined here as one to which the animal had not been exposed before Of course, it may well taste like something the rat had had, and this is the reason for the design used here Since all the flavours experienced by the varied group are represented in separate experimental conditions any differential effects found relating to the dimensions of diversity and restriction should reflect something more than a simple generalisation (or summation of generalisation) from training flavour(s) to test flavour(s)

Our findings show that young rats will accept an unfamiliar flavour more readily if their early taste experiences are varied rather than restricted Furthermore, the effect seems to persist into maturity, at least for the conditions described here A comparable effect was not found for rats who were older at the start of training These rats did show, however, a dramatic decrease in chocolate consumption during test 1 and a subsequent (sustained) increase in test 2 Though we have no satisfactory explanation, a commonsense account of these results suggests simply that the older rats, treated as they were in this experiment, first tried chocolate, tired of it after a day or so, and then rebounded a month later because of their earlier (non-aversive) exposure to it Obviously this is more description than explanation and additional research is needed before more can be said

Our results suggest something different from what is

ordinarily implied by the concept 'stimulus' (that is, 'taste') generalisation, or the related concept of 'summation of generalisation' This is we believe for two reasons first, the effect was found only with immature rats (thus it is age-dependent), and second, none of the flavour-restricted immature rats, especially the water controls, reached the high levels of chocolate consumption shown by those trained on all three flavours—either during the immediate tests or a month later In some sense, more flavours were familiar to these latter animals than to their more gustatorily sheltered counterparts This is in keeping with an interpretation based on the notion of 'transfer of diversity', whereby the animal's earlier experiences (maybe at some 'sensitive' period in life) either do or do not prepare it for diversity or unfamiliarity later on[3,5]

Independence of channels in colour contrast perception

IN the perception of brightness the responses from all three classes of cone in the human eye are pooled Evidence from recent electrophysiological measurements[1], however, indicates that the contrast detected by a particular colour channel is assessed independently of the summation Specifically, the existence of a red sensitive channel in which this occurred was demonstrated

In the course of experiments concerned with the effectiveness of displays for use in aircraft cockpits[2,3] we have compared the performance of subjects viewing red and green displays in a background of very high illuminance (10^5 lx) The results of these experiments, conducted in very different conditions at a much higher illuminance, support the suggestion of at least one visual colour channel in which contrast is assessed to some extent independently of other channels These results also have important implications in the field of display design

Each subject read two sets of 36 numbers and letters (each set forming the complete alphabet plus the numbers 0 to 9) presented singly in random order The vertical dimension of the characters subtended $0 3°$ at the eye A complete set in one colour was read before the colour was changed Alternate subjects saw the colours in the reverse order and the results were averaged in order to eliminate learning or fatigue effects The characters were back projected on to a small aperture in a screen in the high illuminance apparatus described previously[2] The screen is white in the upper half plane and black in the lower and thus simulates the conditions of an aircraft cockpit Each character had a luminance of 100 cd m⁻² and was presented for $0 7$ s Care was taken to balance the luminances of the red and green displays (peak wavelengths 660 and 560 nm respectively) and this was achieved to within 17%

More than 120 subjects participated in the experiment, of whom 68 (55 male, 13 female) were free from visual defects The results for these 68 subjects, expressed as an average error rate per subject are shown in Table 1 from which it is evident that the error rate for the green display was approximately

Table 1 Error rates for reading characters of different colours

	Error rate (%)	Omission rate (%)
Red display	5 8	1 1
Green display	15 9	5 6

Relative error rates for 68 observers (average age 31 5 yr) without visual defects, viewing red and green displays of equal luminance in an illuminance of 10^5 lx. The error rate includes characters wrongly identified and those for which no identification was offered (omissions)

3 times that for red This finding is statistically significant at the 0 05% level

Since the red and green displays were of equal luminance and the background illumination was the same for both, the contrast, considering total radiation, was the same for each display Thus the large difference in error rates found in this experiment is consistent with the existence of one or more colour channels in which contrast is assessed independently of the assessment of the overall brightness

We have estimated the ratio of the contrast in the red channel to that in the green channel although such calculations involve considerable uncertainties Two approaches were used For the first, we used the data of Wald[4] for the action spectra of the red and green cone pigments These data are supported by later results[5] which give similar ratios (within 25%) of red to green cone response over the range of measurement (540-640 nm) Although the response to the red display was found to be exclusively associated with the red cones, the response to the green display was divided fairly evenly between the red and green cones (42 58) The effect of the background illumination was somewhat higher for the red cones (56 44) A comparison of the response of the red cones to the red display with that of the green cones to the green display, allowing for the different responses of these receptors to the background, showed the contrast in the red channel for the red display to be higher by a factor of 1 35

The second estimate was based upon the high intensity colour mechanisms of Stiles[6] and this calculation showed the contrast for the long wavelength mechanism π_5' when the red display was viewed to exceed that of the π_4' mechanism viewing the green display by a factor of 1 80

Both of these estimates seem to be rather low to account for the large difference in error rates They should be regarded as tentative, however, reflecting the difficulties of obtaining separate spectral responses for colour vision receptors as well as differing experimental conditions

These considerations do not affect the conclusion that the large difference in error rates is consistent with the independent assessment of contrast in one or more colour channels and which therefore lends support to Regan's findings Similar conclusions are emerging from response time experiments at present being conducted in this laboratory[7]

A complete account of these and related experiments including details of the variation of performance with age, display format and character fount, is in preparation It is, however, worth mentioning that the consequences of the results given here for cockpit displays are of some significance There is a popular belief that green displays are likely to be superior to red "because the eye response peaks in the green" Our results show that in very high ambient illumination this belief is ill founded and it is more difficult to make an effective green display.

Inhibition and disinhibition of direction-specific mechanisms in human vision

MOTION-SENSITIVE mechanisms in human vision are selective for direction of stimulus movement Psychophysical experiments reveal direction-specific channels which can be selectively desensitised or adapted[1,2] At threshold these direction-specific mechanisms operate independently, they have little or no sensitivity for the opposite direction of motion[3-8] Independence at threshold does not, of course, preclude interaction at suprathreshold stimulus levels Indeed, inhibition has been found above threshold between otherwise independent spatial frequency-specific mechanisms[7,8], orientation-selective mechanisms[9,10], and binocular disparity-specific mechanisms[11] We report here comparable measurements of inhibition between direction-specific channels We also show that in appropriate conditions the inhibition can itself be reduced or eliminated, a disinhibition effect

To search for direction-specific inhibition at suprathreshold levels, we used a composite adaptation method[7,8] The term 'adaptation' refers only to the elevation of detection threshold produced by exposure to an appropriate high contrast stimulus, we make no assumptions as to the processes underlying adaptation[12,13] Contrast is defined as the peak-to-trough luminance amplitude of a grating divided by twice the average luminance Stimuli were vertical sinusoidal gratings created on a cathode ray tube, using a television technique[14] (10° square raster, average luminance 3 4 cd m^{-2})

Thresholds for a moving grating were measured following adaptation to either a high-contrast grating (same spatial

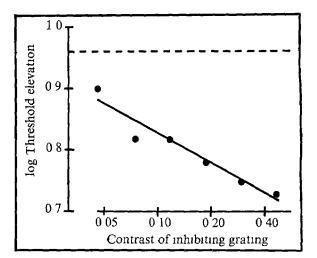

Fig 1 Threshold elevation (1 75 cycles per degree, 7 9 Hz) for a rightward-moving test grating as a function of the contrast of a leftward-moving inhibiting grating Contrast is specified separately for each component of the composite adaptation stimulus Zero log threshold elevation represents the threshold for the rightward test grating after simple light adaptation (a zero contrast adaptation stimulus) The dashed line indicates threshold elevation produced by the rightward-adapting component alone Each point is the mean of six measurements (s e < 6%) The slope of the solid line (fitted by least squares) is significantly less than zero ($P < 0 005$) Gratings were made to drift using motor-driven synchro-resolvers[15] Viewing was monocular and foveal, fixation was carefully maintained A session began with 3 min continuous exposure to an adaptation stimulus Every 4 s thereafter the adaptation stimulus was replaced for 1 s by a test grating of variable contrast The observer adjusted a potentiometer to reduce the contrast of the test grating until it was just indistinguishable from a uniform field of the same average luminance

frequency and drift rate as the test) moving in the same direction as the test grating, or the same high-contrast grating to which had been linearly added another grating, moving in the opposite direction An adapting stimulus which drifts in the same direction as a test grating (that is, the first type of adaptation stimulus) elevates test threshold, an adaptation grating which moves in the opposite direction (when presented alone) also elevates test threshold, although the amount of elevation is considerably less than is produced by a same-directional grating of equal contrast[1,2] One might expect these individual adapting effects to sum when a composite adaptation grating (the second type of adapting stimulus) is used We have found, on the contrary, that addition of the opposite-directional grating gives less threshold elevation than does the same-directional grating alone This constitutes an inhibitory effect

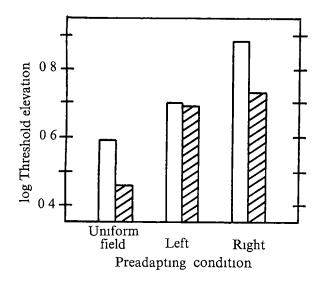

Fig 2 Demonstration of disinhibition Threshold elevation (1 75 cycles per degree, 7 9 Hz) for a rightward-moving test grating produced by adapting to rightward movement alone (open columns) or to rightward plus leftward movement (hatched columns) is shown separately for each preadapting stimulus The bars are means of 12 measurements, s e < 6%

Figure 1 shows the log threshold elevation for a test grating moving to the right as a function of the contrast of an inhibiting component (opposite direction) of the adaptation stimulus The contrast of the adapting grating drifting to the right was fixed at 0 23 As the contrast of the opposite-directional component moving to the left increases, threshold elevation is reduced The maximum inhibition effect is just over 0 2 log unit Increasing the contrast of the component moving to the left reduces the adapting power of the grating moving to the right The leftward grating seems to inhibit the activity of the rightward component Similar data have been obtained at other spatial and temporal frequencies and with a second observer The measurements have been verified under conditions of forced-choice testing as well

These results show that direction-specific mechanisms can inhibit one another We should also expect to see a related phenomenon, disinhibition, a reduction in the amount of generated inhibition when the inhibiting channel has itself been desensitised Disinhibition is generally regarded as occurring when the original inhibition-generating channel is itself inhibited by a third channel This is clearly impossible in the present experiment, since stimulus orientation must be held constant at vertical, and only two oppositely-tuned direction-specific channels may be considered Disinhibition by adaptation of the inhibiting channel, however, should produce the same result, and can provide at least as much information about the inhibitory process

To demonstrate disinhibition, we measured inhibition as above, but preadapted the inhibiting channel by exposure to its preferred direction of movement For a test grating moving to

the right, the inhibiting component of the adapting stimulus moves leftward, the preadapting grating, then, must also move to the left The direction-specificity of the adaptation process[1,2] ensures that the preadapting stimulus will desensitise the leftward, inhibiting channel much more than the rightward, adapting channel This should reduce the amount of inhibition exerted by the leftward mechanism on the rightward

Each adaptation period was divided into two intervals, each of 1 s duration and continuously alternating throughout the experimental session The first sort, a preadapting interval, was filled either with a leftward-moving preadaptation grating (contrast 0 46) or with an unmodulated field at the average luminance During the second, the inhibition interval, the observer viewed either the rightward-moving adapting grating (contrast 0 23) or the same adapting stimulus plus the additional leftward-moving inhibition grating (contrast 0 46)

When the preadaptation stimulus was a uniform field (Fig 2) a sizeable inhibition effect could be measured (about 0 13 log unit reduction in threshold elevation, $P < 0 001$, two-tailed t test) After preadaptation to the leftward-moving grating, however, no inhibition occurred ($P > 0 5$) To verify that this change did not result from the presence of any grating at all during the preadapting interval, we also preadapted to a rightward-moving (same-directional) grating (contrast 0 23), and obtained 0 16 log unit of inhibition ($P < 0 001$) Disinhibition seems to depend on preadaptation in the inhibiting direction (opposite to test direction)

This demonstration of disinhibition shows that the inhibition effect is not an artefact of nonlinear signal summation, either in the apparatus or in early stages of the visual system Across all three types of preadaptation stimulus shown in Fig 2, the configuration of the adapting and inhibiting gratings remained constant The only changes were in the adaptive states of the observer's direction-specific mechanisms Nevertheless, the inhibitory effect was eliminated in one condition Thus, the inhibition effect cannot result from physical peculiarities of the composite stimulus

Direction-specific neurones are known to be abundant in cat and monkey visual cortex[16-20] A direction-specific cell discharges strongly when stimulated by movement in one, preferred direction, the same cell fails to fire, or discharges at less than its maintained rate, when stimulated by movement in the opposite direction Such reduction in a neurone's response to movement in its non-preferred direction can repiesent an active inhibitory process[21-23] The inhibition may be generated by other cortical cells, with different direction preferences[24] The present psychophysical demonstration of inhibition between human direction-specific mechanisms is thus compatible with the hypothesis that human direction-specificity is mediated by directionally selective neurones in human visual cortex

Genetic control of haploid parthenogenetic development in mammalian embryos

THE establishment of haploid cell lines in mammals would be of value for studies on developmental biology, genetics and carcinogenesis It should be possible to produce such lines by culturing cells from haploid parthenogenetic embryos Only a limited degree of haploid parthenogenetic development has been obtained with mammals[1-4], possibly as a result of the effects of deleterious recessive genes in haploid cells During the process of selection necessary to produce an inbred strain of animals, there may be a reduction in the number of deleterious genes Haploid embryos from random-bred animals that have not been subjected to the selection that occurs in inbreeding may, therefore, have a lower development potential than haploid embryos from an inbred strain To test this possibility, we have compared the development of haploid embryos from one inbred strain of golden hamsters with random-bred animals and have found better development of haploid embryos in the inbred animals

We used an inbred strain (LSH/SS) and random-bred golden hamsters, because embryonic hamster cells can be readily transformed into cell lines by various viral, chemical and physical agents[5,6] and their chromosomes can be easily identified Parthenogenetic development has been induced in the mouse by electrical stimulation of the oviduct after superovulation with gonadotrophins[3,4] This technique also induces a high frequency of parthenogenetic development in hamsters

The frequency of haploids and diploids was determined in parthenogenetically developing eggs at the single cell pronuclear stage, 10–12 h after electrical stimulation, and in embryos with more than two cells at 72–74 h after stimulation (Fig 1) About 60% of the eggs were activated in both the inbred and random-bred hamsters at 10–12 h as determined by the presence of one or two pronuclei At 72–74 h, about 30%

Table 1 Activation rate, egg development and haploid–diploid ratio, at 10–12 and 72–74 h after electrical stimulation of the oviducts of random-bred and inbred hamsters*

Time after electrical stimulation (h)	Random-bred or inbred animals	No of females	Total no of eggs examined	No of embryos Two-cell	No of embryos More than two-cell	% Activated eggs or embryos per animal† Cells with pronuclei	% Activated eggs or embryos per animal† Embryos with two or more cells	% Non-activated eggs per animal†, ‡	Haploid–diploid ratio§
10–12	Random	5	96	0	0	57 7 ± 10 2	0	13 5 ± 4 4	3 2 1
10–12	Inbred	5	189	0	0	59 6 ± 9 0	0	7 2 ± 3 4	1 8 1
72–74	Random	26	725	107	65	0	25 5 ± 4 5	34 1 ± 5 4	0 2 1
72–74	Inbred	11	349	81	47	0	33 5 ± 4 4	24 4 ± 5 5	1 7 1

* Females (7–12 week old) from random-bred and the LSH/SS inbred strain of golden hamster, were superovulated by intraperitoneal injections of 25 IU of pregnant mare's serum gonadotrophin followed 48 h later by 20 IU of human chorionic gonadotrophin (HCG) Females were anaesthetised with an intraperitoneal injection of 0 3–0 4 ml of a 24 mg ml^{-1} solution of Nembutal in physiological saline 19 5–21 h after the HCG injection

Eggs were activated *in situ* by electric shocks (50 V), as described for mouse eggs[3,4] The tips of two steel needles, which served as electrodes, were applied along the length of the ampullar region, and 20–25 shocks applied in rapid succession The animals were killed either 10–12 h or 72–74 h after treatment Their oviducts were removed and flushed with phosphate-buffered saline to collect the eggs or embryos Control groups without electrical stimulation were examined after superovulation and after Nembutal anaesthesia About 20% of these eggs from the controls developed pronuclei, but no two-cell embryos were observed When females were stimulated 15–16 h after HCG, only about 13% of the eggs isolated 72–74 h later were either two-cell or more advanced embryos Higher rates of activation were obtained when the oviducts were electrically stimulated 19 5–21 h after HCG, so that this time was used in the experiments Pronuclear eggs were cultured at 37 °C in NCTC 135 medium[10] with 10% foetal calf serum, under light paraffin oil in plastic Petri dishes in an incubator with 5% CO_2 in air The chromosomes of eggs were examined using an air-drying technique[11] in the first cleavage mitosis As with mice[12,13] all eggs which originally had a single pronucleus had a single haploid set of chromosomes, whereas those which originally had two pronuclei had a diploid first cleavage metaphase Cleavage embryos (8–9) beyond the two-cell stage recovered at 72–74 h after electrical stimulation, were examined after culturing for 2–3 h at 37 °C in phosphate-buffered saline containing 4 μg ml^{-1} colcemid The chromosome ploidy and cell number of these embryos was then determined The golden hamster has a normal diploid number of 44 chromosomes[14] Some 70% of the embryos with mitotic figures had two or more metaphase plates

† Eggs were only classified as activated if they had developed a pronucleus or had cleaved to the two-cell or later stage The percentages of activated and non-activated eggs or embryos per animal are given as the mean ± s e

‡ In the 72–74 h groups there were two classes of eggs Those which progressed to the first cleavage mitosis but failed to cleave to the two-cell stage, and those which were not activated These two classes could not be distinguished In all the experimental groups there were 30–40% degenerated eggs

§ In the 10–12 h groups, the ratios were determined both on the number of pronuclei present, one or two, and on subsequent chromosome counts The ratios in the 72–74 h groups were determined by chromosome counts on embryos that were more advanced than the two-cell stage In the 72–74 h groups, the ploidy could not be determined in 50% of embryos from the random-bred and 37% of the inbred animals, because there were no dividing cells

Table 2 Number of cells in embryos that had developed beyond the two-cell stage at 72–74 h

Random-bred or inbred animals	Haploid No of embryos	Haploid No of cells per embryo*	Diploid No of embryos	Diploid No of cells per embryo*	Embryos without cells in mitosis No of embryos	Embryos without cells in mitosis No of cells per embryo*
Random	4	7 0 ± 1 3 (4)	19	7 4 ± 1 1 (19)	23	7 1 ± 0 8
Inbred	17	6 8 ± 0 7 (17)	10	10 7 ± 1 2 (10)	16	5 7 ± 0 8

* Mean ± s e
Numbers in parentheses are numbers of embryos

Fig. 1 *a*, Parthenogenetically activated eggs from a random-bred hamster: three single-cell eggs with one pronucleus and one embryo at the two-cell stage 16 h after electrical stimulation ($\times$ 350). *b*, Diploid 16-cell parthenogenetic blastocyst from a random-bred hamster 72 h after electrical stimulation ($\times$ 250). *c*, Haploid metaphase plate from an 11-cell parthenogenetic morula from a random-bred hamster 72 h after electrical stimulation ($\times$ 1,500). *d*, Diploid metaphase plate from a 20-cell parthenogenetic blastocyst from an inbred hamster 72 h after electrical stimulation ($\times$ 2,500).

of the embryos were either at the two-cell or a more advanced stage. At both times there were 30–40% degenerated eggs. Since the proportion of degenerated eggs was not higher at 72–74 than at 10–12 h, this suggests that 30% of the activated eggs found at 10–12 h after stimulation failed to develop to the two-cell stage in both groups of animals and were indistinguishable from non-activated eggs. Although in previous studies with golden hamsters parthenogenetic development did not occur beyond the two-cell stage[7-9] we observed some well developed blastocysts with about 20 cells.

The ratios of haploids to diploids in the random–bred and inbred animals were 3.2:1 and 1.8:1 in the eggs at 10–12 h, and 0.2:1 and 1.7:1 in the embryos at 72–74 h, respectively (Table 1). The haploid to diploid ratio of eggs and embryos was, therefore, similar in inbred hamsters, with more haploids than diploids. In the random-bred animals, the ratio of haploid to diploid eggs was similar to that found in the inbred hamsters, but there was a much lower ratio of haploid to diploid embryos. The results indicate that in the random-bred animals, there was a block in more than 90% of the haploid eggs, so that they did not develop beyond the two-cell stage, but not in the inbred strain of hamsters (nor was there a block in two inbred strains of mice[3,4]). The average number of cells in embryos which had developed beyond the two-cell stage at 72–74 h, was about the same in both haploids and diploids (Table 2).

These results indicate that the development of haploid parthenogenetic embryos can be genetically controlled. The better developmental potential of haploid embryos from the inbred compared to the random-bred animals presumably results from a reduction in the number of deleterious genes occurring during the process of selection associated with inbreeding.

Polymer exclusion, cell adhesion and membrane fusion

FROM physicochemical studies on the adhesion of fibroblasts to synthetic substrata[1,2] I suggested that, in general, surface-bound polymers (for example adsorbed serum proteins) probably inhibit cell attachment because of their steric exclusion volume. This effect is well known in colloid science (Faraday used gelatin to stabilise gold sols[3]) but does not seem to be widely appreciated in cell biology. Thus, a recent review on the role of proteins and divalent cations in cell adhesion, viewed as a problem in colloid stability, discusses only charge repulsion and calcium bridging[4]. Furthermore, standard texts on the cell surface[5] present the classical DLVO (Derjaguin, Landau, Verwey and Overbeek) theory of charge repulsion against dispersive attraction, but omit the later development by Overbeek and coworkers of the principle that even uncharged surfaces, if covered by adsorbed polymer molecules, may repel each other[6]. I now show that steric exclusion by glycocalyx polymers on the plasma membrane would explain some recent observations on fusion and attachment, by a variety of cells. The term steric exclusion[3] comprises not only geometric exclusion by rigid molecules, such as rods and spheres, but also unfavourable thermodynamic parameters such as free energy, summed up over many segments, and, for random coil polymers, entropy resulting from the ability of each molecule to claim extra lebensraum by flexing its segments.

This model predicts mutual repulsion between two closely apposed membranes, because of the exclusion volumes of their respective glycocalyx macromolecules. Conversely, fusion should be facilitated if glycopolymers are cleared from between the two membranes, by lateral displacement, to appose the naked lipid bilayers. Such a mechanism of fusion, by 'the interaction and mixing of the disturbed lipid molecules of closely apposed membranes in regions denuded of intramembranous proteins and glycoproteins' has been proposed[7]. The steric exclusion model, developed independently from studies on cell adhesion (S. P. Pegrum and N.G.M., unpublished), provides a general physicochemical basis for these observations on fusion. For instance, in discussing the

role of cryoprotective solvents in the lateral aggregation of intramembranous particles, Ahkong *et al.*[7] concentrate on lipid effects, but exclusion implies interaction with the proteins of membranes. In terms of colloid chemistry, regarding the glycocalyx polymers as hydrophilic sols, such dehydrating solvents would be expected to cause their flocculation (for example, ref. 8). Moreover, the excluded volume for flexible polymers can be shown on general theoretical grounds[9] to decrease in poor solvents, because of the increased preference for segment–segment contacts over segment–solvent interactions. (In fact the lateral aggregation of polymer molecules on a fluid interface may be a convenient method for the study of such interactions.)

A different aspect of cell adhesion which suggests the importance of avoiding fusion is based on the observation that cells do not adhere to pure, solid hydrocarbon[1]. These experiments were originally carried out in serum, but have been extended to a protein-free medium[2], so that steric exclusion is not then a factor. In this medium cells attach and spread on condensed, rigid substrata with critical surface energy greater than 43 dyne cm^{-1} (ref. 1) that is, those presenting pure amide, hydroxyl, ester and acid groups—so why not methyl and methylene? At first sight the inertness of hydrocarbon might seem to lack biological relevance—it is well known that solid paraffin is not a natural substratum for cell adhesion. This result seems remarkable if one recalls that cellular tissues contain high concentrations of almost pure hydrocarbon, both solid and liquid, near the front line of adhesion—in the lipid bilayer. I conclude that, contrary to the basic postulate of DLVO theories for cell adhesion[5], the cell does not rely on non-polar, lipid–lipid interactions, because such interactions would lead to an increased probability of fusion between the hydrocarbon interiors of apposing lipid bilayers. Hence I postulate a model in which the mechanism of cell adhesion starts with two lines of defence against spontaneous and indiscriminate fusion of membranes—the first, steric exclusion by glycocalyx polymers; the second, reliance on polar, short range attractions rather than long range, non-polar dispersive forces.

Steric exclusion would also explain the low adhesivity of neutral, hydrophilic gels, such as agarose[1] or cross linked serum[10]. In a previous comparison of the supramolecular structures of agarose and collagen, I attributed the adhesivity of the latter both to the greater mechanical rigidity of its fibres and to their more substantial molecular packing[1]. Subsequent experimental data has emphasised the importance of molecular aggregation. With or without serum, adhesion to rigid agarose is greatly improved if the latter is first annealed, near its setting temperature, to produce dense, granular microaggregates; this method of clustering double-helical agarose molecules in close side-by-side association was suggested by Dr D. A. Rees (N.G.M., unpublished). Similarly, Gordon and Dingle found that preincubation of soluble collagen, to form submicroscopic fibrils, increases its binding by platelets in serum-free buffer[11]. I have found that increasing the concentration of a hydrophilic gel (sauflon polyvinylpyrrolidone; PVP) from 40% to 96% renders it adhesive for fibroblasts. These observations on the role of molecular clustering relate to preliminary reports, by Lyman and coworkers, that both thrombocytes and fibrocytes react to some microarchitectural or 'tacticity' difference between homologous copolymeric substrata[12].

They also suggest an answer to the problem of how cells overcome the exclusion barrier and adhere to polymer-coated surfaces. Divalent cations[4,13] and bridge-forming 'adhesion factors'[14] have been implicated, but longitudinal, that is, surface-to-surface, bridging does not explain one widespread feature of cell adhesion—the presence of dense, localised 'plaques'[15] and desmosomes. These structures imply a role for lateral bridging as well. Cells fixed by cross-linking with aldehyde (and thus, I presume, with their membrane proteins intact but incapable of lateral movement) bind more weakly, whether to collagen directly[11] or to each other by way of a bridging factor[14]. Lateral aggregation ('patching') is readily induced by lectin-like or antibody-like factors, in practice; but hitherto there has been no general reason to expect this as a feature of cell adhesion, in principle. The theory of excluded volume seems to provide a reason for the cell to concentrate glycocalyx polymers at the point of adhesion, because the excluded volume decreases as molecular crowding increases[9]. Since a large excluded volume depends on the possibility of molecules flexing[6], the formation of dense lateral aggregates in the glycocalyx would restrict this effect, especially if matched by a corresponding clustering of the substratum (as in the above experiments on hydrophilic gels). Thus the cell may require divalent cations not only as a bridge with the substratum but also for the aggregation of membrane particles into plaques.

This raises the question of adhesive interactions between plaque and substratum. Although positive charge improves adhesivity[10], the wide variety of non-physiological substrata, both negative[2] and neutral (agarose, PVP) implies bonding additional to that of fixed charge, on the one hand, or biochemically specific groups, on the other. Preliminary electron-microscope studies (with S. P. Pegrum) show direct contact and incipient fusion between membrane and substratum, in protein-free medium. These observations are more in agreement with Zisman's theory of adhesion as a process akin to wetting[1,2] and thus additionally subject to close-range but nonspecific forces, such as hydrogen bonds and hydrophobic bonds.

I conclude that a model of cell adhesion must possess the following general features, which depend on physical chemistry, in addition to biological specificity of the sort found in antibodies, lectins and enzymes: minimal attraction between the hydrocarbon interiors of two apposing membrane bilayers; preference for solid, polar substrata; membrane glycopolymers inhibit adhesion and fusion through their exclusion volumes; exclusion effect countered by dense, local aggregates in glycocalyx (as in hydrophilic gels); this allows 'adhesion as wetting', that is, through short range but nonspecific bonds. A model cell based on these principles would be architecturally both stable (because the first three protect crowded membranes from spontaneous fusion and indiscriminate adhesion) and flexible (because the other two allow localised attachment to a variety of substrata).

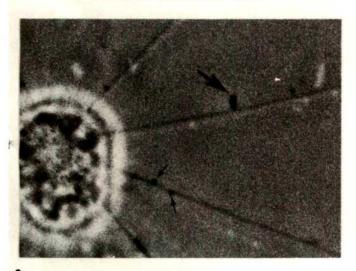
Possible involvement of the plasma membrane in saltatory particle movement in heliozoan axopods

THE suggestion that saltatory particle movements in heliozoan axopods, melanophores, nerve axons, as well as in other less specialised cells, are mediated by microtubules has been tendered[1-5]. This notion is based on morphological observations, and experiments demonstrating the cessation or alteration

of movement in response to colchicine, a drug which destroys microtubules[3,6-8]. Recent evidence, however, does not favour microtubules as the immediate driving force for such systems[9-10].


Heliozoans are suited to studies of intracellular movement, because the kinetocysts[11] which shuttle back and forth within their axopods do so with a readily definable sign and path. The axopods contain a straight rigid core of microtubules[11,12]. This report analyses the movement of kinetocysts in a heliozoan, and of bacteria, themselves non-motile, which occasionally adhere externally to the axopods. The results suggest that the plasma membrane, rather than the axonemal microtubules, may be involved.

Heterophrys sp., a small marine centrohelidian, was filmed at 10.25 frames per second At five frame intervals the positions of continuously moving kinetocysts and bacteria were determined. The points obtained were tested for goodness of fit to a regression line[13] of the form $y = a + bx$, where y represents particle displacement, a elevation, and x time. The regression coefficient b is then the best measure of particle velocity. To obtain enough points for an analysis of each displacement, only those movements which lasted at least 20 frames (1.8 s) were considered. The direction of movement, the distance traversed (d), and the approximate distance (D) of the particle from the cell body at the start of movement were also recorded.

Almost all of the displacements fitted a linear regression at the 5% significance level, indicating that, once in motion, the particles move with uniform velocity and thus their movements are clearly saltatory. The regression coefficients, however, ranged from 0.4 to 2.8 µm s^{-1} ($n = 47$), demonstrating that the speed varies strongly between displacements. Since b for several displacements of the same particle also frequently varied significantly, the velocity of a given particle cannot be related simply to its mass or density.

Comparison of the average velocities of centripetally ($b_{in} = 1.09 \pm 0.11$ µm s^{-1}, $n = 25$) and centrifugally ($b_{out} = 0.64 \pm 0.05$ µm s^{-1}, $n = 13$) moving kinetocysts showed that these were significantly different ($0.01 < P < 0.05$). The Behrens–Fisher test was used because the variances were found to be significantly different in an F test ($P < 0.001$). A one-sided hypothesis permits the conclusion that kinetocysts move faster inward than outward ($P < 0.025$). A correlation test and a regression analysis showed that b_{in} and the distance moved

toward the cytosome (d_{in}) are significantly positively correlated ($r = 0.6516$, d.f. = 23, $P < 0.001$) and fit well the expression $d_{in} = -1.10 + 3.72\ b_{in}$ ($P < 0.001$). Thus the faster the kinetocysts move toward the cell body, the longer are the distances traversed. No such correlation could be shown for centrifugally moving kinetocysts ($r = -0.4216$, d.f. = 11, $P > 0.1$). Additional correlation tests demonstrated that b_{in} and b_{out} and d_{in} and d_{out}, are not significantly correlated with D. Therefore, the velocity and path lengths of moving kinetocysts are independent of their position along the axopod at the start of saltation. Finally, tests of the null hypotheses, H_0: $d_{in} = d_{out}$ and H_0: $D_{in} = D_{out}$, were not significant. This supports the experimental technique, because they do not demonstrate a bias in the selection of inwardly and outwardly saltating particles with respect to their average path length or initial distance from the cytosome.

Although the data obtained for saltating bacteria were few, a significant correlation of b_{in} with d_{in} could be demonstrated ($r = 0.8890$, d.f. = 3, $0.02 < P < 0.05$). The expression for the regression of path length on velocity was $d_{in} = -1.08 + 4.42 b_{in}$ ($P < 0.05$). A correlation test of b_{out} and d_{out} was not significant ($r = 0.9019$, d.f. = 2, $P > 0.1$). Thus the kinetocyst and bacteria saltatory movements seem to be similar in character, both showing correlation of b_{in} with d_{in}, but not of b_{out} with d_{out}. The regressions of d_{in} on b_{in} for kinetocysts and bacteria were compared in an analysis of covariance[13]. No significant differences between their residual variances ($F = 0.72$, d.f. = 23, 3), slopes ($F = 0.22$, d.f. = 1, 26) or elevations ($F = 0.70$, d.f. = 1, 27) were found, showing that the regression lines are not significantly different.

The different average velocities and variances of centripetally and centrifugally moving kinetocysts, and the correlation of velocity with path length during inward, but not outward movements of both kinetocysts and bacteria, imply that two fundamentally different mechanisms are responsible for transport to and from the cell body. A similar situation exists in melanophores where aggregation and dispersion are known to be differentially sensitive to drugs[14,15]. The correlation of b_{in} with d_{in} also suggests that centripetal movement in axopods is an ordered process with elastic properties reminiscent of the snapping of a rubber band; the more the band is stretched before it is released, the faster and farther something attached to it will be moved. Centrifugal movement, in contrast, is unordered and wholly inelastic.

The microtubules of the axoneme can hardly be involved in saltation, for when they are destroyed by colchicine, similar movement continues, although not in straight lines (ref. 16 and D.T., unpublished). Since the kinetocyst and bacteria centripetal movements are statistically indistinguishable, it is possible that the forces motivating both are the same. The kinetocysts, however, move under the plasma membrane, whereas the bacteria are clearly extracellular, exhibiting unmistakable Brownian motion in the surrounding medium, especially when adherent at only one end (Fig. 1). If both types of particle are moved by the same mechanism, the possibility cannot be ignored that the probable site of force application is the plasma membrane itself, the only structure in common contact with kinetocysts and bacteria. Speculation that the membrane is involved receives support from a recent demonstration that the rate of area change and initial area of a triangle of plasma membrane delimited by three extracellularly adherent gold particles are correlated when the particles aggregate, but not when they disaggregate[17]. In other words, aggregating particles on the membrane move with precisely the same elastic qualities as shown here for centripetally saltating structures; particle disaggregation, like centrifugal saltation, is unordered.

Whether movement in axopods involves gradual autonomous stretching and subsequent elastic release of the membrane itself, or an interaction between membrane islands[17] or anchorages[18] and extrinsic contractile protein remains to be seen. That actin[19] and myosin[20] exist in other cells in an appropriate position to be capable of causing the kind of membrane-

Fig. 1 Frame from a film of *Heterophrys* sp. A bacterium (large arrow) adheres at its end to an axopod. The small arrows indicate kinetocysts. Phase contrast, ×3,400.

associated movement described here has already been shown. *Heterophrys* sp. was provided by Dr M. Hauser.

Tryptic destruction of aggregative competence in *Dictyostelium discoideum* and subsequent recovery

WHEN they reach the stationary phase, the vegetative cells of *Dictyostelium discoideum* become adhesive and form multicellular aggregates before forming fruiting bodies. In shaken liquid suspension they form aggregates in two stages[1]. First,

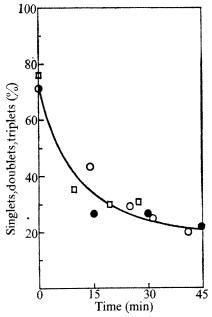

Fig. 1 Aggregates at the 15 h stage of fruiting body construction were harvested from filters in 17 mM K/Na$_2$ phosphate, pH 6.8, mechanically dispersed to a cell suspension by repeated forceful pipettings through a 10 ml pipette, and diluted to a density of 10^7 cells ml^{-1} in phosphate buffer containing the following additions: ○, no additions, ●, 2% v/v glycerol, 10 mM EDTA, 0.5 mg ml^{-1} type III trypsin (T, Sigma), 0.5 mg ml^{-1} type 1 S trypsin inhibitor (T I, Sigma); □, all of the previous additions plus 0.5 mg ml^{-1} cycloheximide (Sigma). Volumes (20 ml) of suspension in 150 ml Erlenmyer flasks were incubated at 22 °C on a rotary shaker at 110 r.p.m. At intervals samples were examined in a haemocytometer to determine the distribution of cells as either singlets, doublets, triplets or larger aggregates. A significant reduction in the first category was accompanied by an equivalent increase in the second.

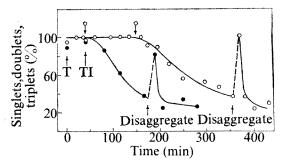
they produce loose amorphous clusters which, if deposited on a solid substratum, immediately disperse. In the second stage (6–7 h) the clusters have become tight, round or ovoid aggregates eventually covered with a thin cortical sheath. If deposited on solid substratum, they remain intact and immediately proceed to the next stage of fruiting body construction. The loose clusters are EDTA-sensitive, the tight aggregates are not[2].



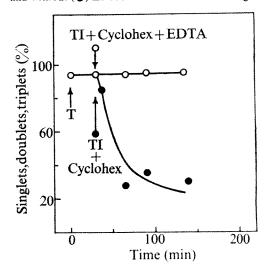


Fig. 2 Cells were collected at 15 h culture, dispersed and diluted to a density of 10^7 cells ml^{-1} in phosphate buffer containing glycerol, EDTA, and trypsin. After 40 min, trypsin inhibitor was added with (○) and without (●) cycloheximide (first arrow). Cycloheximide was removed (second arrow) from the former by centrifuging the suspension for 10 min at 400g in a Sorvall swinging bucket rotor, washing twice in phosphate buffer containing glycerol and EDTA and resuspending the cells in 20 ml of that solution. The incubation was then resumed. When noted, aggregates were dispersed by repeated pipettings, as before to measure the kinetics of reaggregation. Concentrations as in Fig. 1.

Aggregated cells can be mechanically dispersed to yield a single cell suspension which if shaken gently reforms tight aggregates within a few minutes. The experiments to be described demonstrate that, first treatment of disaggregated cells with trypsin destroys their capacity to form tight EDTA-resistant aggregates without affecting their capacity to adhere in loose, EDTA-sensitive clusters; second, on continued incubation after removal of the trypsin by inactivation, the cells slowly reacquire aggregative competence but cannot do so in the presence of cycloheximide; and third, the initial aggregative competence, its destruction after trypsin treatment, and its subsequent reacquisition are precisely reflected in the adhesive properties of ghosts derived from the untreated and treated cells.

Figure 1 shows the kinetics of reaggregation by freshly disaggregated cells. Confirming the earlier finding[2], the process is EDTA-resistant. It is unaffected by trypsin already inactivated

Fig. 3 Trypsin treatment was carried out as before but in the absence of EDTA. At 10 min intervals the reclustered cells were redispersed by repeated pipettings. After 30 min, trypsin inhibitor and cycloheximide (cyclohex) were added with (○) and without (●) EDTA. Concentrations as in Fig. 1.

by trypsin inhibitor, by glycerol (present to provide osmotic protection against trypsin) and by cycloheximide. In contrast cells treated with trypsin for 40 min before the addition of trypsin inhibitor reaggregated very slowly (Fig. 2) but after about 2.5 h had regained full EDTA-resistant, aggregative competence. The presence of cycloheximide prevented this reacquisition but the inhibition was shown to be reversible after removal of the drug. Clonal platings demonstrated that cell viability was unaffected by any of the treatments employed.

Disaggregated cells treated with trypsin in the absence of EDTA continually reclustered and had to be kept apart by frequent mechanical disruption. If after the trypsin was inactivated, EDTA (and cycloheximide) were added, the cells remained dispersed (Fig. 3). In the absence of EDTA, however, loose clustering was immediately resumed. Thus, trypsin treatment destroys only the second-stage adhesive capability and does not affect the first.

Recently it was demonstrated that ghosts derived from pre- and postaggregative cells retain the adhesive behaviour of the cells from which they were derived. A cofactor requirement for aggregation could be satisfied by addition of any of a specific group of divalent cations (Mn^{2+}, Ca^{2+}, Zn^{2+} and Cu^{2+})[3]. Figure 4 shows that in the presence of Ca^{2+} and EDTA, ghosts prepared from disaggregated cells, from trypsin-treated cells and from cells allowed to recover from trypsin treatment in the presence and absence of cycloheximide reflected precisely the adhesive capacities of the cells from which they were derived. This provides assurance that the trypsin-mediated lesion is located in the plasma membrane and is intimately associated with the specific adhesive sites. We are attempting to determine what is removed from the membrane by trypsin treatment and what is replaced during the recovery period. It will also be interesting to determine the relationship, if any, between these tryptic lesions and the antigenic determinants on the membrane which accumulate during the preaggregative period and which have been implicated in the adhesive process[4,5].

Fig. 4 Untreated control cells (*a*), cells treated with trypsin for 40 min (*b*), and cells allowed to recover after addition of trypsin inhibitor for 2.5 h with (*c*) and without (*d*) cycloheximide were collected, suspended at a density of 10^8 cells ml^{-1} in 5 ml aliquots of solution containing 20 mM K/Na_2 phosphate, pH 6.5, 50 mM NaCl, and 2% glycerol, and frozen at -20 °C. After thawing, the disrupted cells, now ghosts, were washed three times in phosphate buffer containing 1 mM $CaCl_2$ and 10 mM EDTA and resuspended therein at a density of about 10^7 ghosts ml^{-1}. Aliquots (1 ml) in tubes were incubated at 22 °C on a shaker. After 45 min, the population was examined microscopically to determine the distribution in groups of 1–3 (A), 4–5 (B), 6–10 (C), 11–15 (D), 16–50 (E), 51–100 or more (F).

Carbohydrate-mediated elimination of avian plasma glycoprotein in mammals

THE heavily glycosylated[1] plasma protein α_1-acid glycoprotein (α_1AGP) is known to occur in numerous mammalian species[2]. Its biological significance is still largely unknown[3] but together with fibrinogen and caeruloplasmin it belongs to a particular group of plasma proteins (acute phase reactants)[4], the synthesis of which is a response to trauma.

We isolated from chicken serum an α_1-acid glycoprotein which resisted precipitation at pH 3.0 and 2 °C with a combination of ammonium sulphate and trichloroacetic acid at the respective final concentrations of 2.18 and 0.075 M. Further purification of this protein was accomplished by ion exchange chromatography on Amberlite IRC-50 resin[5]. The product migrated with the mobility of human α_1AGP as a single band when electrophoresed in 7.5% polyacrylamide gel at pH 8.3. Its molecular weight, as determined by ultracentrifugation using a low speed equilibrium technique[6], was about 45,000 and it contained 44% (w/w) total carbohydrate (12.5% sialic acid[7], 16.0% hexosamine[8] and 16.0% neutral sugars[9]). Judged by these criteria this avian protein compares well with, and is therefore assumed analogous with, human α_1AGP.

Human α_1AGP and chicken α_1AGP were labelled[10] with different isotopes of iodine and injected simultaneously into adult chickens. The plasma protein-bound radioactivity curves closely paralleled each other, indicating no major difference in the catabolic rates of these proteins in the chicken (Fig. 1). By sharp contrast, when the same preparations were injected into New Zealand White rabbits the human protein underwent catabolism at rates which closely resembled rabbit α_1AGP,

Table 1 Means ± s. d. for the recovery of various iodine-labelled glycoproteins with the rat liver

Experiment		Marker protein		Test protein		Treatment*
Code	No.	Type	Dose in liver (%)	Type	Dose in liver (%)	
A_1	7	$H\alpha_1AGP$	12.7 ±4.7	$CH\alpha_1AGP$	57.6 ±8.7	None

G	4	$H\alpha_1AGP$	8.6 ±1.5	$HAs\alpha_1AGP$	98.1 ±0.8	None
H	5	$H\alpha_1AGP$	7.4 ±2.4	$HAs\alpha_1AGP$	79.5 ±5.5	$CH\alpha_1AGP$ (2.3 mg per 100 g)

H, human; CH, chicken; R, rat; Tr, transferrin; As, selectively desialylated with neuraminidase.
* Given intravenously 1 min before the dose.
Complete desialylation of human α_1AGP was achieved by incubating purified neuraminidase[8] (0.03 units) with 10 mg α_1AGP at pH 5.2 for 18 h at 37 °C. The enzyme was removed by passing the incubate through a column (10 cm × 1 cm) of Amberlite IRC-50 equilibrated with 0.015 M Na phosphate, pH 6.0. Under these conditions asialo-orosomucoid passed through the column and neuraminidase was adsorbed by the resin.
The preparation of human asialotransferrin, free from neuraminidase activity, has been described elsewhere[16].

whereas more than 90% of the chicken α_1AGP was eliminated in the first 4 h of the experiment (Fig. 2).

To determine the mechanism responsible for the premature elimination of the avian α_1AGP by the rabbit, male Sprague–Dawley rats, of 297 ± 38 g mean body weight, were given an intravenous dose of an iodine-labelled test glycoprotein (10–20 µg per 100 g body weight) together with a differently labelled protein marker for trapped plasma volume, such as human transferrin (Behringwerke, Germany) or human α_1AGP (prepared by the same technique as the chicken α_1AGP). After an interval of 5–6 min, 2.8 ± 0.6 ml blood were withdrawn per 100 g body weight from the heart, under sodium pentobarbital anaesthesia. The liver was removed and immediately homogenised in 50–70 ml 0.89% NaCl containing 16% 2-octanol by volume. Duplicate aliquots of the homogenates were assayed for radioactivity in a Packard model 5986 multichannel analyser.

Experiments A_1, A_2 and A_3 (Table 1) demonstrate the respective behaviour of three chicken α_1AGP preparations in

Fig. 1 Protein-bound radioactivities in the plasma of a hen (1.8 kg) which received a mixture of chicken ^{125}I-α_1AGP (●) and human ^{131}I-α_1AGP (▲) intravenously.

the rat, each of which was obtained from the pooled sera of more than 125 chickens. A reproducibly large fraction of the dose was recovered with the liver after administering any of these preparations. Injection of an excess amount of rat α_1AGP beforehand had no effect on the recovery of this fraction (experiment B). Similar quantities of human α_1AGP, however, significantly ($P < 0.001$) reduced the accumulation of chicken α_1AGP in the rat liver (experiment C), and desialylated human α_1AGP abolished it altogether (experiment D). These observations strongly suggest that, when placed in a mammalian system, chicken α_1AGP competes for the same hepatic plasma membrane receptor, identified[12] as being responsible for the rapid elimination of mammalian asialoglycoproteins. This view

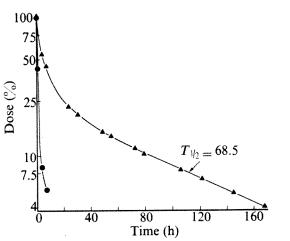

Fig. 2 Protein-bound radioactivities in the plasma of a rabbit (3.8 kg) following the intravenous injection of chicken ^{125}I-α_1AGP (●) and human ^{131}I-α_1AGP (▲).

is further strengthened by the marked interference with the hepatic clearance of human asialotransferrin and human asialo-α_1AGP by preinjected chicken α_1AGP. Thus, hepatic uptake of human asialotransferrin[13] was almost completely blocked by chicken α_1AGP (experiments E and F), whereas that of human asialo-orosomucoid was significantly ($P < 0.001$) reduced (experiments G and H).

Since the hepatic asialoglycoprotein receptor operates by recognising exposed galactose residues following the removal of sialic acid from glycoproteins[14], we determined whether native chicken α_1AGP contained such residues in a terminal position. The protein was treated with galactose oxidase and subsequently reduced by tritiated sodium borohydride[15]. By reference to the

radioactivity incorporated into a human asialotransferrin standard in these conditions, the quantity of terminal galactosyl groups in chicken α_1AGP was estimated to be 2.61 residues per molecule. The corresponding value for human α_1AGP was 0.97 residues which probably explains the partial blocking effect of this protein (experiment C).

The chemical and *in vivo* evidence presented suggests that chicken α_1AGP represents a naturally occurring glycoprotein which cannot survive in the mammalian circulation because a significant number of its carbohydrate chains terminate in galactose. Its affinity for the hepatic asialoglycoprotein receptor of rats is stronger than that of human asialotransferrin but weaker than that of human asialo-α_1AGP. The occurrence of such a glycoprotein in the avian circulation indicates that the chicken liver is either devoid of an asialoglycoprotein receptor altogether or that its requirement for a minimal number of exposed galactosyl groups is fundamentally different from the mammalian system[14].

New theory for receptor mechanism of carotid body chemoreceptors

EVER since De Castro[1] first ascribed a chemosensory function to the carotid body (later confirmed by Heymans, *et al.*[2]), there has been much discussion and controversy over the precise mechanism whereby stimulation of the afferent fibres is achieved[3,4]. The controversy initially centred around the nature of the neurotransmitter released by the glomus cell, which was assumed to be highly sensitive to hypoxia and less sensitive to hypercapnia and acidaemia. Perhaps the most generally accepted theory was that the glomus cells respond to hypoxia by releasing a neurotransmitter that initiates an increase in firing rate of the nerve fibres terminating on the glomus cells. The afferent nature of these fibres was originally deduced by De Castro[5] from light microscopic examination of the nerve fibres innervating the carotid body. The early ultrastructural studies, however, failed to show clear evidence of afferent types of nerve ending in synaptic contact with the glomus cells. On the contrary, these nerve endings were purported to be pre-synaptic and therefore efferent in function because they contain

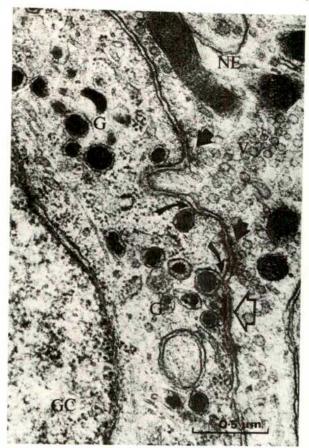

Fig. 1 Electron micrograph of the synaptic contact between a glomus cell (GC) and a nerve ending (NE) from the carotid body of the duck, *Anas platyrhynchos*. The glomus cell contains large numbers of electron-dense granules (G) which are thought to contain dopamine. In contrast, the nerve ending contains agranular vesicles (V) of the cholinergic type. Areas of synaptic contact between the glomus cell and nerve ending are interpreted as being efferent (solid arrows) and afferent (open arrow) on the basis of the location of the storage vesicles and associated membrane thickenings. Some electron-dense granules in the glomus cell seem to contact the cell membrane (curved arrows). Material prefixed with glutaraldehyde, postfixed with osmium tetroxide and embedded in Epon.

large numbers of agranular 'synaptic' vesicles[6-8]. This conclusion was further substantiated by Biscoe *et al.*[9], who showed that intracranial decentralisation of the IXth cranial nerve caused degeneration of nerve endings on glomus cells. These findings led to an alternative theory of chemoreceptor action[3]. In this case the chemosensory function is attributed to numerous free nerve endings of small diameter, which are found in the carotid body tissue. The glomus cells and associated nerves are held to form part of an efferent inhibitory feedback system, in which release of biogenic amines, that are known to be present in large quantities in glomus cells, depresses chemoreceptor activity.

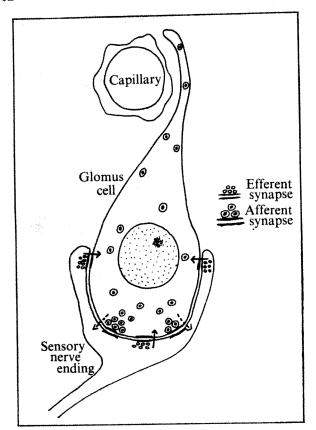
Work, however, on cats[10] and on ducks (P. J. Butler and M. P. Osborne, unpublished) has shown, in agreement with De Castro[5], that decentralisation of the nerves leading to the carotid body does not result in degeneration of any of the nerve terminals in synaptic contact with the glomus cells. Furthermore, recent electron microscope studies have shown that both afferent and efferent synaptic complexes occur between the glomus cells and nerve endings[11]. Our own investigations on the duck have shown that both afferent and efferent synaptic contacts occur between the glomus cell and the same nerve ending (Figs 1 and 2). This latter observation thus supports the suggestion made by Hess and Zapata[10] that "the sensory terminals on the glomus cells might well have in addition to their afferent functions, efferent functional effects like the presynaptic dendrites of the brain, which also pre-


Fig. 2 Structure of a glomus cell and its associated nerve ending. The glomus cell has one or more elongated processes which come into close proximity with the capillaries. The nerve endings are usually cup-shaped (chalice-like) engulfing the basal region of the glomus cell. Afferent and efferent synaptic contacts are shown. The arrows show synaptic conduction during hypoxic conditions, that is, a reduction in neurotransmitter secretion at the afferent synapses (– – – →) and an increase in neurotransmitter release at the efferent synapses (——→).

choline (ACh) increases the rate of chemosensory afferent discharge. They therefore suggested that the glomus cells release ACh in response to natural stimuli, and that it is this chemical that excites the afferent fibres. There are unfortunately several strong arguments against this hypothesis, the most important of which are: the glomus cells contain large amounts of catecholamines, in particular dopamine[13], and this substance, as well as other catecholamines, has a marked depressant effect on spontaneous chemoreceptor discharge[14]; cholinergic blocking agents, although they abolish ACh sensitivity, do not abolish the response to natural stimuli[12,15]. Consequently if a neurotransmitter is released from the glomus cells there would seem to be little support at present for the proposal that ACh is the substance in question[4].

Taking all of the above evidence into account we have developed a new theory for carotid body chemoreceptive activity. The theory (Fig. 3) is that, in the absence of any physiological effect of the glomus cells, the sensory nerve fibres spontaneously discharge, that is, they are endogenously active[16]. This spontaneous activity could result from a constant sodium current flowing at the nerve terminals which could act like a generator potential and depolarise the spike-generating zone to initiate action potentials[17]. The frequency of discharge is controlled by secretion of an inhibitory transmitter, dopamine, from the glomus cells. Thus a high rate of dopamine secretion would hyperpolarise the nerve endings, possibly by increasing their potassium conductance[18], and reduce the discharge frequency. When blood gas tensions are normal the rate of dopamine secretion is high, thus attenuating the sensory fibre discharge frequency. In hypoxic conditions, the release of dopamine from the glomus cells is reduced, allowing the nerve endings to return to their depolarised state. Apart from increasing the afferent discharge frequency, depolarisation of the nerve endings in our scheme also causes release of a neurotransmitter, possibly ACh, from the efferent synapses of the nerve terminals. This efferent neurotransmitter acts on the glomus cells to reduce further their rate of dopamine secretion. This results in a larger depolarisation of the nerve terminals which instigates an even greater increase in discharge frequency. Thus in our model the efferent synaptic contacts act as a positive feedback loop. If ACh is the efferent neurotransmitter, then this could explain why cholinergic blocking agents suppress the afferent discharge, but do not abolish the response to hypoxia[12]. Also the positive feedback loop could account for the hyperbolic response curve of single-unit preparations to hypoxia[19]. We also believe that this model

sumably play a dual role". Present ultrastructural evidence therefore is strongly indicative of the glomus cell being part of an afferent system.

The assumption that the glomus cells are indeed the chemoreceptive cells is difficult to reconcile with neuropharmacological studies. Eyzaguirre and Zapata[12] have shown that acetyl-

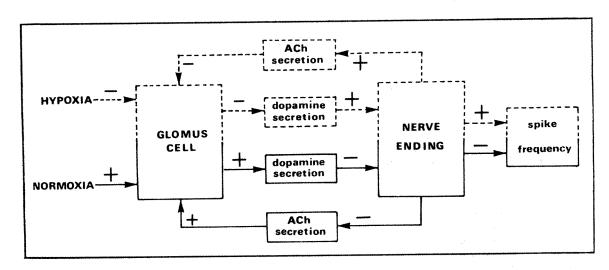

Fig. 3 Schematic flow diagram of a carotid body receptor during hypoxia (upper, dotted lines) and normoxia (lower, solid lines). During normoxia the glomus cell secretes dopamine which reduces afferent discharge frequency. In these conditions little or no ACh is released from the nerve endings at the efferent synapses. During hypoxia the glomus cell reduces its rate of dopamine secretion which leads to an increase in afferent discharge frequency. At the same time ACh is released from the efferent synapses and further suppresses dopamine release from the glomus cell, thus forming a positive feedback loop.

adequately explains the presence of ACh within the carotid body[12] and the presence of acetylcholinesterase[20] and dopamine[13] within the glomus cells It also accounts for the evidence that ACh[12] and dibenzyline[14] (an α adrenoceptor blocking agent) elevate afferent chemosensory activity and that catecholamines, notably dopamine, block the afferent discharge[14]

The novel feature of our theory is the proposal that in normoxic conditions, the glomus cells secrete an inhibitory transmitter, and in hypoxic conditions the rate of secretion of this transmitter is reduced Also, during hypoxia we envisage the nerve endings increasing the rate of release of their neurotransmitter substance These two opposite changes in metabolic rate need not be mutually exclusive if we suppose the low affinity cytochrome a_3 present in the carotid body[21] is located in the sensory (glomus) cells and that the normal cytochrome a_3 (that is, high affinity) is present in the nerves The rate of dopamine secretion from the glomus cells could be linked to a metabolic process(es) which is dependent on the oxygen tension Thus a change in rate of this process might act directly on the secretory mechanism or produce a change in membrane potential of the glomus cell Therefore it is possible that a depolarisation of the glomus cell would increase, and a hyperpolarisation decrease, the rate of secretion of dopamine Several attempts have been made to record changes in membrane potential of the glomus cells which are associated with natural or artificial stimuli In one study[22] the authors found no changes, but they could not be sure which type of cell they were recording from Other authors[23] reported that glomus cells were difficult to depolarise and that the sole potential change they recorded was a hyperpolarisation, and this was only in response to high levels of cyanide ions The response of the glomus cells, however, need not necessarily involve large changes in membrane potential Data from vertebrate photoreceptors[24] and lateral line organs[25] show that receptor potentials are of the order of microvolts rather than millivolts Since, in these sense organs, changes of a few microvolts are sufficient to alter the rate of neurotransmitter release, it seems that changes in membrane potential of similar magnitude could equally be effective in altering the rate of dopamine release from the glomus cells Similarly, the efferent neurotransmitter could reduce dopamine secretion from the glomus cells by hyperpolarising effects of less than one millivolt

Our theory does not exclude the possibility of an independent efferent nerve supply to the carotid body for which there is substantial neurophysiological[26-29] and some ultrastructural evidence[30] Whether this supply is to the vasculature[31], to the glomus cells[32], or to both is unresolved, but whatever the case, the presence of an efferent system need not invalidate our proposals

Bursts of antidromic impulses in the chemosensory fibres may be expected to increase afferent discharge in our model by the release of ACh This would occur if it is assumed that the antidromic spikes invade the nerve terminals to cause release of the efferent transmitter This assumption need not necessarily be correct It could equally be argued that antidromic spikes would "induce a build-up of positive afterpotentials in the region of orthodromic spike initiation, and produce an elevation of the threshold and depression of discharge"[33] Such a depression of afferent discharge is known to occur following antidromic stimulation in a number of sense organs including the carotid body[33]

Regeneration studies[34] indicate that a 12–18-month-old neuroma on the sinus nerve has similar physiological properties to the intact carotid body Unfortunately the authors do not mention whether they checked the denervated carotid bodies to see if reinnervation had occurred Until this possibility is eliminated we do not feel that these studies seriously challenge our theory of carotid body function A more detailed account of our ultrastructural studies will be published elsewhere

Pentobarbital modulates transmitter effects on mouse spinal neurones grown in tissue culture

GENERAL anaesthetics depress postsynaptic excitatory transmission in the vertebrate central and peripheral nervous systems[1-4] although preserving or prolonging both presynaptic[5-6] and postsynaptic inhibition[7-10] The mechanisms underlying these cellular events and their precise relationship with the phenomenon of general anaesthesia in mammals have not been elucidated We have used various invertebrate preparations to show that pentobarbital and other general anaesthetics operate at a postsynaptic level to depress Na^+-dependent postsynaptic excitation without affecting either Cl^-- or K^+-dependent postsynaptic inhibition[11,12] Here, using intracellular recording from mouse spinal neurones grown in tissue culture, we show that pentobarbital depresses glutamate excitation and prolongs γ-aminobutyric acid (GABA) inhibition in most cells, through a postsynaptic mechanism

Spinal cord tissue dissected from 13-d mouse embryos was dissociated and plated at a density of 10^6 cells per dish (35 mm diameter) The culture medium consisted of modified Eagle's MEM plus animal serum (see ref 13 for details) Cultures were exposed briefly to a metabolic inhibitor (to suppress growth of background cells) and then allowed to mature for at least 3 weeks before use For experiments, culture dishes were placed in a chamber on the stage of an inverted, phasecontrast microscope Temperature and pH of the medium were controlled Standard electrophysiological techniques were used for intracellular recording and iontophoretic drug application A bridge circuit permitted current to be injected through the recording pipette so that input resistance could be measured $MgSO_4$ was added at the time of study to make a final con-

centration of 10 mM to eliminate spontaneous synaptic activity and suppress presynaptic transmitter release Neuronal responses to transmitters were not affected

The somata of large multipolar spinal cord cells were impaled under direct vision using electrodes filled with 4 M K⁺ acetate Two or more independent iontophoretic pipettes filled with various drugs (0 5 M glutamate, pH 8, 1 M GABA, pH 3 5, 0 5 M glycine, pH 3 5, 0 5 M Na⁺ pentobarbital, pH 9 2) were then positioned close to one another at the surface of the cell Drugs were iontophoresed, using the appropriate polarity current, to cell somata so that the recording pipette could detect maximally the effects of the drugs The results reported here were obtained from a population of neurones with resting potentials more negative than −45 mV and action potentials of 50 mV or more in amplitude Dorsal root ganglion cells were also present in the cultures but the results regarding these cells are still inconclusive

Glutamate, a putative transmitter mediating synaptic excitation[14], depolarised more than 95% of spinal cells examined (Fig 1) The dose-dependent, rapid depolarisation typically elicited spike discharge, was associated with a small decrease in membrane resistance and had an extrapolated inversion potential which was usually around −20 mV (ref 15 and N Brookes, unpublished)

Application of GABA or glycine, putative inhibitory transmitters in the central nervous system (CNS)[14], markedly reduced membrane resistance and depressed spike discharge in a dose-dependent, reversible manner in 85% and 50%, respectively, of cells examined (Fig 1b) The equilibrium potential for these responses was typically near the resting potential and in all instances where the effects of these two drugs could be compared on the same cell, they had identical equilibrium potentials[15] Pentobarbital also decreased the membrane resistance (Fig 1c) in a dose-dependent, reversible manner in about 80% of cells tested The decrease in resistance associated with pentobarbital amounted to 5–15% of the resting input resistance, although decreases of 25% were observed with very large applications The resistance change was often accompanied by a 1–3 mV shift in membrane potential, usually in the hyperpolarising direction The slowly developing pentobarbital effect required more iontophoretic current than the rapidly developing GABA or glycine responses (Fig 1c) Pentobarbital did not seem to affect the height of the spike, its duration or threshold

Focal applications of pentobarbital depressed the depolarising responses to glutamate (Fig 1a) in a dose-dependent, reversible manner (12 of 14 cells tested) without diminishing the membrane responses to either GABA (Fig 1b) or glycine The depressant effects of pentobarbital could be seen in the absence of any measurable effects on membrane properties, when low iontophoretic currents of the drug were used Direct effects of pentobarbital on membrane properties, when present, could account for only a small percentage of the depression of the glutamate response In Fig 1a, for example, a 55% depression of the glutamate response by pentobarbital was associated with a 13% decrease in membrane resistance, while in Fig 1b (panels on the right) a 12% decrease in membrane resistance was present during the 38% depression The decrease in membrane resistance induced by GABA or glycine was never antagonised by pentobarbital (Fig 1b and d) More than 50% of the cells studied showed a prolongation of the GABA response in the presence of pentobarbital (Fig 1b and d) This effect was analysed quantitatively by examining the change in membrane conductance following iontophoresis of GABA as a function of time Semi-log plots of these data revealed linear relationships from which half-times ($t_{1/2}$) for the restoration of the control conductance were obtained (our unpublished data) In Fig 1b, for example, the $t_{1/2}$ increased from 2 5 s for the response under drug-free conditions to 3 9 s for the response in the presence of pentobarbital Pentobarbital did not prolong the glycine response in four cells tested

Pentobarbital also tended to change the polarity of the GABA

Fig. 1 Effects of iontophoretically applied pentobarbital on nerve cells in tissue culture and its interactions with putative transmitters *a*, Pipettes containing pentobarbital and glutamate were positioned at the same site on the cell soma Standard pulses of glutamate (20 nA, 3 s) were applied alone (indicated by labelled bars or filled circles) and in the presence of pentobarbital (50 nA) Membrane potential was −58 mV Upward deflections are positive for all records *b*, Similar experiment using glutamate, GABA and pentobarbital pipettes near the cell soma Records show drug responses to constant pulses of the two transmitters (8 nA, 0 3 s for glutamate and 45 nA, 1 5 s for GABA) before (control), during (pentobarbital) and seconds after (post) application of pentobarbital (30 nA) Downward deflections in GABA traces here and in panels (c) and (d) are voltage responses to constant current pulses reflecting membrane resistance during drug responses $t_{1/2}$ for the relaxation of the conductance change after the termination of GABA application was 2 5 s in control and 3 9 s during pentobarbital application (see text) Peak resistance decrease during GABA response was 52% in control compared with 54% during pentobarbital Membrane potential was −50 mV Calibration 25 mV, 10 s *c*, Comparison of effects of GABA and various doses of pentobarbital applied to the same membrane site Onset of GABA response (45 nA and 2 s) was much faster than pentobarbital effect (45 nA first bar, 25 nA second bar) Membrane potential was −50 mV Calibration 25 mV, 50 s *d*, GABA and pentobarbital applied to same membrane site on cell soma Top three records show the action of a constant pulse of GABA (20 nA and 3 s) before (con), during (pentobarb), and after (post) the application of pentobarbital (12 nA) Bottom three records illustrate the effects of a 24-nA application of pentobarbital The membrane hyperpolarised by 3 mV during the larger dose of pentobarbital and the GABA response inverted (see text) $t_{1/2}$ of the relaxation of the GABA conductance change was 1 8 s for the con and 4 s for the pentobarb response Membrane potential was −56 mV Calibration 35 mV, 50 s

response in a depolarising direction (Fig 1b and d, bottom panels) This could not be explained by a change in the resting potential induced by pentobarbital and may have resulted from an effect of pentobarbital either on an ionic gradient on which the GABA response depends, or on the basic ionic mechanism induced by GABA Alternatively, the GABA response in some neurones may be normally biphasic, as suggested by the control record in Fig 1b The effect of pentobarbital may thus be to accentuate the later, depolarising component of this response

The results demonstrate three specific effects of pentobarbital on mammalian CNS neurones (1) a depression of postsynaptic glutamate excitation independent of direct effects on membrane potential or resistance, (2) a variably present prolongation of the conductance change induced by GABA (an effect not seen in invertebrates), and (3) a dose-dependent, slowly developing increase in membrane conductance (usually 5–15%) These effects of pentobarbital may explain the invariable depression

of CNS excitability during pentobarbital anaesthesia The results suggest that the depression of excitatory postsynaptic potentials in the CNS could be the result of the selective, post-synaptic effects of the drug without necessitating major effects on presynaptic release The observed prolongation of the GABA response may help to explain the prolongation of presynaptic and postsynaptic inhibition, both of which are thought to be mediated by GABA[6,10,14,16-18] Direct membrane effects of pentobarbital might also contribute to general anaesthesia by causing either a slight shunting of neuronal membranes, thereby reducing the size of excitatory synaptic potentials, or a slight hyperpolarisation, thus moving the membrane from its firing level

There are several ways, therefore, in which the cellular effects of barbiturates could lead to generalised depression of neuronal excitability and general anaesthesia (1) selective, postsynaptic depression of glutamate excitation, (2) prolongation of GABA-mediated postsynaptic inhibition, (3) prolongation of GABA-mediated presynaptic inhibition leading to partial deafferentation and (4) direct effects on CNS neurones to depress their excitability The relative importance of each of these in producing general anaesthesia, as well as the effects of pentobarbital on other aspects of synaptology studied under controlled conditions in tissue culture, remain to be investigated

Note added in proof Since this report was submitted we have found similar pharmacological effects of pentobarbital on transmitter responses using anaesthetic concentrations (0 1–0 2 mm) applied from large-bore pipettes

Increase in binding capacity for triiodothyronine in tadpole tail nuclei during metamorphosis

REGRESSION of the tadpole tail is under direct control of the thyroid hormones and provides a system for study of their mechanism of action[1] In this system triiodothyronine (T_3) is two to five times as active as thyroxine (T_4) in causing tail regression[2,3] Studies of the binding of ^{125}I-T_3 and ^{125}I-T_4 after incubation of hormone with sliced tailfin tissues have revealed high-affinity, saturable binding sites in the cell nucleus[4]—a maximum of 1,500 and 800 sites per nucleus for T_3 and T_4, respectively (Similar results have been obtained with tadpole liver cells[5]) The dissociation constants for T_3 and T_4 were almost identical (10^{-10} M) These results suggest that in

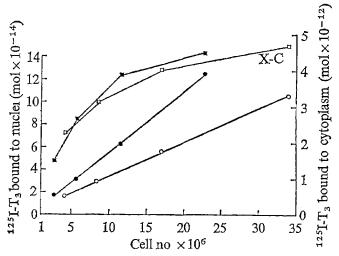

Fig 1 Dependence of binding of ^{125}I-T_3 to nuclei and to cytoplasm on the cell number Tailfin cell suspensions were prepared from stage X and XVIII–XIX tadpoles One ml of the cell suspension containing different amounts of cells was incubated with ^{125}I-T_3 (final concentration, 7 0 × 10^{-9} M) for 3 h at 25 °C ○, Binding to stage X nucleus, ●, stage XVIII–XIX nucleus, □, stage X cytoplasm, ■, stage XVIII–XIX cytoplasm Un-fractionated cell populations were used Contamination by blood cells was less than 3 % These cells appeared to be a mixture of epidermal, mesenchymal, and connective tissue cells[16] Separation of tailfin tissue cells from stage X and XX–XXI was performed on a Ficoll gradient (5–15 %, linear) Both stages had three visible band of cells and the relative widths of each band were almost identical for these two stages Therefore, it seems that there was no significant change in cell type of the tailfin in these preparations

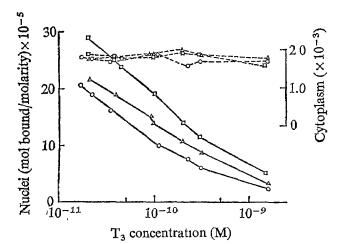
amphibians the maximum number of binding sites rather than the affinity constant correlate with the biological activity of T_3 and T_4 In mammals, however, specific high-affinity binding sites for the thyroid hormones were found in nuclei[6-8] and correlate with the affinity constant

Derby[9] found that the sensitivity of tailfins to T_4 increases as metamorphosis progresses, but did not show whether this resulted from a change in the maximum binding capacity of the nucleus or to a change in the affinity constant for T_3 We have found that the maximum nuclear binding capacity for T_3 doubles during metamorphosis and that the affinity of the nucleus for the hormone decreases slightly during spontaneous metamorphosis

Rana catesbeiana tadpoles were classified according to stages as defined by Taylor and Kollros[10] Dorsal and ventral tailfins were sliced and digested twice in 5–10 volumes of amphibian Ringer phosphate buffer (ARB), pH 7 6, containing 0 10% glucose, 0 1% methylcellulose, 0 20% collagenase and 0 10% hyaluronidase (Worthington) for 30 min After filtration through nylon cloth (mesh size, 125 μm) the cell pellet was washed five times with ARB Cell yield from the sliced tissues was 50%, estimated from DNA recovery Cells were incubated with ^{125}I-T_3 (69 μCi μg^{-1}, Abbott) as described later

Table 1 Changes in maximum binding capacity and dissociation constant for T_3 by tailfin nuclei during metamorphosis

Tadpole stage	Binding sites per cell nucleus (±s e m)	Apparent dissociation constant (pM) (±s e m)
X	1,330±30	112±5
XV	1,580±40	105±4
XVIII–XIX	2,830±70	155±7
XX–XXI	2,410±30	169±4

Values were obtained from Fig 3, where the intercept of the ordinate represents the maximum number of binding sites and the slope represents the negative of the dissociation constant The data for stage XV were obtained by the same method as for the other stages 9 6 × 10^6 cells were incubated for 3 h at different concentrations of ^{125}I-T_3 The correlation coefficient for the linear regression was 0 97 (P < 0 01) While the correlation is high, it is not certain that the data fit only a single class of binding sites


Preparation of tailfin cell nuclei was performed by the method of Samuels and Tsai[6] with 90% recovery of cell DNA[11] ^{125}I-T$_3$ analysed on a Sephadex G-25 column[4,5] contained 99 5% ^{125}I-T$_3$ and 0 5% ^{125}I-iodide The radioactivity of the nuclear pellet dissolved in 1 N NaOH and the extranuclear fraction was measured with a Beckman Model LS-250 liquid scintillation spectrometer with a counting efficiency of 48% using 0 5% Omnifluor, 1%, Cab-o-Sil, and 8% naphthalene in dioxane

The time course of binding of ^{125}I-T$_3$ to nuclei and cytoplasm was studied at 25 °C and 4 °C Both nuclear and extranuclear binding progressed linearly for 2 h and then plateaued Incubation was for 3 h in all subsequent experiments The extent of hormone binding was depressed 50% at 4 °C

The relationship between T$_3$ binding and the total number of cells used was studied at 7 0 × 10^{-9} M ^{125}I-T$_3$, using stage X and XVIII–XIX cells (Fig 1) A linear relationship was observed only in nuclear binding over the range tested From the intercept of the line, it was estimated that a cell nucleus from stage X contains 1,900 binding sites for T$_3$ and that of stage XVIII–XIX contains 3,300 sites, giving values slightly in excess of the values obtained by Scatchard plots (Table 1) At 7 0 × 10^{-9} M, the specific binding sites were saturated and contained some T$_3$, bound nonspecifically

Binding of ^{125}I-T$_3$ to nuclei and the extranuclear fraction was examined at different T$_3$ concentrations (Fig 2) using cells prepared from stages X, XV, XVIII–XIX, and XX–XXI The ratio of bound T$_3$ to the T$_3$ concentration of the medium is plotted against the concentration of T$_3$ in the medium at equilibrium The ratios for the extranuclear fraction remained constant and almost identical for different stages The ratios for the nucleus decreased as the hormone concentration increased, demonstrating that the nucleus contains high-affinity and saturable binding sites These data were replotted in a standard Scatchard plot (Fig 3)[12] Table 1 lists the maximum number of binding sites in the nucleus and their apparent dissociation constants as estimated from Fig 3 Maximum binding sites per nucleus remained almost unchanged through stage XV The present estimation of the maximum number of binding sites and their dissociation constants at stage X agrees with the results of binding experiments using tail slices[4] At stage XVIII–XIX, binding sites almost doubled compared with stage X and then decreased slightly at stage XX–XXI The affinity constant remained almost unchanged until stage XV and decreased

/

Fig 3 A Scatchard plot of the binding of ^{125}I-T$_3$ by tail nuclei Binding of ^{125}I-T$_3$ to the nuclei was determined by incubating cell suspensions with radioactive hormone in 1 0 ml of ARB, containing 0 1% glucose and 0 1% methylcellulose After incubation, the cell pellet was obtained by centrifugation and the medium was saved to determine T$_3$ counts The cell pellet was washed by two successive suspensions and centrifugation in 2 ml of the cold incubation medium A nuclear pellet was prepared as described above Lines were obtained by linear regression with a correlation coefficient of 0 98–0 99 ($P < 0$ 01) Stage X, ●, stage XVIII–XIX, ■, stage XX–XXI, ▲

thereafter Since the available evidence suggests that the thyroid hormone level increases just before climax[13], it is probable that a higher fraction of the T$_3$ binding sites in the nucleus were occupied by endogenous T$_3$ at stages XVIII–XIX and XX–XXI than in early premetamorphic stages (X and XV)

The results presented here suggest that the maximum number of binding sites for T$_3$ in tail nuclei increased during spontaneous metamorphosis The increase in hormone sensitivity of tail tissue during metamorphosis may be the result of an increase in nuclear binding capacity for T$_3$ rather than an increase in the affinity constant, which seems to decrease as tadpoles metamorphose Tata reported that the acquisition of early metamorphic competence in whole *Xenopus* larvae is accompanied by the appearance of temperature-sensitive binding sites for thyroid hormones[14] The binding of very high concentrations of T$_4$ to temperature sensitive sites in tadpole liver nuclei was reported by Griswold *et al*[15] Samuels and Tsai[6] suggested that nuclear receptors for T$_3$ are not constant, but increase after exposure of intact cells to non-radioactive T$_3$ Therefore it is possible that the higher level of endogenous thyroid hormone at the onset of climax stages in the tadpole increases the nuclear receptors of the hormone, resulting in a greater tissue sensitivity to the hormone

Glucagon-like immunoreactivity in insect corpus cardiacum

SINCE Steele attributed hyperglycaemic activity to the corpus cardiacum of the cockroach neurosecretory system[1-3], it has been demonstrated in other species of Orthoptera[4-10] and in Diptera[11,12] and Hymenoptera[13] Although extracts of corpora cardiaca from the blowflies *Phormia*[11] and *Calliphora*[14] and the silk moth *Cecropia*[15] seem to be inactive, the hyperglycaemic hormone is liberated from the *Calliphora* gland by electrical[12] or mechanical[14] stimulation *in situ* Similarly, extracts from *Locusta*[6,16] and *Phormia*[11] are poorly active intraspecifically, but are hyperglycaemic when injected into the cockroach The nutritional state of the recipient is apparently crucial in determining the extent of the response[11]

In the best studied insects, the hyperglycaemic hormone functions similarly to glucagon in vertebrates the hormone increases carbohydrate levels in the circulating haemolymph

Fig. 1 Gel filtration of extracts of corpus cardiacum/corpus allatum complexes and brains from adult *M sexta* Tissue (21 complexes or brains) was suspended in 0 1 M Tris, 0 05 M NaCl, 0 25% bovine serum albumin, 1 mM diisopropylphosphorofluoridate (DFP), pH 7 6, lyophilised and extracted with 0 3 ml of 7 M guanidine hydrochloride containing a trace amount of ^{125}I-glucagon The extracts were separately applied to a column (0 9×42 cm) of BioGel P-10 equilibrated at 4 °C with Tris-albumin buffer containing pancreatic kallikrein inhibitor(300 U ml⁻¹) instead of DFP, and the components eluted at a flow rate of 5 ml h⁻¹ The 0 6 ml fractions were counted for radioactivity and 0 15 ml aliquots of each were removed for radioimmunoassay essentially as described[25] The antiglucagon serum was a gift from Dr L Heding, Novo Laboratories, Copenhagen Glucagon-like immunoreactivity (left axis, solid lines) and [12]I-glucagon radioactivity (right axis, dashed lines) were recorded for the complexes (*a*) and the brains (*b*) The elution positions of protein standards from the same column are indicated by the vertical arrows (*a*) which represent from left to right, albumin (void volume), soybean trypsin inhibitor (STI), cytochrome *c*, pancreatic trypsin inhibitor, and glucagon or ^{125}I-glucagon, respectively Fractions 34 to 42 indicated by the horizontal arrow (*a*) were pooled for further analysis

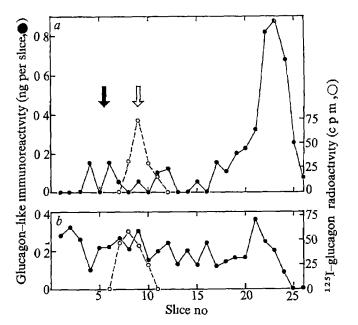

Fig 2 Polyacrylamide gel electrophoresis at pH 8 7 of extracts of corpus cardiacum and corpus allatum from *M sexta* Tissue (9 gland pairs) was extracted with 0 05 ml of 8 M urea containing trace amounts of ^{125}I-glucagon and bromphenol blue The extracts were applied to 10% polyacrylamide gels[28] containing 8 M urea (0 4×6 cm) and were subjected to electrophoresis at 22 °C Gels were sliced into 1 5-mm sections and placed in 0 5 ml of the buffer used for chromatography before counting for radioactivity After elution of the peptide components during 24 h at 4 °C, the supernatant fluid was withdrawn and subjected to immunoassay Glucagon-like immunoreactivity (left axis, solid lines) and ^{125}I-glucagon radioactivity (right axis, dashed lines) were recorded for the corpus cardiacum (*a*) and the corpus allatum (*b*) extracts Migration was from cathode (left) to anode The position of the tracking dye is coincident with the right axis The solid and open arrows (*a*) indicate the migration position of porcine glucagon and ^{125}I-glucagon respectively The additional negative charge in iodinated glucagon at pH 8 7 increases its anodal mobility relative to that of the unlabelled hormone Control experiments showed that the presence of urea or other gel components did not alter the sensitivity of the immunoassay

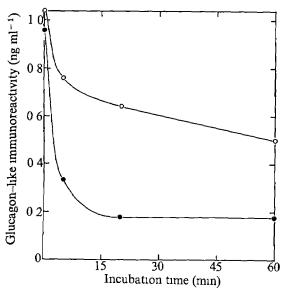
in vivo and stimulates glycogenolysis and the activation of phosphorylase in the fat body *in vitro*[5,6,17,18] By several criteria, the insect hormone also seems to be a low molecular weight polypeptide[2,6,8,10,13,16] We report here the identification of a highly acidic peptide with glucagon-like immunoreactivity from corpora cardiaca of the adult tobacco hornworm *Manduca sexta*

A survey for immunoreactive glucagon in tissues of *M sexta* showed that reactive peptides were present in corpus cardiacum/corpus allatum complexes and haemolymph, but not in brain, aorta, recurrent nerve or fat body The component from the complexes was eluted slightly ahead of [125] I-glucagon (molecular weight 3,500) during gel filtration on BioGel P-10 (Fig 1*a*) The elution volume of the immunoreactive component corresponded to that of a 4,500-dalton peptide As Fig 1*b* shows, gel filtration of an extract of brains from *M sexta* yielded no similar peak of glucagon-like immunoreactivity The peak of apparent reactivity at the far right of each profile in Fig 1 is caused by interference in the assay by guanidine hydrochloride and represents the inclusion volume of the column


A closer examination of the distribution of the immunoreactive peptide showed that it was primarily associated with the corpus cardiacum rather than with the corpus allatum (Fig 2*a*, slices 21-25) Its rate of migration during electrophoresis at pH 8 7 is in agreement with its low molecular weight as determined by gel filtration, and further indicates a high acidity Nevertheless, the abilities of the serially diluted, pooled fractions 34-42 (Fig 1*a*) and porcine glucagon to compete with ^{125}I-glucagon for binding to the antibody

decreased in parallel Although the immunoreactivity profile of Fig 2b suggests that corpus cardiacum contains a single, major glucagon-like peptide, two or more rapidly migrating forms might not be separated under the conditions used here

Since mammalian glucagon[19] and the insect hyperglycaemic hormone[8,13] are sensitive to proteolytic degradation, we compared the susceptibilities of the immunoreactive component and porcine glucagon to trypsin (Fig 3) Although the immunoreactivities of both the insect peptide and glucagon are diminished by digestion with trypsin, the former is degraded either more slowly or to a lesser extent This result may be a consequence of the higher acidity of the insect peptide (Fig 2a) Quantitation of glucagon-like immunoreactivity after gel filtration or after polyacrylamide gel electrophoresis indicated that each pair of corpora cardiaca from *M sexta* contains 0 4–0 5 ng equivalent of glucagon This value should be regarded as a lower limit, however, since affinity of our antibody for the insect material may well be less than for porcine glucagon

Examination of sequence data shows that the structure of the vertebrate hyperglycaemic hormone glucagon has been well conserved during evolution the human,[20] bovine,[21] and porcine[19] hormones are identical, although the structures of the corresponding, slowly evolving cytochromes c differ by an average of 7% (ref 22) Similarly, avian glucagon differs from the human hormone by 7% (ref 23), whereas the difference between the corresponding cytochromes is about 12% (ref 22) Assuming from these limited data that the rate of mutational acceptance for glucagon is only about half that for cytochrome c or 1 5 accepted point mutations per 100 residues per 100 Myr,[24] we expect that a glucagon-like peptide might have changed by only 15% during the approximately 900 Myr since the divergence of insects and mammals[24] Neither this estimated extent of change nor the apparently higher molecular weight of the insect peptide would be likely to preclude reactivity with antibodies directed toward mammalian glucagon[25]

Weins and Gilbert first noted the nearly identical physiological

actions of the insect hyperglycaemic hormone and vertebrate glucagon[5] The tissue distribution of the glucagon-like immunoreactivity in *M sexta* parallels the distribution of the hyperglycaemic hormone in other insects[1,18,26,27] Furthermore, both immunoreactivity and hyperglycaemic activity are sensitive to tryptic degradation and behave similarly during gel filtration at neutral *p*H[13] The high acidity of the immunoreactive peptide is also consistent with the finding that hormone activity does not adsorb to cation-exchange resins[10,13] Although these chemical and physical similarities suggest that the insect hyperglycaemic hormone and the glucagon-like peptide are the same, final proof of their identity must await purification and sequence determination of the hyperglycaemic peptide

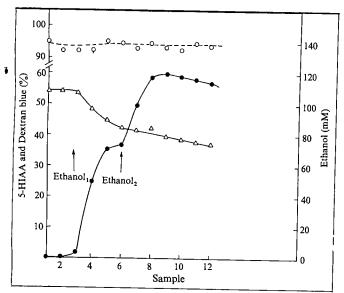
Fig. 3 Effect of trypsin on the glucagon-like immunoreactivity in a gel-filtered extract of corpus cardiacum/corpus allatum complexes from *M sexta* Samples (0 4 ml) of the pooled fractions 34–42 from Fig 1 or of a solution of porcine glucagon (1 ng ml^{-1} in chromatography buffer) were incubated with diphenylcarbamyl chloride-treated trypsin (0 075 mg) at 25 °C for the indicated intervals The reaction was stopped by the addition of 0 1 ml of a solution of STI (8 mg ml^{-1}) All samples were subjected to the immunoassay and glucagon-like immunoreactivity was recorded for *M sexta* (○) and glucagon (●) The data points at zero time were obtained by adding STI to the appropriate solution before the addition of trypsin Control experiments showed that the presence of trypsin plus STI did not alter the sensitivity of the assay

Ethanol inhibition of transport of 5-hydroxyindoleacetic acid from cerebrospinal fluid

MUCH work has been directed at demonstrating the possible interaction of ethanol with levels of neurotransmitter amines or their metabolism in brain[1,2] We have previously demonstrated an increase in brain levels of 5-hydroxyindoleacetic acid (5-HIAA) in mice after both a single and chronic administration of ethanol[3] Our more recent work[4] has focused attention on the inhibition of transport of 5-HIAA from the central nervous system (CNS) by ethanol as the factor responsible for the increase in brain 5-HIAA after ethanol 5-HIAA diffuses from the CNS into cerebrospinal fluid (CSF), from which it is re-


/ **Fig. 1** Transport of 5-HIAA from spinal subarachnoid space after ethanol administration The results illustrate one typical experiment of those treated statistically in Fig 2 A steady-state concentration of 5-HIAA and Dextran blue in outflow fluid during perfusion was established as follows Adult cats were anaesthetised with pentobarbital sodium (30 mg kg⁻¹ intraperitoneally) and prepared for perfusion as described previously[6] After the head of the animal was fixed in a stereotaxic instrument, an inflow cannula connected to a constant infusion pump was positioned in the cisterna manga Polyethylene tubing fixed in the lumbar subarachnoid space[6] served as outflow, its end was positioned 10 cm below the level of the cisterna magna and at the horizontal level of the lumbosacral cord Rectal temperature was recorded during the experiment and kept within normal range (± 0 5 °C) Artificial CSF (ref 7) containing 5-hydroxyindole-acetic-carboxyl-¹⁴C-acid (5-HIAA-¹⁴C, 400 ng ml⁻¹, specific activity 1 μCi 19 2 μg⁻¹) and Dextran blue (100 μg ml⁻¹) pH 7 4, was used for perfusion The rate of perfusion was 0 097 ml min⁻¹ With this perfusion rate approximately 120 min was required to get constant concentration of 5-HIAA-¹⁴C in the outflow fluid Thereafter samples of perfusate were collected at 20 min intervals To shorten the equilibration period the perfusion was started in a few experiments with a rate of 0 191 ml min⁻¹ and continued for 30 min, After this initial period, the perfusion rate was changed to 0 076 ml min⁻¹ and collection of samples was begun 60 min from the start of perfusion Ethanol concentrations in the perfusate were determined by gas chromatography[4] Radioactivity was determined by adding 0 1 ml of perfusate to 15 ml of Bray's solution[8] and subjecting the sample to scintilation counting Changes in concentration of Dextran blue were determined by measuring changes in absorbance at 630 nm from the initial value of 0 093 ± 0 002 which corresponded to 100 μg ml⁻¹ of Dextran blue Percentage transport for 5-HIAA (△) was calculated from

$$\left(1 - \frac{^{14}C \text{ in outflow}}{^{14}C \text{ in inflow}}\right) \times 100$$

Concentration of Dextran blue (○) in collection samples was expressed as percentage of the concentration being infused Ethanol (1 5 g kg⁻¹) was injected intraperitoneally twice with approximately 60 min between injections, and the concentrations of ethanol appearing in the perfusate (●) were determined

moved by a carrier-mediated transport into the bloodstream[5] The effect of ethanol on transport of 5-HIAA from CSF was studied by perfusing this acid through the spinal subarachnoid space from the cisterna magna to the lumbar region of cats This was shown to be a sensitive and reliable model for the study of transport of 5-HIAA from CSF (ref 6)

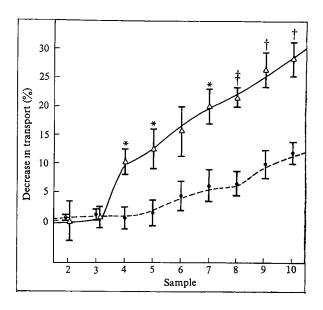
Figure 1 shows levels of 5-HIAA and Dextran blue in perfusate before and after two intraperitoneal injections of ethanol (1 5 g kg⁻¹) The concentration of Dextran blue did not change significantly during the experiment indicating that the bulk flow of the fluid was constant during the experiment On the other hand, a significant decrease in 5-HIAA transport was observed after ethanol administration (P < 0 001, analysis of variance for repeated measures[9])


Figure 2 illustrates the mean decrease in 5-HIAA transport

after ethanol administration The administration of ethanol produced a 25–30% decrease in the transport of 5-HIAA during the course of our experiments Decreases in transport of 5-HIAA correlated well with the administration of ethanol (Fig 2) and the appearance of ethanol in the collection samples (Fig 1) The peak ethanol levels in CSF of cats after injection of ethanol (Fig 1) were similar to those previously noted in CNS of mice receiving 3 g kg⁻¹ ethanol[4] In some preliminary experiments (data not shown), ethanol (5 mg ml⁻¹ artificial CSF) was added to the perfusion fluid Such treatment produced no significant change in the transport of 5-HIAA compared with control cats Concentrations of ethanol in the perfusion outflow fluid, however, were found to be extremely low (that is, <1 mM), indicating that ethanol was quickly lost from the subarachnoid space Therefore, concentrations of ethanol necessary to inhibit 5-HIAA transport could not be maintained by this method

Our present experiments with cats injected with ethanol clearly indicate that ethanol inhibits transport of 5-HIAA from the CSF, and extend our earlier observations on the effects of ethanol on the transport of 5-HIAA from the CNS (ref 4) Previous work has demonstrated that measurable increases in the levels of 5-HIAA in brain do not occur simultaneously with peak ethanol levels in brain but approximately 60 min thereafter[3] Thus, it is interesting to note that in these experiments the inhibition of 5-HIAA transport by ethanol increases with time In addition, the partial inhibition of active transport systems, such as those for organic acids, which may be working at near maximal capacity[10,11], would result in a progressive accumulation of 5-HIAA with time Our studies with mice have also demonstrated that both the accumulation of 5-HIAA and the inhibition of transport systems for this organic acid by ethanol are reversible processes

Zarcone et al[12] demonstrated an increase in 5-HIAA in the lumbar CSF of alcoholics consuming ethanol A similar increase in 5-HIAA in cat cisternal CSF after injection of ethanol has also been observed (G E Goodman, M P Schulman, and M Radulovacki, personal communication) Our findings that ethanol inhibits transport of 5-HIAA out of CSF (Figs 1

Fig 2 Inhibition of 5-HIAA transport from spinal subarachnoid space by ethanol Perfusions of the spinal subarachnoid space were performed as described in the text Values represent mean ± s e of percentage change from steady-stage transport of 5-HIAA established initially Steady-state concentration of 5-HIAA was 50 9 ± 3 6% of infused 5-HIAA in control cats (●, n = 3) and 55 4 ± 2 4% in those cats which were to receive ethanol (△, n = 3) Time of the injection of ethanol as in Fig 1 Results were compared using Student's t test
*P < 0 1 †P < 0 05 ‡P < 0 02.

and 2) and CNS (refs 3 and 4) explain the underlying mechanism of these observations It is also interesting to note that inhibition of transport systems for certain organic acids not only inhibits the exit of acids from the CNS and CSF but also facilitates the penetration of such acids from blood into the CSF and CNS (ref 5) The increase in 5-HIAA or similar organic acids (biogenic acids) in the CNS may interfere with the normal metabolism of biogenic amines Biogenic acids have been shown to inhibit brain aldehyde reductases[13,14] which are responsible for the production of the alcohol derivatives of the biogenic amines (for example, MHPG) Biogenic acids, such as phenylacetic acid, have also been shown to inhibit certain decarboxylases[15,16] necessary for the biosynthesis of neurotransmitters such as catecholamines and γ-aminobutyric acid Further studies are in progress to elucidate the relationship between increases in CNS concentrations of organic acids and 'hangover' and withdrawal symptoms produced by ethanol

Placental production and foetal utilisation of lactate and pyruvate

APPROXIMATELY 75% of foetal oxygen consumption of sheep can be accounted for by the uptake of glucose from the umbilical circulation[1-3] and catabolism of amino acids[4] The contribution to foetal energy metabolism of exogenous long-chain fatty acids[5] and fructose[1] seems to be negligible We report now that the placenta normally provides lactate for the foetus, in sufficient

quantities to account for 25% of foetal oxidative metabolism This finding invalidates the assumption that under normal physiological conditions there is a net flux of lactate from foetus to mother The assumption seemed reasonable in the past because the concentration of lactate in foetal blood is greater than in maternal blood and because of the formerly prominent hypothesis that anaerobic metabolism is very active in foetal life

Twelve Dorset and Western ewes at days 67–147 of gestation were starved for 48 h and then placed under pentobarbitol sedation (5 mg kg^{-1}) and spinal anaesthesia (6 mg pontocaine in hyperbaric glucose) Seven of these animals received polyvinyl catheters in the maternal femoral artery, the uterine vein, the foetal pedal artery and umbilical vein as described previously[2,6] In four cases the foetal vessels only were catheterised In one sheep, only the uterine circulation was studied

All lambs except two were live born spontaneously or by Caesarean section The two lambs found dead after spontaneous delivery were appropriate in size for their gestation ages of 95 and 115 d and had not been sampled for 25 and 7 d respectively before labour

After surgery all animals were placed in rectangular stalls and allowed food and water *ad libitum* Foetal and maternal catheters were flushed daily with heparin Procaine penicillin (600,000 U) and streptomycin (0 5 g) were administered on the day of surgery and the next three days Study began at least 24 h after surgery and extended to day 17 after surgery

Foetal (0 25 ml) and maternal (0 45 ml) blood samples were drawn simultaneously into 3-ml plastic syringes (Sherwood) surrounded by ice These were prepared on the day before sampling by inverting the syringe with needle attached into its prepackaged container The space between syringe and container was filled with water and stored at −4 °C to form an ice jacket around the syringe The blood samples were transferred immediately to preweighed plastic tubes (12 mm × 75 mm) containing 0 5 ml of 5 1% perchloric acid and agitated on a Vortex mixer (Scientific Industries) until precipitation was complete These tubes were then placed in a refrigerated centrifuge (International Equipment Co) and spun at 3,000 r p m for 20 min After separation of the supernatant, centrifugation was repeated before analysis Blood (0 2 ml) for analysis of oxygen content was drawn into heparinised glass capillary tubes (Scientific Products) in which 0 15 mg of sodium fluoride had been dried

Olsen's enzymatic method[7], utilising L-lactate dehydrogenase, was used to determine the concentrations of lactate and pyruvate Oxygen contents were determined with a Lex-O$_2$-Con (Lexington Instrument Corp) calibrated with distilled water saturated with oxygen at 0 °C All samples were analysed in triplicate

Lactate/oxygen quotients across the umbilical circulation were calculated on the basis of umbilical venous arterial differences (*v–a*) of lactate and oxygen, as follows

lactate/oxygen quotient = 3 (*v–a* lactate/*v–a* oxygen)

Expressed in this fashion, the lactate/oxygen quotient represents the fraction of foetal oxygen consumption required to metabolise

the lactate acquired by the umbilical circulation to carbon dioxide and water

Table 1 shows that v-a lactate in the uterine and umbilical circulations was highly significant ($P < 0.001$) There was no significant veno-arterial difference of pyruvate concentration in the umbilical circulation There was, however, a relatively small, but statistically significant difference of pyruvate concentration between uterine veins and maternal arterial blood The lactate/oxygen quotient across the umbilical circulation was calculated on 17 samples from 6 animals (Table 2) The results indicate that lactate was being metabolised by the foetus in amounts that could account for 25% of the foetal oxygen uptake

Many studies performed in vitro have demonstrated that the placenta of several species has a relatively fast rate of aerobic glycolysis Murphey and Hawkins[8] demonstrated the phenomenon in the rat placenta, and Bell et al[9] found that it occurred only in the presence of chorionic epithelium Aerobic production of lactate by human placental tissue has been measured in vitro[10-12]

Our data demonstrate that lactate concentrations are greater in the umbilical and uterine veins than in their corresponding arteries In conjunction with the in vitro studies, these data indicate that the lactate acquired by the foetus from the umbilical circulation is produced by the placenta

This is the first demonstration that lactate produced by the placenta is an important substrate of foetal metabolism As demonstrated by the measurement of lactate/oxygen quotient, catabolism of the lactate acquired from the umbilical circulation to carbon dioxide and water would require one-quarter of the total foetal oxygen uptake This is equal to the estimated amount of oxygen needed for the foetal breakdown of amino acids[4] and half the oxygen required for the aerobic metabolism of the glucose which is delivered normally by the placenta to the sheep foetus[1-3]

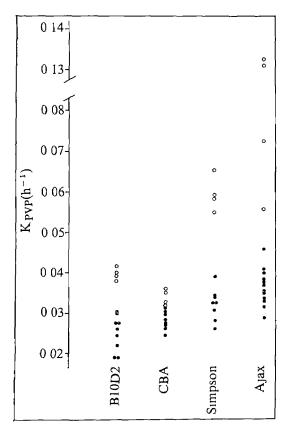
Relationship between macrophage clearance of PVP and affinity of anti-protein antibody response in inbred mouse strains

MACROPHAGES are important in immunity on their own, in delayed-type hypersensitivity, in phagocytosis of immune complexes, and in the afferent limb of antibody responses Evidence for the latter includes the increased immunogenicity of macrophage-processed antigen[1], and the requirement for macrophages in antibody responses involving cooperation between T and B lymphocytes[2] In addition, antibody titres can be increased or decreased by agents, such as adjuvants[3] or colloidal carbon[4], which probably act on macrophages Changes in either quantity or quality (affinity) of antibody, or both, may occur carbon[5] reduces the affinity of mouse anti-protein antibody but does not affect quantity, whereas adjuvant[6] increases both Differences in macrophage activity could therefore be responsible for differences in antibody affinity between mouse strains[7] Carbon clearance differs between strains[5,8], and has been found to be loosely related to affinity[5] We have used a new test of macrophages which shows differences of clearance function which relate closely to differences of antibody affinity

Polyvinyl pyrrolidone (PVP) clearance[9] was measured in normal 10 to 14-week-old mice of six inbred strains (B10D2(new), SWR/J, CBA, Simpson and Ajax) Results are expressed as the rate constant (K_{PVP}, h^{-1}) of the exponential fall in blood radioactivity between 18 and 48 h after intravenous injection of ^{125}I-PVP (Radiochemical Centre, Amersham) Mice of four of these strains were immunised with two weekly injections of 1 μg PVP (molecular weight, 360,000), and clearance of ^{125}I-PVP was tested one week later Affinity (K_R, mol^{-1}) and quantity (Ab_t, μM antibody binding sites) of antibody against human

Fig. 1 PVP clearance (K_{PVP}) in mice of six inbred strains, compared with affinity (K_R) of antibody for HSA (Data for K_R kindly provided by Dr M W Steward[7])


serum albumin (HSA) was determined in normal Ajax mice after saline immunisation[10], and in mice given 10 mg PVP (molecular weight, 360,000) intraperitoneally 24 h before each HSA injection

K_{PVP} differs significantly between the six strains of mice (Fig 1, $F=10\,4$, $P < 0\,01$, one-way analysis of variance), possibly on a genetic basis Variation within each strain exceeds the methodological variation[9], suggesting that environmental factors also contribute The correlation between the strain ranking order for K_{PVP} and antibody affinity (K_R) is striking ($r_s=0\,99$, $P<0\,01$, rank correlation on mean values), but there is no significant correlation between K_{PVP} and Ab_t ($r_s=0\,30$, $P>0\,05$) for the five strains for which values of Ab_t are available[7]

Tests of macrophage function have included *in vivo* clearance measurements using a variety of particles and *in vitro* tests of isolated monocytes or peritoneal cells[11] The different clearance tests may measure, to some extent, different things[8], and their relationship to *in vitro* function has been little studied All other clearance measurements give much faster clearance rates than ours, and use doses large enough to saturate the phagocytic capacity of the Kupffer cells[12] Such doses are likely both to stimulate and to block the function measured, and the magnitude of such effects differs between strains[8] The amount of PVP used is much smaller and does not cause dose-related blockade[9], so that PVP clearance may parallel the handling by macrophages of small quantities of antigen more accurately than do other tests Evidence that it does indeed measure a macrophage function includes the facts that the PVP is detected in macrophages and clearance and the hepatic uptake is reduced by carbon and by corticosteroids, but increased by oestrogens There is no evidence of antibody response at the time of testing, and repeat tests usually give similar values Large doses of unlabelled PVP blockade clearance of both PVP and carbon

The close relationship between PVP clearance and affinity of antibody to HSA suggests that the former measures a biologically important function, and supports the theory that variation

Fig. 2 PVP clearance (K_{PVP}) in normal mice (●) and mice immunised with 1μg PVP (○)

in macrophage function underlies differences in affinity of antibody response, as does the alteration of both antibody affinity and macrophage activity with carbon, adjuvant or oestrogen[5,6] Cells responsible for phagocytosis of PVP are involved in determining antibody affinity, since Ajax mice given 10 mg PVP before each injection of HSA showed significant ($P<0\,025$, Mann–Whitney U test) reduction in K_R (log mean $0\,12\times10^6$ mol^{-1}, compared with control mean of $0\,95\times10^6$ mol^{-1}), but Ab_t was unchanged (mean $2\,0$ μM, control mean $1\,8$ μM, $P>0\,05$)

Poor macrophage function probably leads to a low affinity antibody response because of poor selection of B lymphocytes The optimum response after adjuvantised immunisation[8] makes it unlikely that the limiting factor is a deficiency of suitable lymphocytes Perhaps PVP clearance correlates better with antibody affinity than does carbon clearance because PVP is more similar in size to the immunogenic microaggregates of soluble proteins than are carbon particles, and because the large dose of carbon partially blockades the macrophages[12] Our results do not imply that endocytosis of antigen is necessary for optimal antibody response[13] PVP clearance and antigen handling may both depend on overall macrophage activity and motility, or macrophage phagocytosis of PVP may depend on cell surface characteristics which are also important in cell interactions We do not know how the differences of antibody response we describe are related to those of mice selected for high and low titres of agglutinating antibody[14] These differences may also depend on macrophage function, as peritoneal cells from animals with low response show increased rates of antigen degradation[15] If they are related, the ability of the macrophage surface to bind and retain intact antigen molecules may be the critical function which determines the nature of the antibody response

Immune PVP clearance also differs between strains K_{PVP} was increased after immunisation (Fig 2) in all four strains tested, but more markedly so in the strains with high PVP clearance (Simpson and Ajax) than in the other two Immunised B10D2(new) and CBA mice clear PVP less well than many unimmunised Ajax mice There may be both low affinity antibody and defective clearance of immune complexes, and possibly also less antibody, but we do not know if there are differences in affinity of antibodies to PVP (T-cell independent and mainly IgM, ref 11) similar to those of IgG antibodies to cooperation-dependent protein antigens This individual variation of function may contribute to susceptibility to immunopathological processes such as immune complex disease[6], including that in man, in whom similar variation occurs (A G M and J F S, unpublished)

Tumour-associated transplantation antigens of chemically induced sarcomata cross reacting with allogeneic histocompatibility antigens

INDIVIDUAL tumour-associated transplantation antigens (TATA) of chemically induced tumours and histocompatibility antigens (HA) share the ability of inducing transplantation immunity, and have other properties in common, such as the high degree of polymorphism[1-3] and a similar cell surface behaviour[4] A reciprocal relationship between the quantitative expression of TATA and H-2 antigens has been observed[5-6], suggesting the existence of common mechanisms either in their synthesis or in the control of their phenotypic expression Such indirect similarity prompted us to study the existence of cross reactions between TATA and HA We therefore determined whether 3-methylcholanthrene (MCA)-induced sarcomata possess TATA-containing allogeneic histocompatibility determinants Here we report data from two BALB/c fibrosarcomas, ST-5 and B-2

We investigated whether protection against the syngeneic tumours could be induced by immunisation with normal allogeneic tissues Groups of BALB/c mice were transplanted with skin or with kidney plus liver from syngeneic, C57BL/6J or C3Hf, mice, with skin of W/Fu rat, or were injected intraperitoneally with sheep red blood cells (SRBC) Ten days later all mice received 400 rad (whole-body) and were challenged on the following day with sarcoma ST-5 cells As shown in Fig 1a a significant protection against sarcoma ST-5 (as assessed by χ^2 test) was elicited by C57BL/6J skin or liver plus kidney grafts when compared with syngeneic skin graft ($P < 0.01$ at day 12 and 16, and $P < 0.05$ at day 20 after challenge), C3Hf skin graft was highly effective ($P < 0.001$ from day 8 to 32, and $P < 0.05$ at day 36) and a still stronger protection was achieved by C3Hf liver plus kidney graft ($P < 0.01$ from day 8 to 36), whereas no resistance could be induced by rat skin graft or by injection of SRBC No effect was induced by C57BL/6J or C3Hf liver plus kidney graft against the challenge of sarcoma B-2 (Fig 1b)

It seems, therefore, that TATA from sarcoma ST-5 cross reacted with HA of C57BL/6J and C3Hf strains It is unlikely that a nonspecific increase of the immune response caused by antigenic stimulation was responsible for the anti-tumour resistance induced by allografts, since rat xenograft and SRBC injection had no effect, and since sublethal X-irradiation strongly impairs primary immune response Moreover, no resistance could be induced with the same schedule against sarcoma B-2, which lacks TATA

These results were partially confirmed by serological studies

Fig 1 Antitumour resistance induced by allograft Groups of 10 BALB/c males 2 months old, received either a full thickness skin graft (15×20 mm), or a subcutaneous injection in the back of liver plus kidney fragments in 0 5 ml MEM+antibiotics, or were injected intraperitoneally with 10⁹ SRBC in 0 5 ml saline Liver plus kidney fragments were prepared by teasing and mincing the organs and the equivalent of one-third of the pool of one liver and two kidneys was given to each mouse Challenge 5×10⁴ ST-5 cells (a) or 2×10³ B-2 cells (b) in 0 2 ml MEM, subcutaneously in the flank All mice were examined for palpable tumours every 4 d after challenge Skin graft □, C3Hf, ○, C57BL/6J, ———, BALB/c, - - - -, W/Fa rat Liver plus kidney graft ■, C3Hf, ●, C57BL/6J, - - -, BALB/c, △, SRBC Sarcoma ST-5 originated from BALB/c fibroblasts exposed to MCA in a diffusion chamber placed intraperitoneally in a BALB/c mouse The treated fibroblasts, for experimental reasons not relevant to this study[7], were transferred to a (C3Hf×BALB/c)F₁ hybrid until they developed in a palpable nodule The BALB/c genotype of the tumour was assessed by retransplanting the nodule in BALB/c mice where it took promptly Sarcoma B-2 was obtained by syngeneic subcutaneous transplantation of in vitro spontaneously transformed BALB/c fibroblasts Both tumours were serially transplanted in unconditioned BALB/c mice, and used between the 8th and 15th in vivo passage At the time of the present experiments ST-5 was found to be immunogenic using the in vivo growth-excision assay[7], whereas B-2 showed no immunogenicity, no cross reactivity was found between the two sarcomas The individuality of the ST-5 TATA was also proved by the absence of cross reaction with other MCA-induced BALB/c sarcomas

Absorption with ST-5 cells significantly removed the cytotoxic activity of a BALB/c anti-C57BL/6J serum compared with absorption with BALB/c lymphocytes or with sarcoma B-2 ($P < 0.001$ at 15×10⁶ absorbing cell dose, Fig 2) In contrast, several attempts to absorb the cytotoxic activity of a BALB/c anti-C3Hf serum with either tumour failed

To demonstrate further transplantation antigens belonging to C57BL/6J and C3Hf strains on ST-5 cells, we compared the immunogenic strength of TATA of sarcoma ST-5 in the syngeneic against (BALB/c×C57BL/6J)F₁ (CB6F₁) and (C3Hf×BALB/c)F₁ (C3CF₁) hybrid mice We anticipated that if C57BL/6J or C3Hf determinants were part of TATA of sarcoma ST-5, the immunogenicity of this tumour in the hybrid mice should have been absent or lower than in BALB/c mice Growth-excision of ST-5 in CB6F₁ mice elicited no immunity against a subsequent challenge of the related cells, whereas only a slight reduction in protection was observed in C3CF₁ compared with BALB/c mice (Table 1)

TATA of sarcoma ST-5 seems to be complex Whereas anti-tumour resistance induced by C57BL/6J and C3Hf allografts may be explained as TATA possessing a unique determinant shared by both C57BL/6J and C3Hf HA and absent in BALB/c tissues, such as specificity 5 of k and b H-2 genotypes, or H-4ª antigens, in the hybrid experiment a clear

Table 1 Immunogenicity test of ST-5 sarcoma in syngeneic against hybrid mice

¶Not significant

Fig. 2 Absorption of BALB/c anti-C57BL/6J serum by ST-5 and B-2 cells Serum obtained by immunising BALB/c mice with 4 weekly injections of C57BL/6J lymphoid cells The animals were bled 7 d after the last injection The ^{51}Cr-release test on C57BL/6J radiolabelled lymph node target cells[14] was performed at the serum endpoint dilution of 1 32 in the presence of guinea pig complement (B D Merieux, Marseille, France) The specific ^{51}Cr release was calculated as follows $100 \times$ experimental release-background/maximum releasable ^{51}Cr-background (where background represents ^{51}Cr release in the presence of heat inactivated complement) Tumour cells prepared by trypsin treatment for 20 min at room temperature and suspended in MEM, were incubated for 2 h at 37 °C before absorption Lymph node cells were obtained by mincing and teasing subcutaneous and mesenteric lymph nodes, and resuspended in MEM Absorptions were carried out by incubating 0 12 ml serum with 5×10^6 packed cells for 30 min at 37 °C followed by 30 min at 4 °C, in 2 ml test tubes To avoid excess dilution by a large cell pellet the absorption doses of 10 and 15×10^6 cells was reached by two and three repeated absorptions on 5×10^6 cells, respectively No gross difference was observed between ST-5 and B-2 cell pellet volume Each point is mean of three replicates ○, ST-5 cells, ●, B-2 cells, ■, BALB/c lymph node cells, □, C57BL/6J lymph node cells

reduction in immunogenicity was observed in CB6F$_1$ mice only This suggests that TATA of sarcoma ST-5 contains at least two components, one limited to C57BL/6J strain, tolerated in CB6F$_1$ and recognised as foreign in C3CF$_1$ hybrids, the other shared by both C57BL/6$_1$ and C3H$_1$ strains and therefore tolerated in both CB6F$_1$ and C3CF$_1$ hybrids A prevalence of C57BL/6J in the make-up of ST-5 TATA may also explain the failure of ST-5 cells to absorb the activity of a BALB/c anti-C3Hf serum Note, however, that C3Hf grafts induced a stronger antitumour resistance than the C57BL/6J ones

The possibility that a somatic hybridisation spontaneously occurred in the early passage of the tumour in the C3CF$_1$ host, may be responsible for the observed cross reactions, is unlikely, since the phenomenon has been reported to be infrequent[8], and since the subsequent serial passages in unconditioned BALB/c mice should have selected against hybridised cells In addition, a hybridisation between BALB/c and C3CF$_1$ cells could not explain the presence, on ST-5 cells, of C57BL/6J antigens not shared with C3Hf strain

We consider the origin of TATA of sarcoma ST-5 to be the result of carcinogen-induced random mutations at the level of histocompatibility genes, either of the H-2 system or of the minor loci Such a possibility is supported by the genetic linkage which seems to occur between TATA and the H-2 system[9]

Moreover, assuming that HA have a key function in the economy of cell life[10], only TATA identical or very similar to HA of normal cells should be selected for among the different neoantigens which appear at the initial stages of carcinogenesis[11] Alternatively, the possibility of a carcinogen-induced activation of silent histocompatibility genes normally expressed in allogeneic strains should be considered, as suggested for other systems[12,13] In this case one would expect

to find a perfect identity between TATA and a given foreig histocompatibility antigen

We thank Dr G Della Porta for his support and Mr C Piovesana for assistance This work was partially supporte by CNR, Rome

Antibody to a molecularly-defined antigen confined to a tumour cell surface

TUMOUR-SPECIFIC antigens have usually been demonstrated with little knowledge of their molecular nature, for example by the residual reactivity with tumour shown by an anti-tumour serum which has been absorbed with normal tissue Certain tumours of B lymphoid cells which secrete immunoglobulin (Ig) provide a promising situation for identification of the antigen in molecular terms[1-3] Amino acid sequences in the variable (V) regions of Ig molecules determine not only antibody activity, but also the 'idiotypic' antigenic determinants of the molecule (for review see ref 4) In a normal B lymphoid clone the V regions on the surface Ig of the early members are the same as those on the Ig exported by specialised protein-secreting descendants and are essentially unique to this clone[5,6] The morphology and mode of Ig secretion in neoplastic cells are frozen at some stage in the range shown by their normally differentiating counterparts (Fig 1) Tumours with cells having both surface and export Ig have provided Ig in the host serum in amounts suitable for the conventional raising of anti-V sera These sera, by reacting specifically with the surface Ig of the corresponding tumour, demonstrated that the V regions can represent tumour-specific antigens[2,3] Furthermore, Lynch *et al*[1] demonstrated that mice immunised so as to produce antibodies to the V regions of such a tumour (a syngeneic mouse myeloma) were thereby afforded a measure of specific protection against tumour challenge

It is unlikely that anti-V sera raised in this way could be used therapeutically against the tumours concerned, because the exported Ig would represent a large extracellular barrier against access to the tumour cells Consider, however, the therapeutically interesting case of neoplastic B lymphocytes having only surface Ig (Fig 1) Are there definable idiotypic determinants on this surface Ig and is it possible routinely to raise the anti-V sera? Here we show that this is so in both cases for a guinea pig leukaemia

The L$_2$C leukaemia of strain 2 guinea pigs is a transplantable tumour, maintained by repeated passage *in vivo*, composed of large B lymphocytes[8] with scanty cytoplasm and no significant endoplasmic reticulum They bear IgM on their surfaces, approximately 100,000 molecules per cell being shed with a half life of about 5 h (ref 9) There is no evidence of IgM being delivered to extracellular fluid by any mechanism other than turnover on the cell surface[9]

Blood was collected by exsanguination of animals near

Fig. 1 Three morphological cell types distinguishable in the continuum of a normal maturing B lymphoid clone, with the associated modes of Ig secretion Note that some cells exhibit both surface and export Ig (ref 7) Neoplasms can seemingly arise at various stages to give clones in which differentiation is frozen The horizontal lines depict the ranges of cell types commonly seen among the indicated neoplasms The scheme is drawn for human neoplasms but is probably applicable broadly to all mammals

death as a result of leukaemia, and the leukaemic lymphocytes $(2 \times 10^5 - 3 \times 10^5 \, \mu l^{-1})$ were separated and washed thoroughly Limited proteolysis of the cells with papain[9,10] (0 06 mg ml^{-1} acting on 10^8 cells ml^{-1} for 30 min at 37 °C) cleaved the surface IgM *in situ* and released Fabμ fragments, bearing the V regions, into the supernatant From here the Fabμ was isolated by binding to a microcrystalline cellulose immunosorbent, with an approximate yield of 75 μg per 10^{10} cells[9]

Antibody to the V regions was raised by injecting the washed, Fabμ-laden immunosorbent from 3×10^{10} cells directly into two sheep (ref 11 and Fig 2) It should be noted that the schedule exposes the animals to particles on which the only foreign molecules are the cellulose matrix and the guinea pig Fabμ The Fabμ contains V and constant (C) regions, so passive antibody to the C regions was injected simultaneously with the antigen to promote the anti-V response and depress the anti-C[11-13]

Serum was obtained from the sheep 1-3 weeks after the second injection of antigen It contained low levels of two unwanted antibody activities to the Fabμ C regions, judged by precipitin reaction, and to guinea pig normal cell surfaces

judged by immunofluorescent staining of normal leukocytes These activities were removed by passaging IgG from the sera through normal strain 2 guinea pigs IgG from sheep normal serum was passaged similarly to provide a control The entire schedule (summarised in Fig 2), provided us with guinea pig serum containing sheep IgG, antibody or control, at approximately 2 mg ml^{-1} The 'antibody serum' and 'control serum' were tested for reactivity against L_2C cells and syngeneic normal lymphocytes (from lymph nodes, spleen and thymus) by immunofluorescence and inhibition of migration

Immunofluorescence was by the indirect technique with all manipulations carried out at 4 °C to prevent capping[14] Cells at 2×10^7 ml^{-1} in Eagle's MEM were mixed with an equal volume of antibody or control serum and incubated for 30 min They were then washed, treated with indicator reagent (fluorescein-conjugated IgG from rabbit antiserum to sheep IgG), washed again and examined in suspension The only positive reaction observed was with antibody serum and L_2C cells, which showed uniform circumferential staining with superimposed bright spots

Inhibition of migration was carried out as described by

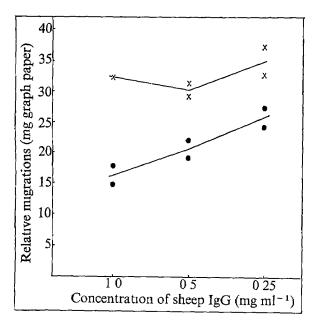
Fig 2 Preparation of antibody to idiotypic determinants on V regions of surface Ig *a*, L_2C cells contain many surface antigens among which the Ig is a trace constituent *b*, Before exposure to the definitive immunosorbent the cellular supernatant undergoes a thorough preliminary absorption with a blank immunosorbent consisting of sheep normal IgG coupled to microcrystalline cellulose, thereby removing material adhering nonspecifically to the cellulose matrix *c*, The definitive immunosorbent was prepared by coupling purified sheep anti-guinea pig Fab'γ to the cellulose[11] *d*, Fabμ-laden immunosorbent was mixed with Freund's complete adjuvant and injected, in two doses five weeks apart, at multiple subcutaneous sites Each dose was accompanied by intravenous administration of 30 ml sheep antiserum to guinea pig serum Fabμ, in effect an antiserum to the C regions of Fabμ *e*, 100 mg IgG from unabsorbed sheep antiserum per 300-g guinea pig The animals were exsanguinated 6 h later, each yielding approximately 20 mg sheep IgG in 10 ml serum


Fig. 3 Migrations of L_2C cells into nutrient medium containing sheep IgG passaged through normal guinea pigs ×, Normal IgG, ●, IgG from anti-V serum Note that a concentration of sheep IgG of 1 mg ml^{-1} is equivalent to approximately a 1 in 20 dilution of a sheep serum Migrations by normal (nodal and splenic) lymphocytes in the presence of normal or anti-V-containing IgG were indistinguishable

Currie and Sime[15] Cells at 5×10^7 ml^{-1} in MEM were taken into capillaries which were then sealed at one end with wax After centrifuging the cells towards the seal each capillary was cut at the cell–medium interface, and the open end of the cell-containing part was attached with silicone grease to the base of a culture well in a Sterilin S25 plastic plate The wells were filled with antibody or control serum and sealed with cover slips Migration into the medium took place for 16 h at 37 °C Relative areas of migration were estimated by projecting the cell patterns on to paper, cutting round the edges and weighing The results (Fig 3) reveal a significant degree of inhibition by the antibody serum

To confirm that the tumour-specific antibody is in fact directed against cell surface Ig, we took advantage of the molecular discrimination of the capping-pinocytosis phenomenon[14], whereby two sets of antigenic determinants cap simultaneously if on the same molecule, but otherwise independently In this case, antibody known to react with the surface Ig (in fact with C region determinants on the light chain) capped the determinants with which the tumour-specific antibody reacted and vice versa For the first experiment L_2C cells were suspended at 2×10^7 ml^{-1} in rabbit anti-guinea pig Fab'γ serum, 50% v/v in Eagle's MEM, and incubated at 37 °C for 30 min At the end of this period capping and internalisation were essentially complete, as indicated by the behaviour of an aliquot of cells allowed to react with fluorescein-conjugated IgG from the same antiserum The cells were chilled and washed, and without being rewarmed, were shown to have lost virtually all their reactivity with the tumour-specific antibody serum in the indirect immunofluorescence test In contrast a sheep anti-guinea pig lymphocyte serum retained full reactivity with the treated cells For the second experiment it was first found that incubation in tumour-specific antibody serum failed to give any capping on the L_2C cells, presumably as a result of the low antibody concentration in this serum A second layer of anti-antibody on the cell could, however, induce capping the cells were allowed to react at 4 °C for 30 min with antibody serum and then, after washing, were incubated at 37 °C for 30 min with a rabbit anti-sheep IgG serum which had previously been absorbed with guinea pig Ig Again examination of an aliquot of cells treated in the second incubation with a fluorescein conjugate of the anti-antibody suggested that

capping and internalisation were essentially complete at the end of the 30-min period The chilled, washed cells now showed greatly reduced reactivity with fluorescein-conjugated IgG from rabbit anti-guinea pig Fab'γ Cells treated similarly with control serum for the first step, showed the usual bright speckled fluorescence with fluorescein-anti-Fab'γ

We suggest that the availability of antisera to a tumour-specific molecule which can be identified and quantified, and which appears in the cellular environs simply as a result of turnover at the cell surface, is of considerable research and therapeutic interest An approach similar to that used here may be appropriate for a variety of tumour-specific antigens

Thymus reactive IgM autoantibodies in normal mouse sera

An important characteristic of the immune system is the ability to discriminate between antigens expressed on normal tissues within the individual and the many foreign antigens expressed on normal tissues of other species (xenoantigens) and even on normal tissues of members of the same species (alloantigens) Thus, although the immune system readily destroys inoculated xenogeneic and allogeneic tissue, autoimmune damage to normal, autologous tissue is rare The rejection of inoculated foreign tissue is thought to reflect an immune surveillance mechanism by which an individual could detect and eliminate his own aberrant cells expressing abnormal surface antigens[1] This mechanism may be important in restricting the development of many nascent tumours[1-3] Little is known, however, concerning either the mechanism by which the immune system destroys nascent tumours or the mechanism preventing the immune system from inflicting autoimmune disease The finding of near normal tumour incidence in congenitally athymic (nude) mice has suggested that immune surveillance may not involve the activity of thymus-dependent immunity but rather be a function of humoral immunity[4] In this respect it is interesting that sera of both normal and nude mice contain antibodies reactive with a wide variety of tumour cells[5,6] There is no evidence, however, that these antibodies function in the destruction of nascent tumours or that they are necessarily directed against tumour specific rather than normal tissue associated antigens It has been demonstrated that naturally occurring antibodies (NOA) reactive with the neural tumour cell line NB1 can be specifically absorbed by syngeneic normal brain tissue[6] We demonstrate further the autoantibody nature of certain NOA by documenting the occurrence in normal mouse sera of IgM antibodies reactive with autologous thymus cells

Sera of C3H/HeJcrf mice (C3H) were tested in the trypan

blue dye exclusion cytotoxicity assay for complement dependent cytotoxic activity against syngeneic thymus and spleen cells In 9 out of 10 experiments, serum of normal C3H mice caused significant lysis of syngeneic thymus cells (Table 1) In 12 experiments, the percentage lysis of syngeneic spleen cells by normal C3H serum varied from -54% to 73% with a mean specific lysis of -26% The anti-thymus cytotoxic activity of normal C3H serum was rabbit complement (RC') dependent since lysis of thymus cells was not observed if the rabbit serum used in the assay had been heat inactivated at 56 °C for 30 min or if guinea pig serum, adequate for the detection of anti-θ^{C3H} antibodies, was substituted for rabbit serum as a source of complement The anti-thymus cytotoxic activity of normal C3H serum was attributed to naturally occurring IgM antibodies since the cytotoxicity could be absorbed from mouse serum with anti-mouse immunoglobulin antibody-bound sepharose beads, and by a monospecific preparation of goat anti-mouse IgM antibody The cytotoxic activity was heat labile and susceptible to 0 1 M 2-mercaptoethanol In addition, when mouse serum was chromatographed on a Sephadex G-200 column, RC' dependent cytotoxic activity was detectable only in the excluded fraction (Table 2)

Undiluted normal sera of various strains were tested for RC' dependent cytotoxicity against autologous thymus cells Sera of all strains tested were cytotoxic for autologous thymus cells (Table 3) Repeated experiments on mice obtained from

Table 1 Complement dependent cytotoxicity of serum of C3H mice against syngeneic thymus cells

Experiment no	Lysis resulting from RC' (%)	Specific lysis (%) resulting from normal serum plus RC'

7	3 7	36 4
8	8 5	39 5
9	3 2	23 7
10	4 1	22 9

Mice 3–6 months old were bled from the tail vein The serum was separated by centrifugation approximately 1 h later and either tested directly or stored in aliquots at -20 °C Cell suspensions were prepared by gentle teasing of the thymuses in Dulbecco's modified Eagle's MEM containing 10% foetal calf serum (DMEM-10) followed by filtration through 100-mesh nylon net In the trypan blue dye exclusion cytotoxicity assay, 50 µl of a suspension containing 3×10^6 cells per ml in DMEM-10 were added to 50 µl of normal mouse serum The mixture was incubated for 60 min in a humidified incubator at 37 °C in a CO_2-air (10 90) atmosphere The cells were washed with 300 µl of medium and resuspended in 50 µl of the optimal dilution of rabbit serum as a source of complement (usually a 1 4 dilution) The rabbit serum had been absorbed previously at 2 °C with a one-third volume of packed thymus and spleen cells to reduce its toxicity Several batches of rabbit serum were used in these experiments Sera from some rabbits were excluded, however, because of either residual toxicity or low complement activity After a 60-min incubation at 37 °C, tubes containing the cells and RC' were placed in an ice bath A volume of 50 µl of trypan blue solution was added to the cell suspension and a sample was removed for microscopic enumeration of the percentage non-viable (stained) cells At least 100 cells were counted in each determination Controls included in each experiment were (1) incubation of cells with normal mouse serum followed by the addition of medium rather than RC' (antibody control), and (2) initial incubation of the cells in medium followed by incubation in RC' (RC' control) The antibody control value was invariably < 5% The RC' control value is indicated in the table In other experiments, unless otherwise indicated, the RC' control value was < 10% Duplicate determinations were performed The correlation observed between duplicate determinations was such that a calculated value of > 10% specific lysis was significant The 10 sera used in the experiments presented in this table were obtained from groups of 3–5 mice, 2–6 months old Specific, mouse serum induced lysis was calculated by

$$\frac{(\% \text{ Cytotoxicity (mouse serum} + \text{RC')} - \text{RC' control}) \times 100}{100 - \text{RC' control}}$$

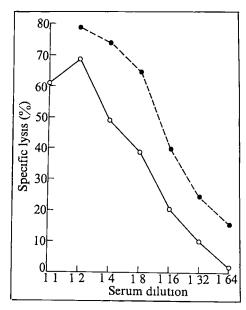

Fig. 1 Complement dependent anti-thymus cytotoxicity of sera obtained from nude (●) and normal C3H (○) mice The titration curve for nude and normal mouse sera represents the mean of values obtained using three distinct pools of sera from both nude and normal mice

the Imperial Cancer Research Fund and from the Rodent and Rabbit Production Section of the National Institutes of Health have confirmed that sera of many mouse strains regularly (> 80% incidence) contain readily detectable levels of thymus reactive cytotoxic autoantibodies Mouse sera are generally cytotoxic for allogeneic thymus cells, although thymus cells from different strains vary in their susceptibility to lysis by a given allogeneic serum (Table 3) Sera from nude mice possess significant levels of NOA reactive with allogeneic thymus cells (Fig 1) To determine whether susceptibility to

Table 2 Evidence for IgM antibody nature of naturally occurring anti-thymus cytotoxic activity in normal C3H serum

Experiment no	Serum treatment	Specific (%) lysis resulting from normal C3H serum plus RC'

ND, not determined

lysis by NOA was confined to functionally immature thymocytes, normal sera of C3H mice were tested for cytotoxicity against thymocytes obtained either from hydrocortisone-treated adult mice or from neonatal mice As Table 4 shows, thymus cells of hydrocortisone-treated mice were susceptible to lysis by NOA Thymus cells obtained from neonatal mice were lysed but only by undiluted normal serum

Schlesinger found thymus reactive autoantibodies in sera of all strain 129 mice 5 weeks or older[8] Shirai and Mellors, however, detected thymus reactive antibodies in only 46 out of 120 strain 129 mice 2–11 months old[9] In a survey of 10 other strains Shirai and Mellors regularly detected antibodies reactive at 37 °C with thymocytes in sera of 2–11 month old mice of the NZB strain (69 out of 97 sera tested) Anti-thymus antibodies were detected in a small proportion of normal sera obtained from several other strains, including C58 (17 out of 40 sera tested), and NZW (6 out of 25 sera tested) and were occasionally present in sera of AKR (14 out of 120), BALB/c (1 out of 29), C3HeB/Fe (3 out of 30), C57BL/6 (2 out of 90) and SJL (1 out of 21) strain mice Thymus reactive cytotoxic antibodies were not detected in 23 sera of DBA/2 mice or in 20 sera of A mice Boyse et al[10] detected thymus reactive autoantibodies in several mouse strains but only after the mice were immunised with allogeneic thymus cells These reports stand in contrast to that of Raff who, using hamster serum as the source of complement, detected high titres of thymus reactive antibodies in sera of all strains tested[11] Our findings confirm and extend

Table 4 Reactivity of normal serum of C3H mice against thymus cells of hydrocortisone-treated adult and untreated neonatal C3H mice

Thymus cell donor	Specific (%) lysis resulting from 1 1 and 1 2 dilutions of C3H mouse serum plus RC'	
	1 1	1 2
Normal adult	58 6	64 4
Hydrocortisone-treated adult*	41 7	49 4
Normal neonatal†	33 8	−2 9

*Six week old mice received 5 mg hydrocortisone acetate intraperitoneally 48 h before removal of their thymus Less than 10^7 thymocytes could be obtained from each hydrocortisone-treated mouse, whereas approximately 10^8 thymocytes were obtained from each normal mouse
†Mice less than 24 h old were used as thymus donors

those of Raff The failure of many investigators to detect thymus reactive autoantibodies in normal mouse sera may be the result of their use of inadequate amounts of complement or of complement with a high level of residual cytotoxicity due to inadequate absorption with normal tissue Thus, for example, when RC' was used at a lower than optimal concentration cytotoxic anti-thymus antibodies were detected in sera of 129 and NZB mice but not in sera of C3H, C57BL or A mice (data not shown)

The finding of thymus reactive antibodies in sera of nude

mice indicates that the thymus is not required as the antigenic source for the production of such antibodies and that the antibody response in normal mice is probably thymus independent Absorption studies have indicated that several thymus antigens are recognised by NOA. The nature and tissue distribution of individual antigens are being analysed The observation that hydrocortisone-resistant thymus cells are susceptible to lysis by NOA indicates that even within the thymus many of these antigens are not restricted to functionally immature thymocytes Whether the cells which actually leave the thymus continue to express these antigens has not been confirmed In any event the injection of thymocytes directly into the circulation provides an experimental system with which to study the consequence of the interaction of NOA and target cell and may help to elucidate the biological function of tumour reactive NOA

Carrier preimmunisation in the anti-hapten response of a marine fish

A STRONG antibody response in mammals and birds requires collaboration of two types of antigen-recognising lymphocytes, T and B Only the B lymphocyte gives rise to antibody-producing plasma cells This concept is partly based on the observed synergistic effect of thymic (non-B) cells and bone marrow (non-T) cells in antibody responses[1-3] Another line of evidence comes from immunisation with an antigen having several antigenic determinants such as A–B–C–D, which can be separated into portions A strong synergistic effect in an antibody response against A is found by combining lymphocytes primed with one part of the antigen (B–C–D = carrier) with lymphocytes primed with another part (A = hapten) and challenging the mixture with A–B–C–D (refs 4 and 5) T lymphocytes seem to be the relevant cells in the carrier-primed population[6]

Whether the collaboration of two types of antigen-recognising lymphocytes is also important for antibody responses of lower vertebrates is not known Studies of fishes, amphibia and reptiles are handicapped by the lack of histocompatible strains This excludes cell transfers from one individual into another, which have been the basis of all the studies cited above and makes *in vitro* collaboration experiments in lower vertebrates unattractive since histocompatibility between collaborating cells may be necessary for a good response *in vitro*[7] A phenomenon which can strongly suggest importance of cell collaboration and does not involve cells from more than one individual animal is an enhanced anti-hapten response caused by carrier preimmunisation This has been shown to correlate well with cell transfer data in mammals and birds[8-11], and we have used this method in the winter flounder (*Pseudopleuronectes americanus*)

Winter flounder, weighing between 0 2 and 0 3 kg, were caught using an otter trawl in Sandy Hook Bay, and were

Table 1 Anti-NIP response in the winter flounder

Group	No of fish	Priming	Challenge	Log mean anti-NIP titre‡ ±s e
A	9	CG–FCA*	$NIP_{13}CG$†	5 534±0 190
B	7	Saline-FCA	$NIP_{12}CG$	4 344±0 163
C	16	None	None	4 435±0 062

*Fishes were primed with 1 mg kg^{-1} chicken globulin (CG) in Freunds complete adjuvant (FCA)

†4-Hydroxy-3-iodo-5-nitrophenyl acetyl conjuguted to CG (1 mol CG to 12 mol NIP 0 5 mg kg^{-1} in FCA)

‡Haptenated phage inactivation titre on day 21

P values for A against B or A against C < 0 001

Difference between B and C was statistically insignificant

kept in continuous flow salt water tanks in the range 16–18 °C The fishes were injected intraperitoneally with chicken globulin (1 mg per kg of body weight) in complete Freunds complete adjuvant (FCA), controls were given saline in FCA After 3 weeks both groups were injected with 0 5 mg kg^{-1} NIP-CG (Table 1) and bled for sera after 3 weeks by puncture of the dorsal aorta under anaesthesia with tricanemethane sulphate The antibody was detected by the haptenated phage inactivation test according to the method of Becker and Makela[12]

The results indicate that one injection of the conjugate did not cause a measurable anti-NIP response in 3 weeks unless the animals were preimmunised with the carrier protein (Table 1) Flounders which had been preimmunised by FCA alone had antibody titres indistinguishable from the level of natural anti-NIP in this species Carrier-preimmunised animals, on the other hand, had more than ten times greater titres than either of the other groups

Flounder sera were unexpectedly strong inactivators of NIP-T4 phage This inactivation may be caused by natural anti-NIP antibodies Flounder sera did not inactivate unconjugated T4 phage, and inactivation of the NIP-T4 was inhibited by 3 × 10^{-6} M NIP but not by 10^{-3} M DNP (highest tested concentration) Both haptens were in the form of protein conjugates (10–15 mol hapten per mol BSA)

Our finding suggests that in fishes carrier-recognising cells also collaborate with hapten-specific cells for an optimal anti-hapten response As fishes are the most primitive major order of antibody forming animals, the available data suggest that collaboration of two types of recognising lymphocytes is a general requirement for the initiation of antibody production

We thank Drs Carl Sindermann and John Pearce of the Sandy Hook Laboratory (MACFC) for providing the facilities for these studies

Symmetrical transcription of herpes simplex virus DNA in infected BSC-1 cells

ALONI[1-3] reported that late in the replicative cycle of polyoma and simian virus 40 (SV40) viruses the viral DNA genomes are symmetrically transcribed in the infected cells The newly synthesised RNA molecules labelled for very short periods were shown to be complementary and on self-annealing yielded high molecular weight double stranded (ds) RNA Aloni and Attardi showed that similar symmetrical transcription occurs in HeLa cell mitochondria[4,5] In further studies Aloni[2] demonstrated that after polyadenylation of the SV40 symmetrical RNA transcripts the RNA is processed to yield uncomplementary viral mRNA molecules

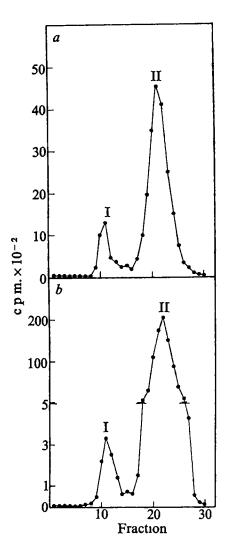
Since uninfected BSC-1 green monkey kidney cells which were used in our studies on herpes simplex virus (HSV) were found by Aloni[1] to have very small amounts of self-annealing RNA, we decided to study the nature of the transcription of HSV DNA, a linear genome with a molecular weight of 100×10^6 (ref 6) Studies by Roizman and his collaborators on the transcription of HSV DNA in infected nuclei revealed the synthesis of a high molecular weight precursor to viral mRNA[7,8] and the presence of polyadenylic acid [poly(A)] sequences in some of the virus-specified RNA[9] Wagner *et al*[10] reported that 90% of the HSV DNA genomes are transcribed late in the infection There is however no information on the mode of transcription and the DNA strand selection for transcription of HSV DNA Here we demonstrate that viral mRNA molecules which lack poly(A), transcribed from HSV DNA in BSC-1 cells late in infection, contain complementary sequences

BSC-1 monolayer cultures were infected with the HF strain of herpes simplex virus type 1 (ref 11) In these cells the HSV DNA is synthesised from 3 to 15 h after infection and the virus growth cycle is completed at 18 h The infected cells were pulse labelled with ^{3}H-uridine at 12 or 13 h after infection for 15 to 20 min, the RNA was extracted and analysed for complementary sequences by self annealing The amount of HSV specific RNA in the total RNA isolates does not exceed 10% as determined by hybridisation with HSV DNA

Figure 1a demonstrates the isolation of dsRNA molecules after self-annealing of labelled RNA HSV infected cells were labelled for 15 min at 13 h after infection and the total labelled

Table 1 Nuclease resistance of self-annealed RNA*

| Enzyme treatment | Trichloroacetic acid precipitable | | |
	^{3}H-self-annealed RNA %	^{3}H-rRNA %	^{3}H-HSV DNA
None	100	100	100
Pancreatic RNase	100	3	ND
Pancreatic RNase +DNase	100	ND	5
Denaturated RNA or DNA with RNase or DNase	5	5	12

*Total RNA from infected cells was prepared as indicated in Fig 1b Self-annealing was done in 4×SSC at 72 °C for 17 h and the self-annealed RNA peak was eluted from the Sephadex G-50 column after RNase (25μg ml⁻¹) treatment RNase treatment was in 0 2 M NaCl, 10 mM Tris-HCl, pH 7 4 10 mM EDTA at 37 °C for 60 min with 2,000 c p m of self-annealed RNA or 2,000 c p m ribosomal RNA (rRNA) DNase treatment was with 2,000 c p m HSV DNA in 100 mM NaCl, 10 mM MgCl₂, 10 mM Tris-HCl pH 7 4 at 37 °C for 60 min For the simultaneous incubation of RNase and DNase, 10 mM MgCl₂ (final concentration) was added to the RNase buffer without EDTA Thermal denaturation was at 100 °C for 5 min after which the samples were cooled in ice water The trichloroacetic acid (TCA) precipitable material was determined


ND, not done

Fig. 1 Exclusion chromatography of self-annealed, RNase-treated RNA on a column of Sephadex G-50 *a*, Total RNA, $1\,5\times10^7$ BSC-1 cells were infected with HSV (10 PFU per cell) and incubated at 37 °C for 13 h The infected cell cultures were then labelled with ^{3}H-uridine for 15 min (200 µCi ml^{-1}, specific activity 29 Ci mM^{-1}) The cells were chilled in ice at the end of the labelling period and scraped into RSB buffer (10 mM Tris-HCl *p*H 7 4, 10 mM NaCl, 1 5 mM MgCl$_2$) The swollen cells were homogenised in a tight glass Dounce homogeniser (30 strokes) Total labelled RNA was extracted twice with a mixture of phenol and chloroform 1 · 1 (v/v) at room tempereture and twice with chloroform–isoamyl alcohol (99 1) The RNA was precipitated in ethanol, dissolved in DNase buffer (10 mM Tris-HCl *p*H 7 6 100 mM NaCl, 10 mM MgCl$_2$) and incubated with DNase (50 µg ml^{-1}) for 15 min at 37 °C The RNA was extracted once more as above and was brought to 60% formamide and 2×SSC (1×SSC = 0 15 M NaCl, 0.01 M sodium citrate) and annealed by incubation at 37 °C for 24 h The RNA was precipitated with ethanol and resuspended in RNase buffer (0 2 M NaCl, 10 mM Tris-HCl *p*H 7 6 and 10 mM EDTA) and treated with RNase (5 µg ml^{-1}) at 37 °C for 60 min The RNA was diluted with the application buffer (0 1 M NaCl, 0 1% sodium dodecyl sulphate (SDS) 2 mM EDTA, 10 mM Tris-HCl, *p*H 7 7) and applied to a 100 cm Sephadex G-50 column Thirty fractions of 2 5 ml each were collected and 25 µl samples were used to determine the radioactivity in each fraction Peak (I) is the self-annealed RNA and peak (II) contains the low molecular weight RNA products, which remain after RNase treatment *b*, Exclusion chromatography of self-annealed, RNase treated RNA which did not bind to a cellulose column (poly(A) minus RNA) HSV infected cells at 12 h after infection were pulse-labelled for 15 min with ^{3}H-uridine (200 µCi ml^{-1}) Total RNA was prepared as in *a* After DNase treatment and phenol extraction, the aqueous phase was diluted with the application buffer containing 0 5 M KCl, 10 mM Tris-HCl *p*H 7 6 and 0 2 mM MgCl$_2$ The solution was applied to a cellulose column using the technique of Schutz *et al* [12] The RNA was washed with the application buffer (0 5 M KCl, 0 2 mM MgCl$_2$, 0 01 M Tris-HCl *p*H 7 6) and the unbound RNA was eluted After extensive washing with the buffer, when no more labelled RNA was eluted the cellulose

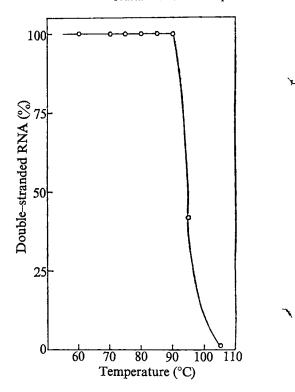


Fig. 2 RNase susceptibility of self-complementary RNA as a function of the denaturation temperature HSV-infected BSC-1 cells were labelled with ^{3}H-uridine (200 µCi ml^{-1}) for 20 min at 13 h after infection Total RNA was extracted as described in the legend to Fig 1*a* and self-annealed for 17 h at 72 °C in 4×SSC buffer The preparation was RNase treated (30% of the radio-activity was RNase resistant) and chromatographed on a Sephadex G-50 column as in Fig 1*b* The labelled RNA which was eluted in the first peak (as shown in Fig 1) was ethanol precipitated overnight and resuspended in 0 1×SSC Samples (each containing 1,600 c p m) from the dsRNA peak were distributed into glass tubes in 0 1×SSC and heated for 5 min at the indicated temperatures and rapidly cooled The samples were then brought to 2×SSC and treated with 50 µg ml^{-1} pancreatic RNase for 60 min at 37 °C The samples were TCA precipitated and the radioactivity was determined

Table 2 Hybridisation of denatured dsRNA with HSV DNA

^{3}H-RNA source	DNA source	Input (c p m)	Hybridised (c p m)	%
Denatured dsRNA	HSV	2,000	450	22 5
	BSC$_1$	2,000	86	4 3
	—	2,000	75	3 7
Cellular RNA	HSV	50,000	450	0 9
	BSC$_1$	50,000	1,600	3 2
	—	50,000	85	0 17

^{3}H-labelled dsRNA was obtained from the infected cells used for the experiment described in Fig 1 The dsRNA was denatured by heating for 5 min at 100 °C, cooled rapidly and hybridised in solution to 30 µg ml^{-1} of alkali-denatured HSV DNA or 350 µg ml^{-1} of alkali-denatured BSC$_1$ DNA The HSV DNA was purified from herpes simplex virions isolated in sucrose gradients The hybridisation was carried out in a buffer containing 0 4 M NaCl, 1 mM Tris-HCl, *p*H 7 4, 0 5 mM EDTA, final volume 100 µl for 24 h at 72 °C At the end of the hybridisation each sample was treated with RNase (50µg ml^{-1} for 60 min at 37 °C) and the hybrids were trapped on Millipore filters The filters were washed with 2×SSC and the radioactivity determined

column was washed with neutralised H$_2$O to elute the poly(A)-containing mRNA which was retained on the column The unbound RNA species which were eluted with the application buffer were used for self-annealing in 4×SSC for 17 h The samples were treated with 25 µg ml^{-1} RNase in RNase buffer as in *a* The RNA solution was chromatographed on a Sephadex G-50 column as in *a* Peak I is the self annealed RNA and peak II contains the low molecular weight RNA products, which remain after RNase treatment

RNA was extracted Similarly, dsRNA molecules were obtained from a ³H-RNA preparation which was chromatographed on a cellulose column to isolate the poly(A) containing RNA molecules by the technique of Schutz *et al*[12] In these conditions 12% of the total labelled RNA was bound to the column About 27% of the labelled RNA molecules synthesised in the nuclei of HSV infected BSC-1 cells are complementary and can form double-stranded RNA molecules, resistant to RNase treatment Further studies on the self-annealing of the poly(A) containing labelled RNA are in progress

We studied further the properties of the dsRNA molecules Heating as described in Fig 1 resulted in the denaturation of the dsRNA molecules and rendered them sensitive to RNase treatment (Fig 2) The dsRNA underwent a sharp transition in nuclease resistance at 95 °C in 0 1 × SSC, a higher temperature than SV40 dsRNA[1,2] The dsRNA was completely resistant to RNase and to a mixture of RNase and DNase at

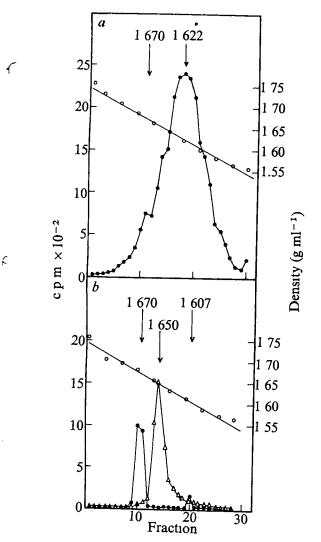

Fig 3 Buoyant density of self-complementary RNA in Cs_2SO_4 gradients HSV infected BSC-1 cells, at 12 h after infection were labelled with ³H-uridine (200 μCi ml⁻¹) for 15 min and the total RNA was extracted as described in the legend to Fig 1*a*, self annealed RNase treated and eluted from a Sephadex G-50 column The RNA preparation was divided into two portions One was left untreated (*a*) and the second was heated (4 min at 100 °C) and quickly cooled (*b*) To the two ³H-RNA preparations in buffer (0 05 M Tris-HCl, *p*H 7 4, 0 005 M EDTA), Cs_2SO_4 crystals were added to an initial density of 1 580 g ml⁻¹ To gradient (*b*) ¹⁴C-labelled ribosomal RNA was added as a density marker The tubes were centrifuged at 35,000 r p m in the Beckman ultracentrifuge at 20 °C in the rotor 50 Ti for 46 h The gradients were collected dropwise from the bottom and the density and the TCA precipitable radioactivity in each fraction were determined Symbols *a*, ●——● self-annealed dsRNA, O——O density *b*, ●——● denatured self-annealed ³H-RNA, △——△ ¹⁴C ribosomal RNA marker, O——O density

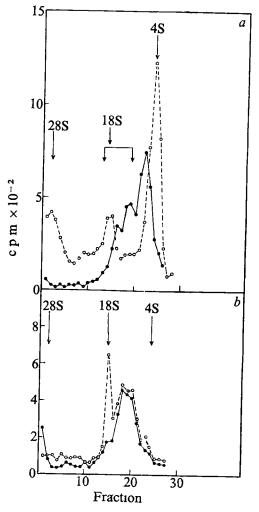

Fig 4 Sedimentation of dsRNA in sucrose gradients before and after denaturation *a*, dsRNA (●——●) was prepared as indicated in Fig 1 The dsRNA resuspended in SDS buffer after Sephadex G-50 filtration was layered onto a linear 5-20 (w/w) sucrose gradient in RSB containing 0 5% (w/v) SDS and centrifuged in SW41 rotor at 40,000 r p m , at 20 °C for 4 5 h Fractions were collected from the bottom of the tube dropwise and the TCA precipitable material was determined in each fraction ¹⁴C-labelled rRNA (O——O) served as internal marker *b*, Fractions 13–19 from the gradient (*a* arrows) were pooled, ethanol precipitated and resuspended in 10 mM Tris-HCl *p*H 7 4, 1 mM EDTA and divided into two portions, one (O) was denatured with formaldehyde at 70 °C as described by Aloni[1], the other (●) was kept untreated The samples were centrifuged in a 5-20 sucrose (w/w) gradient containing 0 5% (w/v) SDS in RSB in the SW41 rotor at 20 °C at 40,000 r p m for 4 5 h Fractions were collected dropwise and the TCA precipitable radioactivity was determined in each fraction, ¹⁴C-uridine-labelled rRNA served as internal marker

37 °C, but became completely sensitive to RNase after heating for 5 min at 100 °C (Table 1)

The labelled dsRNA molecules were centrifuged in Cs_2SO_4 and were found to band at a density of 1 622 g ml⁻¹ (Fig 3*a*) whereas after heat denaturation the RNA molecules banded at a density of 1 670 g ml⁻¹ (Fig 3*b*) The molecular size of the dsRNA molecules was determined by centrifugation in sucrose gradients (Fig 4) Some of the radioactive RNA sedimented to the position of 4S and some ranged from 10S to 16S Denatured RNA molecules also sedimented with a peak at approximately 18S, while the main mass sedimented at 8–10S (Fig 4*b*)

To determine the specificity of the dsRNA in respect to its homology with HSV DNA, the dsRNA molecules were isolated, denatured and hybridised in solution with denatured HSV DNA The dsRNA hybridised to HSV DNA and not to BSC-1 DNA (Table 2) It was noted that only 22 5% of the input RNA hybridised to HSV DNA This value may indicate that the

efficiency of hybridisation is low and that not all the RNA was HSV specific

Our study provides evidence that the primary transcription products in the nuclei of HSV-infected BSC-1 cells are transcribed from the two strands of the viral DNA in a symmetrical fashion The excluded peak from the Sephadex column is dsRNA as indicated by first, complete resistance to RNase at 37 °C, second, complete resistance to the simultaneous action of RNase and DNase, third, the sharp transition curve in nuclease resistance at 95 °C in $0 1 \times SSC$, which is not the melting temperature of the DNA–RNA hybrid, fourth, the density of 1 622 g ml^{-1} of the dsRNA which differs from the density of DNA–RNA hybrids, and finally the transition to the high density of 1 670 g ml^{-1}, which is specific for G+C rich DNA, on heat denaturation of the dsRNA

Conversion of photoexcitation energy in rhodopsin

AN interaction between the 11-*cis*-retinylidene chromophore and nearest-neighbour molecules seems to be important for explaining the mechanism of conversion of photoexcitation energy, because the chromophore is enveloped by opsin It has been reported[1] that the time of the formation of prelumirhodopsin (lifetime of the excited state) is less than 6 ps

A weak electron spin resonance (ESR) signal for the forbidden transition $\Delta m = \pm 2$, as shown in Fig 1, was observed following

Fig. 1 ESR spectrum ($\Delta m = \pm 2$) of rhodopsin irradiated with visible light at 77 K The microwave frequency is about 9,230 MHz and the reproducibility of this ESR signal was about 70% Clear experimental conditions for inducing the triplet state were not discovered Free radicals ($g \simeq 2 00$, $\Delta H \simeq 18$ gauss) were also observed by ultraviolet irradiation (K S , unpublished)

1,450   gauss   1,550

the irradiation with visible light ($\lambda = 450$–600 nm) of frog rhodopsin extracted with 2% digitonin and mixed with an equal volume of glycerol so that it would freeze to a glass at 77 K A set of glass filters was used which cut out any light of less than 450 nm The intensity of illumination was $\sim$ 1,500 lx at the window of the cavity About one-tenth of the rhodopsin molecules (10^{14}–10^{15} unbleached rhodopsin molecules per effective volume) was transformed into the triplet state by irradiation This resonance signal disappeared after melting the irradiated rhodopsin and then freezing it again at 77 K The irradiated rhodopsin and then freezing it again at 77 K The solvent in the same glass tube without rhodopsin did not show such a resonance signal even after the same irradiation The important factors for this signal are the zero-field splitting parameters (D and E), because the spin orientation in the external magnetic field and the microwave frequency are known parameters of the experiments $D^*(=(D^2+3E^2)^{1/2})$ for rhodopsin is estimated from the magnetic field (H_{min}) of this signal as $0 117 \pm 0 002$ cm^{-1} The excitation of rhodopsin results in photochemical transformation of the 11-*cis*-retinylidene chromophore to all-*trans*[2], probably by way of the lowest triplet state T_1 (ref. 3) D for the retinal was evaluated by[4]

$$D = \tfrac{3}{4}g^2\beta^2 \sum_{p<q} (C_{ip}C_{jq} - C_{iq}C_{jp})^2 \times$$
$$\times \langle \chi_p(1)\chi_p(1)|r_{12}{}^2 - 3z_{12}{}^2/r_{12}{}^5|\chi_q(2)\chi_q(2)\rangle \qquad (1)$$

where β is Bohr magneton, C_{ip} and so on are the linear combination of atomic orbital (LCAO) coefficients, χ_p represents an atomic π orbital associated with the pth carbon atom, r_{12} is the distance from electron 1 to electron 2 and z is chosen parallel to the π orbitals of the retinal From equation (1), it is expected that the Hückel (H) and self-consistent-field coefficients are of the same order When D for the retinal was evaluated using the coefficient H, its value was about $0 057$ cm^{-1} E for the retinal is not zero, because of poor symmetry, but D^* for rhodopsin is greater than D^* for the retinal, so that E is generally chosen under the condition $|D| \geqslant 3|E|$ using the values of D (0 117 cm^{-1} and $0 057$ cm^{-1}) mentioned previously The triplet state was not therefore, the result of the conversion of the chromophore during isomerisation of 11-*cis* into all-*trans*, but was assumed to have arisen from photoexcited energy transfer from the chromophore to a molecule having π electrons, for example an aromatic amino acid of opsin The energy differences of the excited and the ground states of aromatic amino acids are,

Table 1 D^* values and linewidths, ΔH, of aromatic amino acids

†Ref 6
‡Calculated values from data of refs 7 and 8

however, higher than those of the chromophore In this system, the inference is that formation of a hydrogen bond between the chromophore and an amino acid is necessary for this energy transfer, that is a charge transfer It may be suggested that the changes of λ_{max} of rhodopsin which is denatured by trichloroacetic acid[5] are attributable to the hydrogen bond between the chromophore and the amino acid The mechanism of the charge

transfer is probably induced by the electron transfer interaction between the π systems of the chromophore and of the amino acid The σ–π interaction of the hydrogen bond, $=\overset{+}{N}–H \cdot$, may be an exchange interaction, presumably involving the proton transfer. The wave function of the retinylidene chromophore may be written as

$$\Psi \simeq C_1\varphi_0 + C_2\varphi_{CT} \qquad (2)$$

where φ_0 and φ_{CT} mean the states containing the hydrogen bond and the charge transfer structure between the chromophore and the amino acid, respectively The observed signal is not attributable to the intermolecular triplet state, because D for rhodopsin is large We compared the D^* of aromatic amino acids and of rhodopsin (see Table 1), these results suggest that the ESR signal arises from the triplet state of tryptophan Although the process (CT complex→triplet state of tryptophan) is not yet known, it is possible that the triplet state of the tryptophan arises by way of a metastable state because the lifetime of the excited state of rhodopsin is short[1]

The mechanism of the charge transfer seems to be an important clue in clarifying the problems of the early receptor potential[9–10] which may be generated by charge separation in the rhodopsin molecule[11]

NH₂-terminal amino acid sequence of the Fc fragment of IgD resembles IgE and IgG sequences

THE function of IgD, a rare immunoglobulin (Ig) class, is unknown[1] It has been shown that most B lymphocytes in cord blood[2] and lymphocytes of patients with chronic lymphatic leukaemia[3] carry IgD on their surfaces, whereas only a small portion of lymphocytes from healthy human adults is IgD-positive[4] Almost all lymphocytes having IgD on the surface also carry IgM and both seem to function as receptors[5] To learn more about the relationship of IgD to other Ig classes, we are investigating the amino acid sequence of the IgD Fc fragment This report describes our first sequence analysis which suggests that IgD is more closely related to IgE and IgG than to IgM

The NH₂-terminal amino acid sequence of the Fc fragment is shown in Fig 1 Two preparations of Fc fragments of protein Di and one of protein Ac were analysed for 42 steps and one preparation of Ac for 53 steps All preparations showed a single sequence starting with the residue Thr, and the Fc fragments of proteins Di and Ac were alike The first 13 amino

acids had a sequence identical to that reported for the peptide of the δ chain that contains the half-cystine residue forming the sole inter-heavy–heavy chain disulphide bond in IgD (ref 8) allowing us to place the determined sequence at the beginning of the Fc fragment The sequence in this area of the δ chain was characterised by a relatively high content of aromatic amino acids One residue each of histidine, tyrosine and tryptophan was found in positions 7, 14 and 24, respectively, and two phenylalanine residues in positions 31 and 34 In addition, there was probably a tryptophan residue in position 52 and a tyrosine

Fig 1 NH₂-terminal amino acid sequence of IgD Fc fragment of myeloma proteins Ac and Di The Fc fragments were isolated after digestion of IgD with trypsin for 2 min[8] We applied 300 to 600 nM into the cup of an updated Beckman Model 890B automated sequencer using the DMAA program No 11374 The cleaved amino acids were identified either by gas chromatography or automated amino acid analysis after hydrolysis with 6 N HCl or HI as previously described[7] The protein was not fully reduced and alkylated with ¹⁴C-iodoacetamide to determine half-cystine residues because such preparations were insoluble and unsuitable for sequence analysis The half-cystine residue in position 4 was recovered as alanine after HI hydrolysis and the residue in position 33 was assumed to be a half-cystine because of the absence of any recoverable residue at this position and homology to the other Ig Fc fragments The tryptophan residue at position 24 was identified by gas chromatography and as an increase of glycine after hydrolysis with HI Position 52 was probably also tryptophan because there was no residue other than a slight increase in glycine after HI hydrolysis No residue could be identified in position 47 The extrapolated initial yield of the Fc preparation (Ac) that could be sequenced for 53 steps was 296 nM, approximately 600 nM had been applied to the cup The average loss per step determined during the first 20 steps was 3 8% The yields over background after step 35 varied slightly from step to step and were decreasing gradually from 30 to 4 nM as in the case of tyrosine in step 53

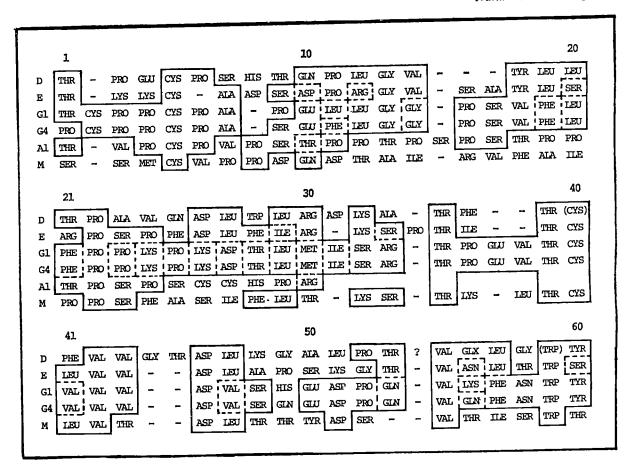
residue in position 53 because three other Ig classes have a tryptophan residue in the analogous position, and no other residue was detected in this position and at step 53 tyrosine was detected in about three times the background The yields of amino acids after step 35 were low, and therefore the sequence after step 35 is less reliable No residues could be identified in position 47 Although low yields in the late steps may have led to erroneous identifications, the residues that could be identified are reported because they demonstrate the great degree of homology among the δ chain and the other


Fig. 2 Comparison of amino acid sequence of the IgD Fc fragment with the analogous sequences of other Ig heavy chains[9-13] Gaps were inserted to achieve maximal homology among all six proteins that were compared

heavy chains whether determined in sections at the beginning or end of the sequenced Fc portion

The δ chain and the other Ig heavy chains were strikingly homologous (Fig 2) when the sequences at the beginning of the Fc fragment that contains the half-cystine residue involved in the inter-heavy-heavy chain disulphide bond were compared Homologies with IgE (ref 9) (41%) closely followed by IgG1 (ref 10) and IgG4 (ref 11) (34%) were greatest, whereas IgM (ref 12) showed the least homology (23%) Relatively little is known about the amino acid sequence of IgA in this area, nevertheless, a hinge peptide of IgA1 (ref 13) had a reasonable degree of homology (24%) and was probably also derived from the beginning of the Fc fragment The degree of homology to any given Ig class was similar over the entire area of the Fc fragment that was sequenced It is therefore most likely that the remaining portion of the δ chain's constant region will show a similar degree of homology to the other heavy chains

Little information is thus far available on the COOH-terminal domain of the δ chain COOH-terminal analyses suggested the sequence Pro-Gly-COOH (ref 6) similar to that of IgG (Pro-Gly-COOH) and IgE (Pro-Gly-Lys-COOH) and contrasting to those of IgM and IgA (Cys-Tyr-COOH) Like the ε chain, the δ chain lacked a methionine residue near the COOH-terminus[6] that was found in γ, α and μ chains IgD has a high carbohydrate content[6] resembling that of IgE, IgA and IgM and differing markedly from that of IgG

Based on these data and resemblance of the different heavy chains to one another I have attempted to place the δ chain into an evolutionary tree that was previously proposed for the other Ig polypeptide chain genes[14,15] (Fig 3) The relatively large difference in structure between the δ chain and the other heavy chains suggests that it evolved rather early Because γ and

μ chains differ the most, they probably diverged first, perhaps about 300 Myr ago[15] The δ chain and ε chain probably

Fig. 3 Scheme of possible evolution of Ig polypeptide chain genes

evolved next, either from a primitive γ- or μ-like heavy chain, 200-300 Myr ago (before the appearance of mammals) The time span of the appearance could be anywhere between 200 and 300 Myr ago, because it has been estimated that the ɣα chain which shows greater homology to the μ chain evolved about 200 Myr ago Obviously, phylogenetic studies of IgD will also be necessary to place evolutionary origin of IgD with greater certainty. If as predicted, however, IgD evolved before mammals appeared, one should be able to find an Ig class analogous to human IgD in lower vertebrates such as teleosts, amphibians, reptiles and birds

Unfortunately, IgD is only a minor serum component[1], and it has been extremely difficult to isolate it from serum without a specific antiserum Since IgD seems to be a lymphocyte receptor, however, an approach recently used to demonstrate an IgD analogue in mice[16,17] could be applicable to the problem These investigators first labelled the lymphocyte surface Ig and precipitated the IgM with a μ chain specific antiserum, in a second step they precipitated any other Ig that was present on the lymphocyte membrane with an anti-light chain antiserum An Ig with characteristics resembling IgD was then discovered Attempts to demonstrate this IgD-like substance on foetal murine lymphocytes were unsuccessful, but IgM was demonstrable by this method, suggesting that in ontogeny IgM appeared before IgD Since ontogeny often parallels evolution, this finding could corroborate the position of IgD proposed in Fig 3

Although the function of IgD is still unknown, an early appearance and persistence in evolution would suggest its importance in the immune system The striking resemblance of IgD to IgE and IgG, both known to have cytophilic properties[18], led us to study the binding of IgD myeloma proteins to lymphocytes, neutrophils and monocytes, however, no binding to any of these cell types could be demonstrated[19] It seems, therefore, most likely that IgD is a lymphocyte receptor the function of which may be quite different from that of IgM, to which it bears the least homology

I thank Drs Penn and Capra for providing plasma of patient Di and Dr Rosenbloom of patient Ac, and Ms Sanna Goyert and Gloria Portillo for assistance This work was supported by a grant from USPHS

Rapid postsynthetic destruction of unstable haemoglobin Bushwick

MOST structural variants of human haemoglobin occur in smaller amounts than HbA in the peripheral blood of heterozygous subjects Abnormal haemoglobins with mutations in the β chain usually comprise 35–45% of the haemoglobin in haemolysates In contrast, haemoglobins with abnormal α chains generally amount to only 20–25% of the total haemoglobin This difference in the proportion of α and β chain variants is thought to reflect the fact that in some populations there are two α loci and only one out of four α globin genes is affected in a heterozygote, whereas one out of two β globin alleles is abnormal in a subject with a β variant[1,2] Certain unstable haemoglobins with critical alterations in β-chain structure also constitute a much smaller proportion of the total circulating haemoglobin than HbA The low concentration of these abnormal haemoglobins is the result of accelerated preferential destruction[3-7] We report here a new unstable β variant, Hb Bushwick, which was detected in an intact form constituting only 1–2% of the total circulating haemoglobin Evidence was found for rapid postsynthetic destruction of the abnormal β chain In spite of this accelerated loss of the product of one of the two β alleles, the affected erythrocytes contained normal amounts of haemoglobin

The variant haemoglobin was discovered during the investigation of an Italian–American woman with a mild chronic anaemia and a history of several episodes of moderately severe haemolysis and jaundice associated with drug administration and intercurrent infections The presence of an unstable haemoglobin was suggested by the generation of multiple, small, coccoid, intraerythrocytic inclusion bodies on incubation of the subject's blood with the redox dye new methylene blue[8] Starch gel electrophoresis in Tris-EDTA-borate buffer, pH 8 6 (ref 9), revealed a faint abnormal haemoglobin band just anodic to HbA₂ (Fig 1) Mild, compensated, chronic haemolysis, slightly increased reticulocyte levels (2 0–5 7%) and the abnormal haemoglobin were also demonstrated in five relatives of the propositus (Table 1)

Hb Bushwick was purified by column chromatography on

Fig 1 Starch gel electrophoresis in Tris-EDTA-borate buffer, pH 8 6, of haemolysates from (AA) normal individual and (II-2) propositus with Hb Bushwick stained with Amido Black The anode is towards the top

DEAE-cellulose in Tris-phosphate buffer, pH 8 6 (ref 10) When estimated by haem absorption at 540 nm, the proportion of Hb Bushwick in the haemolysate was 0.7–1 2% whereas the concentration of HbA_2 was 1 2–2 4% When the relative haem and protein contents of haemoglobin fractions prepared by chromatography were compared, however, the ratios of the parameters reflecting haem content (pyridine haemochromogen[11] and absorbance at 420 and 540 nm) to the parameters of protein concentration (absorbance at 280 nm and total nitrogen content), were one-third to one-half lower in the Hb Bushwick samples than in the HbA samples This suggests that Hb Bushwick is partially depleted of haem groups

Table 2 Amino-acid analysis of $\beta^{Bushwick}TpIX$

	$\beta^A TpIX$	$\beta_{Bushwick}TpIX$	Difference

Ser	1	0 9 (1)	
Asx	3	2 9 (3)	
His	1	0 9 (1)	
Lys	1	1 0 (1)	

The α and β chains of Hb Bushwick were separated by column chromatography on CM-cellulose in 8 M urea at pH 6 7 (ref 12) Both polypeptides eluted in the positions expected for the corresponding normal globin chains The two globin fractions were amino-ethylated, digested with trypsin and peptide maps prepared[12] The fingerprints of both chains of Hb Bushwick were identical to the patterns obtained with

the corresponding polypeptides derived from HbA All the peptides of both the α and β chains of Hb Bushwick were therefore subjected to amino-acid analysis The composition of $\beta^{Bushwick}TpIX$ (positions 67–82) indicated that there was one more valine residue and one less glycine residue than expected for $\beta^A TpIX$ (Table 2) In $\beta^A TpIX$, glycine occupies positions 69 and 74 When $\beta^{Bushwick}TpIX$ was digested with chymotrypsin the resulting peptide corresponding to positions 67–71 had a normal composition, whereas the chymotryptic peptide corresponding to positions 72–75 had the composition Ser, Asp, Val, Leu This result indicated that the substitution of valine for glycine is at position 74 in the β chain of Hb Bushwick

Glycine at β74 occupies position 18 in the E helix and faces inward towards the haem crevice in a crowded cleft which separates the E helix, the EF corner, and the F helix[13] Glycine is invariant in this position for all known β chains except the kangaroo[14] Introduction of an amino acid with a larger side chain into this tightly packed area would be expected to make the molecule unstable The insertion of the large valine residue into the scale model of haemoglobin at position β74 brings the γ carbons of valine closer than the minimal permissible van der Waals distance to several atoms in serine β70 (E14), threonine β84 (EF8) and leucine β82 (EF6) (M F Perutz, personal communication). These short contacts would force apart the E and F helices between which the haem group is suspended This widening of the haem pocket could weaken several haem–globin contacts which probably accounts for the loss of haem from Hb Bushwick Another human haemoglobin mutant, Hb Shepherds Bush, has a substitution of aspartic acid for glycine at β74 (ref 15) The side chain of aspartic acid is thought to be able to swing out of the haem pocket towards the surface avoiding complete disruption of

*By DEAE cellulose chromatography
†By CM cellulose chromatography
‡Corrected for carrier protein,

he tertiary structure[15] Hb Shepherds Bush, which comprises 24% of the haemoglobin in the blood of affected subjects, may thus be more stable than Hb Bushwick

Because only an unusually small amount of Hb Bushwick could be demonstrated by haemoglobin electrophoresis or chromatography, attempts were made to detect the presence of additional amounts of β Bushwick in erythrocytes by amino-acid analysis Since β^ATpIX has a glycine-alanine ratio of 1 0 whereas that of $\beta^{Bushwick}$TpIX is 0 5, βTpIX prepared from an unfractionated haemolysate would have an intermediate Gly–Ala ratio depending on the proportions of the two haemoglobins present Analysis of peptide βTpIX of HbA purified from the haemolysate of the proposita revealed a Gly–Ala ratio of 1 0, suggesting that no Hb Bushwick was contaminating that fraction Three analyses of peptide βTpIX obtained from whole globin prepared by direct acid–acetone treatment of the unfractionated haemolysate, including membranes, gave Gly–Ala ratios of 0 97, 0 93 and 0 92, indicating that the erythrocytes could contain as much as 5–15% of Hb Bushwick Denaturation of the unstable haemoglobin or binding to cell membranes during preparation of a haemolysate could explain the lower amounts of Hb Bushwick demonstrable by chromatography or electrophoresis

The relative synthetic rates of HbA and Hb Bushwick were directly examined in vitro Washed erythrocytes from the propositus were incubated for 5–120 min with ³H-leucine The cells were lysed and HbA and Hb Bushwick were separated by DEAE chromatography The radioactivity in each haemoglobin fraction was measured (Table 3) and globin was prepared The α and β chains were separated and the total radioactivity and specific activity of the fractions were determined (Table 3) After incubation for 5–15 min the total radioactivity incorporated into β^A was only 1 2–3 times that in $\beta^{Bushwick}$ This indicated that the two β globin chains were synthesised in grossly equivalent amounts and suggested that the low proportion of Hb Bushwick found in blood was a result of postsynthetic loss of the unstable variant This rapid loss of newly synthesised Hb Bushwick was confirmed by the steep rise in the ratio of the radioactivity in β^A and $\beta^{Bushwick}$ to 7–20 1 after 50–120 min incubation A pool of non-radioactive excess free α chains in the erythrocytes was suggested by the low specific activity of the α chains relative to β chains in both haemoglobins after short periods of incubation The excess α chains were a result of degradation of preformed Hb Bushwick and were not the result of a deficit in β globin synthesis Synthesis of α and β globin was balanced in an experiment in which the entire haemolysate, including membranes, was converted directly to globin before chain separation (Table 3)

In spite of the evidence of rapid postsynthetic loss of Hb Bushwick, the erythrocytes did not seem hypochromic when examined microscopically and exhibited a normal mean corpuscular haemoglobin of 31 pg (Table 1) These findings suggest that the normal trans β^A allele was able to compensate for the loss of Hb Bushwick by increasing β^A globin synthesis There are several other examples of subjects having unstable β chain variants in amounts less than 20% of the total circulating haemoglobin[16-23] In all reports, except one[16], the erythrocyte mean corpuscular haemoglobin was normal, or nearly so, and the red cells appeared normochromic when examined under the microscope Regardless of whether the low intracellular concentrations of these unstable haemoglobins was primarily a result of increased destruction or decreased synthesis, a compensatory increase in β^A synthesis directed by the trans allele had to occur Such a degree of compensation is lacking in the β-thalassaemia trait[9] where a defect in one of two β globin alleles is associated with a decreased cellular content of β globin mRNA (ref 24), decreased HbA production and a low mean corpuscular haemoglobin content[9] The trans β^A gene thus does not seem to be able to compensate by increasing its gene product in thalassaemic cells as effectively as in cells with the unstable haemoglobins Possible mechanisms

for such failure of compensation in thalassaemia, include the presence of an inhibitor of β-globin synthesis or the lack of a synthesis-promoting substance These mechanisms have been postulated previously[25,26] but confirmation has been lacking It would seem worth while to continue exploration in this area

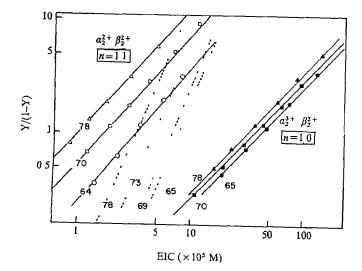
High cooperativity of haemoglobin M Boston in the completely reduced state

HAEMOGLOBIN (Hb) M Boston and Hb M Iwate, in which distal and proximal histidines, respectively, in the haem pockets of α chains are replaced by tyrosines, bind ligands only to the normal β chains, and have α chains stabilised in the ferric form These M Hbs contain mutant α chains and have abnormally low oxygen affinity, almost no Bohr effect, and virtually no haem–haem interaction[1,2] The β chain mutants, Hb M Hyde Park and M Saskatoon, have normal oxygen affinity and a


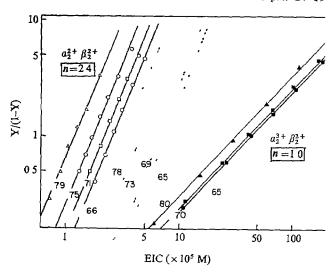
normal Bohr effect but show almost no haem–haem inter-action[3,4] Thus among the M Hbs, the proximal and distal mutants of the same chain display similar ligand binding properties When abnormal α chains of Hb M Iwate are completely reduced using dithionite, the affinity for CO and Bohr effect were almost normal, but Hill's constant was still one[1] It has been suggested that the ligand binding properties of completely reduced Hb M Boston are approximately the same as those of Hb M Iwate[5,6] We have studied the equilibria of Hb M Boston and Hb M Iwate in both the half ferric and completely reduced states using ethylisocyanide (EIC), a non-oxidising ligand which equilibrates rapidly with haemoglobin, and here report that the completely reduced Hb M Boston shows ligand binding properties similar to those of Hb A.

Hb M Boston and Hb M Iwate were separated from Hb A using an Amberlite CG-50 column (1 5×40 cm) previously equilibrated with 0 05 M phosphate buffer, pH 7 0 After Hb A had been washed out with 2 1 of the same buffer, Hb M remaining on the column was eluted using a linear gradient from 0 05 to 0 2 M phosphate buffer (pH 7 0) with 300 ml of each buffer Purity was examined by starch gel electrophoresis of methaemoglobin M, prepared by oxidation of the sample with potassium ferricyanide

Completely reduced Hb M was prepared by bubbling with O gas (helium–isobutane, 99.05 . 0 95), subsequent addition of 3 mg ml^{-1} sodium dithionite and standing overnight at room temperature in a cell with a light path of 1 cm and a rubber stopper seal Half ferric Hb M Iwate, in which normal β chains contain ferrous haems and abnormal α chains ferric haems, was prepared by deoxygenation of the sample solution and the addition of sodium ascorbate to give a final concentration of 5 mM Half ferric Hb M Boston was prepared as follows Completely reduced Hb M Boston was separated from dithionite by passage through a Sephadex G-25 column, and abnormal α chains were oxidised using dissolved oxygen for 20 min at room temperature Absorption spectra of half ferric Hb M Iwate and Hb M Boston showed that only abnormal α chains were ferric Equilibrium with EIC was determined spectrophotometrically following the method of Anderson *et al*[7].

The EIC dissociation curves for Hb M Iwate at various pH are shown in Fig 1 In the half-ferric state, CO affinity was very low and the Bohr effect very small When abnormal α chains were reduced and all haems in Hb M Iwate were capable of binding EIC, affinity was a little greater than that of Hb A and

Fig. 1 EIC equilibrium curves of Hb M Iwate in 0 2 M phosphate buffer at 25° C The fractional saturation of haemoglobin with EIC, Y, against the EIC concentration, c, is plotted according to a modified form of Hill's equation, $\log Y/(1-Y) = n\log c + \log K$ Open and filled symbols represent the experimental points for the completely reduced and the half ferric state, respectively ———, Hb M, - - - -, Hb A pHs shown beside plots



the magnitude of Bohr effect was almost normal Hill's constant however, was approximately one in both the states The results are qualitatively similar to those obtained for C binding to Hb M Iwate[1] EIC equilibrium curves for half ferric Hb M Boston were almost the same as those for Hb M Iwa (Fig 2) Completely reduced Hb M Boston, however, showe haem–haem interaction as strong as Hb A, although its affinit and Bohr effect were similar to those of completely reduce Hb M Iwate

X-ray analysis of Hb M Boston shows that the ferric iro atoms in the abnormal α chains are bonded to the phenolat side chains of the tyrosines which have replaced the dista histidines[6] The α haem groups of Hb M Iwate are probabl bonded to both the distal histidines and proximal tyrosines[6] The resulting changes in tertiary structure of the α-chain mutants are considered to stabilise the haemoglobin tetrame in the quaternary T structure, which causes the abnorma ligand binding properties[5,6] When the iron atoms of th α haems of Hb M Boston are reduced by dithionite, bond between the haem irons and the phenolates may be broken an bonds with the proximal histidines may be formed The resulting structure seems to be similar to that of Hb A as judged from th EIC binding properties Similarly, reduction of ferric irons in abnormal α chains of Hb M Iwate may break bonds betweer α haem irons and distal histidines, which increases both th ligand affinity and Bohr effect Replacement of proxima histidine by tyrosine in Hb M Iwate, however, abolishes th cooperativity in EIC binding, the importance of the proxima histidine in cooperative ligand binding is suggested

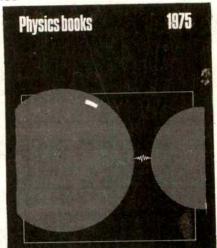
How man has seen the world

THE declared aim of this ambitious handbook* is "to bring together essential aspects of the very large, diverse and widely scattered literature on human perception." The present volumes are the first of 12; a third volume, *Biology of Perceptual Systems,* was published in 1973. Volumes 4–6 will cover the individual senses; and in the last six volumes it is planned to include areas such as speech and language, aesthetics, the perception of form, of space and of objects, and the perceptual aspects of thought.

Yet this is not a handbook. It is a very large collection of essays. There are many notable chapters by individual contributors, but the sum of the parts cannot fairly be represented as a true handbook. Cross-references within and between volumes are almost completely absent and there is much internal evidence to suggest that contributors have not read each other's chapters: thus, R. M. Boynton, who gives an account in Volume 1 of J. J. Gibson's theory of visual perception, cannot have been invited to read those passages in the same volume in which M. Wertheimer makes the elementary mistake of speaking of visual receptors firing impulses.

Indeed, there is grave doubt as to whether the editors themselves have read all the contributions. Very often the same ground is covered two or three times without comment or cross-reference, so that the reader is left wondering whether he is missing some subtlety; there seem, for example, to be three introductions to epistemology, two introductions to psychophysics and two accounts of multidimensional scaling. The very sequence of chapters is sometimes bizarre: a chapter by J. R.

Handbook of Perception. Vol. 1: Historical and Philosophical Roots of Perception. Pp. xix+431. $23.50; £11.30. Vol. 2: *Psychological Judgement and Measurement.* Pp. xix+556. $29.50; £14.15. Edited by Edward C. Carterette and Morton P. Friedman. (Academic: New York and London, 1974.)


Royce on epistemological psychology appears, inexplicably, in the historical section of Volume 1, whereas, if it belonged anywhere in that volume, it would have been as a bridge between the philosophical and the psychological sections. Similarly, in Volume 2, a relatively technical paper by A. Sandusky on memory effects in psychophysics is separated from A. Parducci's paper on contextual effects and is instead inserted between a short and very readable introduction to psychophysics by F. Nowell Jones and a long and very readable introduction to psychophysics by E. Galanter. In short, in spite of the 2 editors and 17 members of the editorial board, almost the only evidence of an editorial hand is the use throughout of *cf* where *v* is properly required.

The editors must, however, enjoy some credit for their choice of contributors. Many of the individual chapters are of a very high standard, particularly Hochberg's excellent review of the history and present state of the Gestalt tradition; Berlyne's introduction to attention; Garner's introduction to attention; and the comprehensive account of multidimensional scaling by Carroll and Wish. Luce and Green combine to write a supplement to the 1966 book on signal detection theory by Green and Swets. R. L. Gregory, in a section of Volume 1 devoted to grand

Though both are viewed under the same lighting and have the same texture, the face on the right does not appear as a mould of that on the left.

theories of perception, does what the editors have failed to do and contrasts different theoretical approaches, considering the capacity of each to accommodate a number of facts that he has carefully chosen to support his own view that "perceptions are hypotheses". Elsewhere in the same volume there is a critique of this class of theory by Metzger but, characteristically, there are no cross-references between his chapter and those by Gregory and Hochberg.

Although Volume 1 is entitled *Historical and Philosophical Roots of Perception,* the history of perceptual theory is covered very inadequately. The origins of the sensory sciences in physics and medicine are almost completely neglected, as is the history of the study of senses other than vision. Such history as is dealt with reads soundly, but it is often drawn from secondary sources and professional historians of science would judge it presentist and Whiggish. In recent years historians of science have notoriously drawn upon psychological illustrations of the hypothetical nature of perception and thus it is the more unhappily ironic that this opportunity has not been taken to introduce a more hermeneutic approach to the history of perceptual theory and to discuss theories of perception in the context of the way man has seen the world.

Physics books 1975

Acoustics 1974

The Invited Lectures Presented at the Eighth International Congress on Acoustics London 1974

Edited by R.W.B. STEPHENS

February 1975 : 220 pages : illustrated
412 12400 9 : hardback : £5.00

The emphasis in many of the lectures in this book is on environmental acoustics.

The objective is to review the present state of knowledge of the principal sources and propagation of noise, the prospects for its reduction, the role of building acoustics in noise control, and the psychological and biological effect of sound on man.

Acoustics and Vibration Progress Volume 1

Edited by R.W.B. STEPHENS and H.G. LEVENTHALL

November 1974 : 254 pages : illustrated
412 11560 3 : hardback : £6.00

This volume contains reviews on traffic noise, chemical ultrasonics, ambient noise, acoustic emission, and vibration and noise in building structures.

Model standard for hydrogen bonding

Hydrogen Bonding. By Melvin D. Joesten and L. J. Schaad. Pp. vi+622. (Marcel Dekker: New York, 1974.) $45.00.

THIS book is explicitly planned as supplemental to Pimentel and McClellan's *Hydrogen Bond,* " . . . to provide comprehensive coverage of those topics which account for a large percentage of the hydrogen bonding (HB) papers published since . . . (1960)". It reaches a standard not unworthy of its model.

Four of the five excellent chapters are by Professor Joesten, and cover the detection of HB, thermodynamics and kinetics, (spectroscopic) correlations, and intramolecular and homo-intermolecular HB. The other chapter, by Professor Schaad, deals with the theory of HB exceedingly well; with minimal mathematics, he surveys the application of quantum mechanics to molecules, carefully explains the types of approximation necessary with HB, and assesses their limitations—all this with masterly elegance. He ends his chapter with a list of theoretical studies of HB systems carried out between 1960 and 1973. He

writes: "It is tempting for the expe mentalist to conclude that since f theoretical predictions are complet certain one can ignore all theoreti results. The difficult alternative weighing each separately is proba more useful".

Besides some 250 pages of strai text, there are 130 pages of tabula results and 2,703 references. The bc is largely concerned with spect scopic studies and their thermodynar consequences. This is the way most the current HB literature runs; implies no adverse criticism to sta that this book concentrates on re ively weak HB; that it has less to about strong HB or its study by diff tion methods. The book is an exam of the pleasing results that are sor times achieved by photo-offset. The are few errors—something is aw with the legend to Fig. 5.1. The pr will deter most individuals from buy their own copy; but perhaps these d even 4 pence a page is not preposter for so valuable a book.

Limited horizons

Television review by Robbie Vickers

THE BBC are to be commended in launching *Choices for Tomorrow*, a new series of half-hour programmes on the environment and how we use or misuse it. The first, *Woodland or Wasteland* (Monday April 7; 11.05 p.m.) went only part of the way to solving the problems facing educational television.

Michael Pye of the *Sunday Times,* aired his own personal views on the trials and tribulations of the tree in Britain—government forestry policy, recycling of paper products, and so on. His impressions—they were essentially his, and on a topic very much related to his own sphere of interest—were interesting and should provoke thought and discussion.

The comments on the way we are likely to affect the world we live in were, however, left too open-ended, making the whole programme look very much like a miniature and limited *Horizon.* the time available, a 'chat' programme this sort cannot attempt to supply itive answers—and we wouldn't war this—but it could forward suggestons; it is simply not constructive never explicitly to state alternatives. Such comments as "every time I write an article, the paper publishes one and a quarter million copies of it and that means 4,000 trees die"— do not get us anywhere other than making us aware of the problems.

Before making suggestions, however,

perhaps we should get our facts straig At the moment, the cost of de-inki and bleaching paper far outweighs benefits that may accrue from its re-us It is not until a balance is reached th this method of conserving a resour can become viable and economical, though the organised collection of wa paper is a method worth investigati on a commercial scale.

For some time now, the Forest Commission have, as a matter of h priority, considered the integration maximum wood production and amenity value or aesthetic value of c woodlands. National Parks were c ceived to meet this need, at a ti when the idea of increased leisure tir came to the fore. To some peop therefore, Mr Pye's ideas may ha been misleading, particularly at such late hour in the evening.

What was given was a popularise one-sided, slightly inaccurate vie at least there was sufficient comedy ar wit to sustain enough interest for peop to take the punch-lines, but people ne easily accessible informed comment make reasoned judgements about t world in which they live.

Allowing for the limitations and personal nature of the views express with a bigger budget, more time a research staff, this programme cou become worth a slot during peak vie ing hours. Future programmes will co sider the energy shortage, polluti control and the effects buildings ha on our behaviour.
